CONTRIBUTORS AND CONSULTANTS

Janice T. Chussil, RN,C, MSN, DNC, ANP
Nurse Practitioner
Dermatology Associates
Portland, Ore.

Ellie Z. Franges, RN, MSN, CNRN
Director of Neuroscience Services
Sacred Heart Hospital
Allentown, Pa.

Marcia L. Geiger, RN, MSN, MA
Instructor
Bryan School of Nursing
Lincoln, Neb.

Margaret M. Gingrich, RN, MSN
Associate Professor
Harrisburg (Pa.) Area Community College

Rebecca Crews Gruener, RN, MSN
Associate Professor of Nursing
Louisiana State University
Alexandria

Connie S. Heflin, RN, MSN
Professor
Paducah (Ky.) Community College

Shelton M. Hisley, RN,C, PhD, ACCE, WHNP
Assistant Professor, School of Nursing
University of North Carolina
Wilmington

Sherry Kupchick, MSN, FNP-C
Clinical Research Associate
Coromed, Inc.
Valley Forge, Pa.

Kay L. Luft, RN, MN, CCRN
Assistant Professor
Saint Luke's College
Kansas City, Mo.

Kate McGovern, RN, BSN, CCRN
Staff Nurse, Surgical Trauma Unit
Abington (Pa.) Memorial Hospital

Marilyn J. Vontz, RN, PhD, MSN
Nurse Educator
Bryan School of Nursing
Lincoln, Neb.

We extend special thanks to the following people, who contributed to previous editions.

Mary Ann Cali-Ascani, RN, MSN, OCN
Kerry H. Cheever, RN, MSN, CCRN, CEN
Patricia L. Clutter, RN, MEd, CEN
Ellen Digan, MA, MT (ASCP)
Nancy G. Evans, RN, BSN, CGRN
Marilyn A. Folcik, RN, MPH, ONC
Susan Fralick, RN, MSN
Karen Alyce Graf, RN, BSN, CURN
Linda B. Haas, RN, CDE
Sande Jones, RN,C, CS, MSN, MSED
Karen Landis, RN, MS, CCRN
Amanda Keller Martin, RN, BSN, MEd, CNOR
Margaret Massoni, RN, MS, CS
Linda Rae Merrow, RN,C, MS, CNSN
Cheryl Milford, RN, MS, MBA, CCRN
Patricia L. Radzewicz, RN, BSN
Linda E. Reese, RN, MA
Lynne Rosenberg, RN, MSN
Nancy V. Runta, RN,C, BSN, CCRN
Steven J. Schweon, RN,C, BSN, CCRN
Regina Shannon-Bodnar, RN, MSN, OCN
Brenda K. Shelton, RN, MS, CCRN, ONC
Johanna K. Stiesmeyer, RN, MS, CCRN
Donald A. St. Onge, RN, MSN
Rosemary Theroux, RN,C, MS
Joseph B. Warren, RN, MSN, CNRN
Patti Zuzelo, RN, MSN, CCRN

FOREWORD

Disease—its causes, symptoms, treatments, and management—is the main focus of a health professional’s practice, especially a nurse’s. Nurses are involved with disease in all of its states: acute, chronic, infectious, lifestyle-related, physiologically or behaviorally expressed, trauma-induced, and genetically programmed.

Of the 10 leading causes of death in the United States in 1997, 7 were diseases of specific body systems that resulted from infection, heredity, lifestyle, or combinations of these factors. The remaining 3—accidents, suicide, and homicide—were brought about by the pace and frenzy of modern society. The surgeon general has set goals for the nation, which were published in “Healthy People 2005,” that put great emphasis on living healthy to prevent disease and premature death.

Today, we have an increased understanding of the mechanisms of disease and improved pharmacologic, nutritional, and lifestyle-change interventions, so disease trajectories, especially from acute to chronic, are dramatically changing. Patients are living longer with chronic diseases; in 1995, more people died from chronic disease, rather than acute, in the United States. This trend will persist as the population grows older; therefore, nurses need constant updating on the evolving nature of diseases and their incidence, progression, and management. *Diseases*, Third Edition, provides a comprehensive, well-organized, concise overview of the major categories of disease, from causative factors to assessment, treatment, and nursing intervention. It’s an essential tool for both the student and the practicing nurse because dealing with disease, whether its prevention or treatment, is the heart of nursing practice.

Diseases, Third Edition, retains the same high level of organization, quality, and accuracy of information that characterized previous editions and has several added features. Every disease entry has been updated, and this edition includes the latest developments on emerging diseases, particularly new viral diseases and such conditions as necrotizing fasciitis and nosocomial infections. A new feature is the addition of key outcomes of care for each disease. Nursing diagnoses have been updated throughout, greater emphasis has been placed on delivering nursing care in a variety of practice arenas, and the book now includes information on trends in demographics and practice. Finally, to complement the book’s logo system for quick reference, new logos on cultural tips, disease prevention, and advanced practice have been added.

Disease is an integral part of the human experience. *Diseases*, Third Edition, clearly and effectively highlights the knowledge, skills, and practices that every nurse needs to know in order to deliver high-quality care to patients and caregivers and to keep pace with diseases—including concepts, interventions, and realities of practice.

CHAPTER 1 MENTAL AND EMOTIONAL DISORDERS

Introduction

Disorders of Infancy, Childhood, and Adolescence

Psychoactive Substance Abuse Disorder

Schizophrenia and Other Psychotic Disorder

Mood Disorders

Anxiety Disorders

Somatoform Disorders

Dissociative and Personality Disorder

Sexual Disorders

Selected References

INTRODUCTION

The mental health field has changed dramatically in recent years, driven by social, economic, and professional forces. Community and professional organizations have established family advocacy programs, substance abuse rehabilitation programs, stress management workshops, bereavement groups, victim assistance programs, and violence shelters. The public education system has instituted widespread information programs about mental health issues. Self-help and coping books have proliferated, and media attention to mental health has increased.

Social changes

In today's society, more people than ever before experience mental health problems. Some researchers blame social changes for this increase in mental and emotional disorders. These changes have altered the traditional family structure and contributed to the loss of the extended family. The result is increased numbers of single parents, dysfunctional families, troubled children, and homeless people.

The loss of effective support systems strains a person's ability to cope with even minor problems. For example, a working mother may lack the necessary support to meet the demands of her job, her home, her spouse, and her children. When she views herself as ineffective in these roles, her self-esteem falters and her level of stress intensifies.

Women aren't the only members of society who face an increased risk of mental disorders; the problem affects persons of all ages and socioeconomic levels. For example, the rate of teenage depression and suicide has more than tripled in the past 20 years. Alcohol and substance abuse are proliferating and taking younger victims. Isolation, fear of violent crime, and loneliness have contributed to a similar increase in depression among elderly people. Combat veterans, rape victims, and child abuse victims struggle to cope with the trauma they've experienced.

Economic changes

Recent cuts in federal funding for mental health programs place future control of mental health services at the state and local community levels, and they drastically reduced the funds available for training new professionals. This funding squeeze has forced increased collaboration between community psychiatric facilities (short-term inpatient, outpatient, and auxiliary services) and long-term inpatient state facilities. Services have been dramatically reduced as a result of diminished funding.

Professional changes

Mental health professionals have experienced enormous changes in perspective, focus, and direction. These changes—documented in the *American Psychiatric Association's Diagnostic and Statistical Manual of Mental Disorders, 4th edition (DSM-IV)*—provide a unified system of classifying mental disorders. This system requires the clinician to consider many aspects of the patient's behavior, mental performance, history, and culture. The emphasis is on observable data rather than subjective and theoretical impressions. This emphasis on operational criteria makes psychiatric diagnoses more reliable and has led to improvements in treatment and management.

Defining mental disorders

The *DSM-IV* defines a mental disorder as a clinically significant behavioral or psychological syndrome or pattern that is associated with current distress (a painful symptom) or disability (impairment in one or more important areas of functioning) or with a significantly greater risk of suffering, death, pain, disability, or an important loss of freedom. This syndrome or pattern must not be merely an expected, culturally sanctioned response such as grief over the death of a loved one. Whatever its original cause, it must currently be considered a sign of a behavioral, psychological, or biological dysfunction.

To add diagnostic detail, the *DSM-IV* uses a multiaxial approach. This approach specifies that every patient be evaluated on each of five axes, as follows:

- u Axis I: clinical disorders—the diagnosis (or diagnoses) that best describes the presenting complaint and that indicates the presence or absence of a major mental disorder
- u Axis II: personality disorders and mental retardation
- u Axis III: general medical conditions; a description of any concurrent medical conditions or disorders
- u Axis IV: psychosocial and environmental problems that may affect the diagnosis, treatment, and prognosis of the mental disorder
- u Axis V: global assessment of functioning (GAF), based on a scale of 1 to 100. The GAF scale allows evaluation of the patient's overall psychological, social, and occupational function.

The first three axes, which constitute the official diagnostic assessment, encompass the entire spectrum of mental and physical disorders, ensuring consideration of disorders that frequently are overlooked. This system requires multiple diagnoses whenever necessary. For example, on Axis I, a patient may have both a psychoactive substance use disorder and a mood disorder. He may even have multiple diagnoses within the same class, as in major depression superimposed on cyclothymic disorders. A patient also may have a disorder on Axes I, II, and III simultaneously.

Axis IV identifies psychosocial and environmental problems that affect the patient's condition. Such problems can stem from the patient's primary support group, social environment, education, occupation, housing conditions, economic status, access to health care, contact with the legal system, involvement in crime, or other sources.

Axis V uses the GAF scale to measure how well the patient has functioned over the past year. It also encompasses his current level of functioning.

A patient's diagnosis after being evaluated on these five axes may look like this:

- u Axis I: adjustment disorder with anxious mood
- u Axis II: obsessive-compulsive personality
- u Axis III: Crohn's disease, acute bleeding episode

- u Axis IV: recent remarriage, death of father
- u Axis V: GAF = 83.

Related professional forces

A new emphasis on holistic care has promoted a closer relationship between psychiatry and medicine. Increasing numbers of hospitalized patients benefit from psychiatric consultations, reflecting a growing recognition of the emotional basis of physical disorders. Conversely, advances in neurobiology have revolutionized our understanding of the physiologic basis of mental function. These advances have improved the diagnosis and treatment of mental disorders.

Psychosocial assessment

In all clinical areas and settings, you'll encounter patients with mental and emotional problems. Begin care of these patients with a psychosocial assessment. For this assessment to be effective, establish a therapeutic relationship based on trust. To develop such a relationship, your words and actions must communicate to the patient that his thoughts and behaviors are important to you. Effective communication involves both sending and receiving messages. It doesn't depend entirely on the spoken word. Nonverbal communication—eye contact, posture, facial expression, gestures, clothing, affect, even silence—can convey a powerful message. (See [Reducing communication barriers](#).)

Choose a quiet, private setting for the assessment interview. Interruptions and distractions threaten confidentiality and interfere with effective listening. If you're meeting the patient for the first time, introduce yourself and explain the interview's purpose. Sit at a comfortable distance from the patient, and give him your undivided attention.

During the interview, adopt a professional but friendly attitude. A calm, nonthreatening tone of voice will encourage the patient to talk more openly. Avoid value judgments. Don't rush through the interview; building a trusting therapeutic relationship takes time.

Patient history

Obtaining a patient history helps establish a baseline for future assessments and gives clues to the underlying or precipitating cause of the current problem. When gathering the history, keep in mind that the patient may not be a reliable source of information, particularly if he's mentally ill. If possible, verify his responses with family members, friends, or health care personnel. Also check hospital records from previous admissions, if possible, and compare his past behavior, symptoms, and circumstances with the current situation.

When taking the patient's history, explore the following information: chief complaint, current symptoms, psychiatric history, demographic data, socioeconomic data, cultural and religious beliefs, medication history, and physical illnesses.

- u *Chief complaint.* The patient may not voice his chief complaint directly. Instead, you, another nurse, family members, or friends may note that the patient is having difficulty coping or is exhibiting unusual behavior. If this occurs, determine whether the patient is aware of the problem. When documenting the patient's response, write it verbatim, and enclose it in quotation marks.
- u *Current symptoms.* Find out about the onset of symptoms, their severity and persistence, and whether they occurred abruptly or insidiously. Compare the patient's condition with his normal level of function.
- u *Psychiatric history.* Discuss past psychiatric disturbances, such as episodes of delusions, violence, attempted suicides, drug or alcohol abuse, or depression, and previous psychiatric treatment.
- u *Demographic data.* Determine the patient's age, sex, ethnic origin, primary language, birthplace, religion, and marital status. Use this information to establish a baseline and validate the patient's record.

Reducing communication barriers

Acknowledging and reducing communication barriers can help you conduct a successful interview.

Language difficulties or differences

If the patient speaks English, try to use language that is appropriate to his educational level. Avoid medical terms that he may not understand.

If the patient speaks a foreign language or an ethnic dialect, an interpreter can help you communicate. But remember that the presence of a third person may make the patient less willing to share his feelings.

Be aware of words that can have more than one meaning. For instance, the word “bad” also can be used as slang to mean “good.”

Inappropriate responses

Inadvertently, your responses to the patient could suggest disinterest, anxiety, or annoyance. Or they could imply value judgments. Examples include abruptly changing the subject or discounting the patient's feelings.

Hearing loss

If the patient can't hear you clearly, he may misinterpret your responses. If you're interviewing a patient with impaired hearing, check whether he's wearing a hearing aid. If so, is it turned on? If not, can he read lips? If possible, face him and speak clearly and slowly, using common words and keeping your questions short, simple, and direct.

If the patient is elderly, use a low tone of voice. With aging, the ability to hear high-pitched tones deteriorates first. If the patient's hearing impairment is severe, he may have to communicate by writing, or you may need to collect information from his family or friends.

Thought disorders

If the patient's thought patterns are incoherent or irrelevant, he may be unable to interpret messages correctly, focus on the interview, or provide appropriate responses.

When assessing such a patient, ask simple questions about concrete topics and clarify his responses. Encourage him to express himself clearly.

Paranoid thinking

When dealing with a paranoid patient, approach him in a nonthreatening way. Avoid touching him because he may misinterpret your touch as an attempt to harm him. Also, keep in mind that he may not mean the things he says.

Hallucinations

A hallucinating patient experiences imaginary sensory perceptions with no basis in reality. These distortions prevent him from hearing and responding appropriately.

Show concern if the patient is hallucinating, but don't reinforce his perceptions. Be as specific as possible when you give him commands. For instance, if he says he's hearing voices, tell him to stop listening to the voices and listen to you instead.

Delusions

A deluded patient defends irrational beliefs or ideas despite factual evidence to the contrary. Some delusions may be so bizarre that you'll immediately recognize them; others may be difficult to identify.

Don't condemn or agree with a patient's delusional beliefs, and don't dismiss a statement because you think it's delusional. Instead, gently emphasize reality without being argumentative.

Delirium

A delirious patient experiences disorientation, hallucinations, and confusion. Misinterpretation and inappropriate responses often result.

Talk directly to such a patient, and ask simple questions. Offer frequent reassurance.

Dementia

The patient who suffers dementia—an irreversible deterioration of mental capacity—may experience changes in memory and thought patterns, and his language may become distorted or slurred.

When interviewing such a patient, minimize distractions. Use simple and concise language. Avoid making any statements that could be easily misinterpreted.

» *Socioeconomic data.* Assess the patient's economic and personal situation to determine the impact on his current psychological status. Patients who are experiencing economic or personal hardships are more likely to show symptoms of distress during an illness. Information about your patient's educational level, housing conditions, income, current employment status, and family may provide clues to his current problem.

» *Cultural and religious beliefs.* Determine the patient's background and values because they will affect his response to illness and his adaptation to hospital care.

CULTURAL TIP Remember that certain questions and behaviors considered inappropriate in one culture may be sanctioned in another. For example, a Brazilian person of lower class may avoid direct eye contact with health care professionals to show respect. In addition, be aware that mental illness is considered a stigma in many cultures and may be kept hidden if it exists within the family structure. A patient's cultural beliefs also may affect decisions about treatment. For example, in Black or African groups, mental illness may be attributed to a person's level of spiritual balance.

Coping mechanisms

Coping, or defense, mechanisms help to relieve anxiety. The most common ones are defined in this list:

- u *denial*—refusal to admit truth or reality
- u *displacement*—transference of an emotion from its original object to a substitute
- u *fantasy*—creation of unrealistic or improbable images to escape from daily pressures and responsibilities
- u *identification*—unconscious adoption of the personality characteristics, attitudes, values, and behavior of another person
- u *projection*—displacement of negative feelings onto another person
- u *rationalization*—substitution of acceptable reasons for the real or actual reasons motivating behavior
- u *reaction formation*—conduct in a manner opposite from the way the person feels
- u *regression*—return to behavior of an earlier, more comfortable time in life
- u *repression*—exclusion of unacceptable thoughts and feelings from the conscious mind, leaving them to operate in the subconscious.

u *Medication history.* Certain drugs can cause symptoms of mental illness. Review any medications the patient is taking, including over-the-counter drugs, and check for interactions. If he's taking an antipsychotic, antidepressant, anxiolytic, or antimanic drug, ask if his symptoms have improved, if he's taking the medication as prescribed, and if he has experienced any adverse reactions.

u *Physical illnesses.* Find out if the patient has a history of medical disorders that may cause disorientation, distorted thought processes, depression, or other symptoms of mental illness. For instance, does he have a history of renal or hepatic failure, infection, thyroid disease, increased intracranial pressure, or a metabolic disorder?

Patient appearance, behavior, and mental status

Observe and record your assessment of the patient's appearance, behavior, mood, thought processes, cognitive function, coping mechanisms, and potential for self-destructive behavior.

u *General appearance.* The patient's appearance helps to indicate his emotional and mental status. Specifically, note his dress and grooming. Is his appearance clean and appropriate to his age, sex, and situation? Is the patient's posture erect or slouched? Is his head lowered? What about his gait? Is it brisk, slow, shuffling, or unsteady? Does he walk normally? Note his facial expression. Does he look alert, or does he stare blankly? Does he appear sad or angry? Does the patient maintain direct eye contact? Does he stare at you for long periods?

u *Behavior.* Note the patient's demeanor and overall attitude as well as any extraordinary behavior such as speaking to a person who isn't present. Also record mannerisms. Does he bite his nails, fidget, or pace? Does he display any tics or tremors? How does he respond to the interviewer? Is he cooperative, friendly, hostile, or indifferent?

u *Mood.* Does the patient appear excited or depressed? Is he crying, sweating, breathing heavily, or trembling? Ask him to describe his current feelings in concrete terms and to suggest possible reasons for these feelings. Note inconsistencies between body language and mood (such as smiling when discussing an anger-provoking situation).

u *Thought processes and cognitive function.* Evaluate the patient's orientation to time, place, and person, noting any confusion or disorientation. Look for delusions, hallucinations, obsessions, compulsions, fantasies, and daydreams.

Check the patient's attention span and ability to recall events from both the distant and recent past. For example, to assess immediate recall, ask him to repeat a series of five or six names of objects. Test his intellectual functioning by asking him to add a series of numbers and his sensory perception and coordination by having him copy a simple drawing. Inappropriate responses to a hypothetical situation ("What would you do if you won the lottery?") can indicate impaired judgment. Keep in mind that a patient's cultural background and personal values influence his answers.

Finally, assess the patient's degree of insight by asking if he understands the significance of his illness, the proposed treatment plan, and the effect it will have on his life.

Note any speech characteristics that may indicate altered thought processes, including minimal monosyllabic responses, irrelevant or illogical replies to questions, convoluted or excessively detailed speech, repetitious speech patterns, a flight of ideas, and sudden silence without an obvious reason.

u *Coping mechanisms.* The patient faced with a stressful situation may adopt coping or defense mechanisms (behaviors that operate on an unconscious level to protect the ego). Examples include denial, regression, displacement, projection, reaction formation, and fantasy. Look for an excessive reliance on particular coping mechanisms. (See [Coping mechanisms](#).)

u *Potential for self-destructive behavior.* Mentally healthy people may intentionally take death-defying risks such as participating in dangerous sports. The risks taken by self-destructive patients, however, aren't death-defying but death-seeking. Not all self-destructive behavior is suicidal in intent. Some patients engage in self-destructive behavior because it helps them feel alive. A patient who has lost touch with reality may cut or mutilate body parts to focus on physical pain, which may be less overwhelming than emotional distress.

Assess the patient for suicidal tendencies, particularly if he reports signs and symptoms of depression. Not all such patients want to die, but the incidence of suicide is higher in depressed patients than in patients with other diagnoses. Schizophrenic patients also may attempt suicide, responding to voices that command them to kill themselves. Unfortunately, recognizing suicide potential in these patients may be difficult. (See [Warning signs of suicide](#).)

Diagnostic tests

The laboratory tests, psychological and mental status tests, and EEG and brain imaging studies summarized below provide information about the patient's mental status and possible physical causes of his signs and symptoms.

Laboratory tests

Urinalysis, hemoglobin and hematocrit levels, serum electrolyte and serum glucose levels, and liver, kidney, and thyroid function tests screen for physical disorders that can cause psychiatric signs and symptoms. Toxicologic studies of blood and urine can detect the presence of many drugs, and current laboratory methods can quantify the blood levels of these drugs. Patients undergoing treatment with psychotherapeutic drugs may need routine toxicology screening to ensure that they aren't receiving a toxic dose. (See [Toxicology screening](#).)

Warning signs of suicide

During the patient interview, be alert for the following signs of suicidal behavior:

- u withdrawal and social isolation
- u signs and symptoms of depression, which may include crying, fatigue, helplessness, poor concentration, reduced interest in sex and other activities, sadness, constipation, and weight loss
- u farewells to friends and family
- u putting affairs in order
- u giving away prized possessions
- u covert suicide messages and death wishes
- u overwhelming anxiety (the most frequent precipitant of a suicide attempt)
- u obvious suicide messages such as "I'd be better off dead."

Psychological and mental status tests

These tests evaluate the patient's mood, personality, and mental status. Frequently used tests include the following:

- u The *Mini—Mental Status Examination* measures orientation, registration, recall, calculation, language, and graphomotor function.
- u The *Cognitive Capacity Screening Examination* measures orientation, memory, calculation, and language.
- u The *Cognitive Assessment Scale* measures orientation, general knowledge, mental ability, and psychomotor function.
- u The *Global Deterioration Scale* assesses and stages primary degenerative dementia based on orientation, memory, and neurologic function.
- u The *Functional Dementia Scale* measures orientation, affect, and the ability to perform activities of daily living.
- u The *Beck Depression Inventory* helps diagnose depression and determine its severity. This test may provide objective evidence of the need for treatment; it's also used to monitor the patient's response during treatment.
- u The *Eating Attitudes Test* detects patterns that suggest an eating disorder.
- u The *Minnesota Multiphasic Personality Inventory* helps assess personality traits and ego function in adolescents and adults. Test results include information on coping strategies, defenses, strengths, gender identification, and self-esteem. The test pattern may strongly suggest a diagnostic category, point to a suicide risk, or indicate the potential for violence.

Toxicology screening
<p>Toxic levels of many drugs associated with abuse can be detected in blood, urine, or both.</p> <p>Blood</p> <ul style="list-style-type: none">u alcohol (ethyl, isopropyl, and methyl)u ethchlorvynol (Placidyl) <p>Urine</p> <ul style="list-style-type: none">u chlorpromazine (Thorazine)u cocaineu desmethyldoxepin (metabolite of doxepin)u heroin (metabolized to and detected as morphine)u imipramine (Tofranil)u methadoneu morphineu phencyclidine <p>Blood and urine</p> <ul style="list-style-type: none">u acetaminophenu amitriptyline (Elavil)u amobarbital (Amytal)u butabarbital (Butisol)u butalbital (one component in Fiorinal)u caffeineu carisoprodol (Soma)u chlordiazepoxide (Librium)u codeineu desipramine (Pertofrane)u desmethyldiazepam (metabolite of diazepam)u diazepam (Valium)u diphenhydramine (Benadryl)u doxepin (Sinequan)u flurazepam (Dalmane)u glutethimide (Doriden)u ibuprofen (Motrin, Medipren)u meperidine (Demerol)u mephobarbital (Mebaral)u meprobamate (Miltown, Equanil)u methapyrileneu methaqualone (Quaalude)u methyprylon (Noludar)u norpropoxyphene (metabolite of propoxyphene)u nortriptyline (Aventyl)u oxazepam (Serax)u pentazocine (Talwin)u pentobarbital (Nembutal)u phenobarbital (Luminal)u propoxyphene (Darvon)u salicylates and their conjugatesu secobarbital (Seconal)u talbutal (Lotusate)

EEG and brain imaging studies

To screen for brain abnormalities, the doctor may order tests that visualize electrical brain wave pattern disturbances or anatomic alterations.

- u An *EEG* graphically records the brain's electrical activity. Abnormal results may indicate organic disease, psychotropic drug use, or certain psychological disorders.
- u A *computed tomography (CT) scan* combines radiologic and computer analysis of tissue density to produce images of intracranial structures not readily seen on standard X-rays. This test can help detect brain contusions or calcifications, cerebral atrophy, hydrocephalus, inflammation, space-occupying lesions, and vascular abnormalities.
- u A *magnetic resonance imaging (MRI) scan* is a noninvasive imaging technique. MRI localizes atomic nuclei that magnetically align and then fall out of alignment in response to a radio frequency pulse. In a process called precession, the MRI scanner records signals from nuclei as they realign; it then translates the signals into detailed pictures of body structures. Compared with conventional X-rays and CT scans, the MRI scan provides superior contrast of soft tissues and sharper differentiation of normal and abnormal tissues. The MRI scan also provides images of multiple planes, including sagittal and coronal views, in regions where bones usually interface.
- u A *positron emission tomography (PET) scan* provides colorimetric information about the brain's metabolic activity by detecting how quickly tissues consume radioactive isotopes. PET scanning is used mainly for diagnosing neuropsychiatric problems such as Alzheimer's disease and some mental illnesses.

The disorders in this section include anorexia nervosa and bulimia nervosa, which mainly affect adolescents; attention deficit hyperactivity disorder, which is usually diagnosed after age 4 or 5; autistic disorder, which usually becomes apparent before age 3; Down syndrome and mental retardation, which are transmitted genetically; and tic disorders, which begin before age 21.

ANOREXIA NERVOSA

The key feature of anorexia nervosa is self-imposed starvation resulting from a distorted body image and an intense and irrational fear of gaining weight, even when obviously emaciated. An anorexic patient is preoccupied with her body size, describes herself as “fat,” and commonly expresses dissatisfaction with a particular aspect of her physical appearance. Although the term *anorexia* suggests that the patient's weight loss is associated with a loss of appetite, this is rare.

Anorexia nervosa and bulimia nervosa can occur simultaneously. In anorexia nervosa, the refusal to eat may be accompanied by compulsive exercising, self-induced vomiting, or abuse of laxatives or diuretics.

Anorexia occurs in 5% to 10% of the population; more than 90% of those affected are females. It occurs primarily in adolescents and young adults but also may affect older women and, occasionally, males.

The prognosis varies but improves if the patient is diagnosed early or if she wants to overcome the disorder and seeks help voluntarily. Mortality ranges from 5% to 15%; the highest mortality is associated with a psychiatric disturbance. One-third of these deaths can be attributed to suicide.

Causes

No one knows exactly what causes anorexia nervosa. Researchers in neuroendocrinology are seeking a physiologic cause but have found nothing definite. Clearly, social attitudes that equate slimness with beauty play some role in provoking this disorder; family factors also are implicated. Most theorists believe that refusing to eat is a subconscious effort to exert personal control over life or to protect oneself from dealing with issues surrounding sexuality.

Complications

Serious medical complications can result from the malnutrition, dehydration, and electrolyte imbalances caused by prolonged starvation, vomiting, or laxative abuse. For example, malnutrition may cause hypoalbuminemia and subsequent edema or hypokalemia, leading to ventricular arrhythmias and renal failure. Poor nutrition and dehydration, coupled with laxative abuse, produce changes in the bowel similar to those in chronic inflammatory bowel disease. Frequent vomiting can cause esophageal erosion, ulcers, tears, and bleeding as well as tooth and gum erosion and dental caries.

Cardiovascular complications can be life-threatening and include decreased left ventricular muscle mass, chamber size, and myocardial oxygen uptake; reduced cardiac output; hypotension; bradycardia; electrocardiographic changes, such as nonspecific ST interval, T-wave changes, and prolonged PR interval; heart failure; and sudden death, possibly caused by ventricular arrhythmias. Anorexia nervosa also may increase susceptibility to infection.

Amenorrhea may occur when the patient loses about 25% of her normal body weight. It usually is associated with anemia. Possible complications of prolonged amenorrhea include estrogen deficiency (increasing the risk of calcium deficiency and osteoporosis) and infertility. Normal menses usually return when the patient weighs at least 95% of her normal weight.

Assessment findings

The patient's history usually reveals a 15% or greater weight loss for no organic reason, coupled with a morbid dread of being fat and a compulsion to be thin. The anorexic patient tends to be angry and ritualistic. She may report amenorrhea, infertility, loss of libido, fatigue, sleep alterations, intolerance to cold, and constipation.

ASSESSMENT TIP The anorexic patient may wear oversized clothing in an attempt to disguise body size. She may layer clothes or wear unseasonably warm clothing to compensate for cold intolerance and loss of adipose tissue.

Hypotension and bradycardia may be present. Inspection may reveal an emaciated appearance, with skeletal muscle atrophy, loss of fatty tissue, atrophy of breast tissue, blotchy or sallow skin, lanugo on the face and body, and dryness or loss of scalp hair. Calluses of the knuckles and abrasions and scars on the dorsum of the hand may result from tooth injury during self-induced vomiting. Other signs of vomiting include dental caries and oral or pharyngeal abrasions.

Palpation may disclose painless salivary gland enlargement and bowel distention. Slowed reflexes may occur on percussion. Oddly, the patient usually demonstrates restless activity and vigor (despite undernourishment) and may exercise avidly without apparent fatigue.

During psychosocial assessment, the anorexic patient may express a morbid fear of gaining weight and an obsession with her physical appearance. Paradoxically, she also may be obsessed with food, preparing elaborate meals for others. Social regression, including poor sexual adjustment and fear of failure, is common. Like bulimia nervosa, anorexia nervosa often is associated with depression. The patient may report feelings of despair, hopelessness, and worthlessness as well as suicidal thoughts.

Diagnostic criteria

A diagnosis of anorexia nervosa is confirmed when the patient meets the following criteria documented in the *DSM-IV*:

- u refusal to maintain body weight over a minimal normal weight for age and height (for instance, weight loss leading to maintenance of body weight 15% below that expected) or failure to achieve expected weight gain during a period of growth, leading to body weight 15% below that expected
- u intense fear of gaining weight or becoming fat, even though underweight
- u disturbance in perception of body weight, size, or shape (that is, the person claims to feel fat even when emaciated or believes that one body area is too fat even when obviously underweight)
- u in females, absence of at least three consecutive menstrual cycles when otherwise expected to occur.

In addition, laboratory tests reveal clinical status and help to rule out endocrine, metabolic, and central nervous system abnormalities; cancer; malabsorption syndrome; and other disorders that cause physical wasting.

Abnormal findings that may accompany a weight loss greater than 30% of normal body weight include:

- u low hemoglobin level, platelet count, and white blood cell count
- u prolonged bleeding time due to thrombocytopenia
- u decreased erythrocyte sedimentation rate
- u decreased levels of serum creatinine, blood urea nitrogen, uric acid, cholesterol, total protein, albumin, sodium, potassium, chloride, calcium, and fasting blood glucose (resulting from malnutrition)
- u levels of alanine aminotransferase and aspartate aminotransferase in severe starvation states
- u elevated serum amylase levels when pancreatitis isn't present
- u in females, decreased levels of serum luteinizing hormone and follicle-stimulating hormone
- u decreased triiodothyronine levels, resulting from a lower basal metabolic rate
- u dilute urine caused by an impairment in the kidneys' ability to concentrate urine
- u nonspecific ST interval, T-wave changes, and prolonged PR interval on the electrocardiogram. Ventricular arrhythmias also may be present.

Treatment

Appropriate treatment aims to promote weight gain or control the patient's compulsive binge eating and purging and to correct malnutrition and the underlying psychological dysfunction. Hospitalization in a medical or psychiatric unit may be required to improve the patient's precarious physical state. Hospitalization may be as brief as 2 weeks or may stretch from a few months to 2 years or longer. (See [Criteria for hospitalizing anorexic patients.](#))

A team approach to care—combining aggressive medical management, nutritional counseling, and individual, group, or family psychotherapy or behavior modification therapy—is the best approach. Treatment is difficult, and results may be discouraging. Many clinical centers are now developing inpatient and outpatient programs specifically for managing eating disorders.

Treatment may include behavior modification (privileges depend on weight gain); curtailed activity for physical reasons (such as arrhythmias); vitamin and mineral supplements; a reasonable diet, with or without liquid supplements; subclavian, peripheral, or enteral hyperalimentation (enteral and peripheral routes carry less risk of infection); and group, family, or individual psychotherapy.

All forms of psychotherapy, from psychoanalysis to hypnotherapy, have been used in treating anorexia nervosa, with varying success. To be successful, psychotherapy should address the underlying problems of low self-esteem, guilt, and anxiety; feelings of hopelessness and helplessness; and depression.

Nursing diagnoses

- u Activity intolerance
- u Altered growth and development
- u Altered nutrition: Less than body requirements
- u Anxiety
- u Body image disturbance
- u Chronic low self-esteem
- u Constipation
- u Denial
- u Fluid volume deficit
- u Hyperthermia
- u Ineffective individual coping
- u Noncompliance
- u Social isolation

Key outcomes

- u The patient will acknowledge change in body image.
- u The patient will participate in decision-making about her case.
- u The patient will express positive feelings about self.
- u The patient will demonstrate skills appropriate for age.
- u The patient will demonstrate ability to practice two new coping behaviors.
- u Fluid balance will remain stable, with intake equal to or greater than output.
- u The patient will interact with family or friends.
- u The patient will achieve expected state of wellness.

Nursing interventions

u During hospitalization, regularly monitor vital signs, nutritional status, and intake and output. Weigh the patient daily, before breakfast if possible. Because the patient fears being weighed, vary the weighing routine. Keep in mind that weight should increase from morning to night. Help the patient establish a target weight, and support her efforts to achieve this goal.

ASSESSMENT TIP Weigh the patient in the same clothing and under the same circumstances. Observe the patient carefully before weighing to detect added objects, such as in pockets, or the intake of large amounts of fluids intended to falsely increase weight measurement.

u Negotiate an adequate food intake with the patient. Be sure that she understands that she'll need to comply with this contract or lose privileges. Frequently offer small portions of food or drinks if the patient wants them. Allow the patient to maintain control over the types and amounts of food eaten, if possible. Maintain one-on-one supervision of the patient during meals and for 1 hour afterward to ensure compliance with the dietary treatment program. For the hospitalized anorexic patient, food is considered a medication. During an acute anorexic episode, nutritionally complete liquids are more acceptable because they eliminate the need to choose between foods—something an anorexic patient often finds difficult. If tube feeding or other special feeding measures become necessary, fully explain these measures to the patient and be ready to discuss her fears or reluctance; limit the discussion about food itself.

Criteria for hospitalizing anorexic patients

Anorexic patients can be successfully treated on an outpatient basis. But if the patient displays any of the signs and symptoms listed below, hospitalization is mandatory:

- u rapid weight loss equal to 15% or more of normal body mass
- u persistent bradycardia (50 beats/minute or less)
- u hypotension with a systolic reading less than or equal to 90 mm Hg
- u hypothermia (core body temperature less than or equal to 97° F [36.1°C])
- u presence of medical complications, suicidal ideation
- u persistent sabotage or disruption of outpatient treatment—resolute denial of condition and the need for treatment.

- u Anticipate a weight gain of about 1 lb/week.
- u If edema or bloating occurs after the patient has returned to normal eating behavior, reassure her that this phenomenon is temporary. She may fear that she's becoming fat and stop complying with the treatment plan.
- u Encourage the patient to recognize and assert her feelings freely. If she understands that she can be assertive, she gradually may learn that expressing her true feelings won't result in her losing control or love.
- u If a patient receiving outpatient treatment must be hospitalized, maintain contact with her treatment team to facilitate a smooth return to the outpatient setting.
- u Remember that the anorexic patient uses exercise, preoccupation with food, ritualism, manipulation, and lying as mechanisms to preserve the only control she thinks that she has in her life.
- u Because the patient and her family may need therapy to uncover and correct dysfunctional patterns, refer them to Anorexia Nervosa and Related Eating Disorders, a national information and support organization. This organization may help them understand what anorexia is, convince them that they need help, and help them find a psychotherapist or medical doctor who's experienced in treating this disorder.

Patient teaching

- u Emphasize to the patient how improved nutrition can reverse the effects of starvation and prevent complications.
- u Teach the patient how to keep a food journal, including the types of food eaten, eating frequency, and feelings associated with eating and exercise.
- u Advise family members to avoid discussing food with the patient.

ATTENTION DEFICIT HYPERACTIVITY DISORDER

The patient with attention deficit hyperactivity disorder has difficulty focusing his attention, engaging in quiet passive activities, or both. Some patients have an attention deficit without hyperactivity; they're less likely to be diagnosed and receive treatment.

Although attention deficit hyperactivity disorder is present at birth, diagnosis before age 4 or 5 is difficult unless the child exhibits severe symptoms. Some patients,

however, aren't diagnosed until they reach adulthood.

This disorder occurs in roughly 3% to 5% of school-age children. Males are three times more likely to be affected than females. The presence of other psychiatric disorders also needs to be determined.

Causes

Attention deficit hyperactivity disorder is thought to be a physiologic brain disorder with a familial tendency. Some studies indicate that it may result from altered neurotransmitter levels in the brain.

Complications

Emotional and social complications can result from the child's impulsive behavior, inattentiveness, and disorganization in school. Hyperactivity can also lead to poor nutrition.

Assessment findings

The patient is usually characterized as a fidgeter and a daydreamer. He also may be described as inattentive and lazy. The parents may state that their child is intelligent but that his school or work performance is sporadic. They may also report that he has a tendency to jump quickly from one partly completed project, thought, or task to another.

If the child is younger, the parents may note that he has difficulty waiting in line, remaining in his seat, waiting his turn, or concentrating on one activity long enough to complete it.

An older child or an adult may be described as impulsive and easily distracted by irrelevant thoughts, sights, or sounds. He may also be characterized as emotionally labile, inattentive, or prone to daydreaming. His disorganization becomes apparent when, for example, he has difficulty meeting deadlines and keeping track of school or work tools and materials.

Diagnostic criteria

Commonly, the child with attention deficit hyperactivity disorder is referred for evaluation by the school. Accurate diagnosis of this disorder usually begins by obtaining information from several sources, such as the parents, the teachers, and the child himself.

Complete psychological, medical, and neurologic evaluations are then performed on the child to rule out other problems. Next, the child undergoes tests that measure impulsiveness, attention, and the ability to sustain a task. The findings portray a clear picture of attention deficit hyperactivity disorder and of the specific areas of support the child needs. (For characteristic findings in patients with this condition, see [Diagnosing attention deficit hyperactivity disorder.](#))

Treatment

Education is the first step in effective treatment of attention deficit hyperactivity disorder. The entire treatment team (which ideally includes parents, teachers, and therapists as well as the patient and the doctor) must fully understand the nature of this disorder as well as the disorder's effect on the individual's ability to function.

Specific treatments vary, depending on the severity of signs and symptoms and their effects on the patient's ability to function adequately. Behavior modification, coaching, external structure, use of planning and organizing systems, and supportive psychotherapy can all help the patient more effectively cope with the disorder.

Some patients benefit from medication to relieve symptoms. Ideally, the treatment team identifies the symptoms to be managed, selects appropriate medication, and then tracks the patient's symptoms carefully to determine the effectiveness of the medication. Stimulants, such as methylphenidate and dextroamphetamine, are the most commonly used agents. However, other drugs, including tricyclic antidepressants (such as desipramine and nortriptyline), mood stabilizers, and beta blockers, sometimes help control symptoms. Tomoxetine, currently in clinical trials, has been found in preliminary studies to be effective; further research will involve extending the duration of treatment to determine the effects of the medication.

The *DSM-IV* groups selected symptoms into inattention and hyperactivity-impulsivity categories. Diagnosis of attention deficit hyperactivity disorder is based on the person demonstrating at least six symptoms from one or both of these categories. A patient with symptoms mainly from the inattention category is classified as a predominantly inattentive type; a patient with mainly hyperactivity-impulsivity symptoms is diagnosed as a predominantly hyperactive-impulsive type. Someone with at least six symptoms from both groups has combined-type attention deficit hyperactivity disorder—the most common type. The symptoms must have persisted for at least 6 months to a degree that they are maladaptive and inconsistent with the person's developmental level.

Symptoms of inattention

- The person manifesting *inattention* often:
- u fails to pay close attention to details or makes careless mistakes in schoolwork, work, or other activities
 - u has difficulty sustaining attention in tasks or play activities
 - u doesn't seem to listen when spoken to directly
 - u doesn't follow through on instructions and fails to finish schoolwork, chores, or duties in the workplace (not because of oppositional behavior or failure to understand instructions)
 - u has difficulty organizing tasks and activities
 - u avoids, dislikes, or is reluctant to engage in tasks that require sustained mental effort, such as schoolwork or homework
 - u loses things necessary for tasks or activities (for example, toys, school assignments, pencils, books, or tools)
 - u becomes distracted by extraneous stimuli
 - u demonstrates forgetfulness in daily activities.

Symptoms of hyperactivity-impulsivity

- The person manifesting *hyperactivity* often:
- u fidgets with hands or feet or squirms in his seat
 - u leaves his seat in the classroom or in other situations in which remaining seated is expected
 - u runs about or climbs excessively in situations in which remaining seated is expected
 - u has difficulty playing or engaging in leisure activities quietly
 - u is characterized as “on the go” or acts as if “driven by a motor”
 - u talks excessively.
- The person manifesting *impulsivity* often:
- u blurts out answers before questions have been completed
 - u has difficulty awaiting his turn
 - u interrupts or intrudes on others.

Additional features

- u Some symptoms that caused impairment were evident before age 7.
- u Some impairment from the symptoms is present in two or more settings (for example, at school, at work, and at home).
- u Clinically significant impairment in social, academic, or occupational functioning must be clearly evident.
- u The symptoms don't occur exclusively during the course of a pervasive developmental disorder, schizophrenia, or another psychotic disorder and aren't better accounted for by another mental disorder.

Nursing diagnoses

- u Altered family processes u Altered nutrition: Less than body requirements u Impaired social interaction u Ineffective family coping: Compromised u Ineffective management of therapeutic regimen: Families u Loneliness u Risk for altered parenting

Key outcomes

- u The patient will acknowledge and respond to efforts by others to establish communication.
- u The patient will demonstrate effective social interaction skills in both one-on-one and group settings.
- u The patient and family members will report concern about difficulties in social interactions.
- u The patient and family members will communicate understanding of special dietary needs.
- u Family members will discuss the impact of the patient's illness and feelings about it with a health care professional.

Nursing interventions

- u Set realistic expectations and limits because the patient with attention deficit hyperactivity disorder is easily frustrated (which, in turn, results in decreased self-control).
- u Always remain calm and consistent with the child. Your calm manner will help him to maintain his self-control.
- u Try to keep all your instructions to the child short and simple.
- u Provide praise, rewards, and positive feedback whenever possible.
- u Help the child's parents and other family members develop planning and organizing systems to help them cope more effectively with the child's short attention span.
- u Make certain that the parents fully understand the child's prescribed medication regimen. Teach them about any adverse reactions that may occur, emphasizing those that may require immediate medical attention.
- u Provide the patient with diversional activities suited to his short attention span.
- u Encourage the parents to provide the child with nutritious snacks such as fruit to supplement his dietary intake.
- u Refer the parents to appropriate support groups and community organizations.

AUTISTIC DISORDER

Autistic disorder is a severe, pervasive developmental disorder marked by unresponsiveness to social contact, gross deficits in intelligence and language development, ritualistic and compulsive behaviors, restricted capacity for developmentally appropriate activities and interests, and bizarre responses to the environment. (See [Other pervasive developmental disorders](#).)

The disorder usually becomes apparent before the child reaches age 3, but in some children the actual onset is difficult to determine. Occasionally, autistic disorder isn't recognized until the child enters school, when his abnormal social development becomes obvious.

Autistic disorder is rare, affecting 4 to 5 children per 10,000 births. It affects four to five times more males than females, usually the firstborn male. Although the degree of impairment varies, the prognosis is poor and most patients require a structured environment throughout life.

Causes

The causes of autistic disorder remain unclear but are thought to include psychological, physiologic, and sociologic factors. Previously, it was thought that most parents of autistic children were intelligent, educated people of high socioeconomic status; recent studies suggest that this may not be true.

The parents of an autistic child may appear distant and unaffectionate toward the child. However, because autistic children are clearly different from birth, and because they are unresponsive or respond with rigid, screaming resistance to touch and attention, parental remoteness may be merely a frustrated, helpless reaction to this disorder, not its cause.

Some theorists consider autistic disorder related to early understimulation that causes the child to seek contact with the world through self-stimulating behaviors or consider it related to overwhelming overstimulation that leads to regression, muteness, and unresponsiveness to external stimuli. Controlled studies haven't confirmed

this etiology.

Recent studies have pointed to an association between neurobiological factors and autism. Defects in the central nervous system that may arise from prenatal complications (such as rubella or phenylketonuria), high maternal stress in the first trimester, and genetic factors appear to play a role in the development of autism.

Complications

Autistic disorder may be complicated by epileptic seizures. Seizures usually begin before adolescence and occur most commonly in patients whose IQ is below 50. Depression is common in adolescence and early adulthood, especially in patients with normal or above-average IQs. The onset of depression usually is triggered by the patient's recognition of the extent of his handicap.

During periods of stress, catatonic phenomena, such as excitement or posturing, or an undifferentiated psychotic state with delusions and hallucinations may occur. These symptoms usually resolve quickly when the stress is relieved.

Assessment findings

A primary characteristic of infantile autistic disorder is unresponsiveness to people. Infants with this disorder won't cuddle, avoid eye contact and facial expression, and are indifferent to affection and physical contact. Parents may report that the child becomes rigid or flaccid when held, cries when touched, and shows little or no interest in human contact.

As the infant grows older, his smiling response is delayed or absent. He doesn't lift his arms in anticipation of being picked up or form an attachment to a specific caregiver. Nor does he show the anxiety about strangers that is typical in the 8-month-old infant.

The autistic child fails to learn the usual socialization games (peek-a-boo, pat-a-cake, or bye-bye). He's likely to relate to others only to fill a physical need and then without eye contact or speech (for example, by dragging the adult to the sink when he's thirsty). The autistic child is said to “look right through” a person as though he weren't physically present. The end result may be mutual withdrawal between parents and child.

Severe language impairment and lack of imaginative play are characteristic. The child may be mute or may use immature speech patterns. For example, he may use a single word to express a series of activities; he may say “ground” when referring to any step in using a playground slide.

His speech commonly shows echolalia (meaningless repetition of words or phrases addressed to him) and pronoun reversal (“you go walk” when he means “I want to go for a walk”). When answering a question, he may simply repeat the question to mean “yes” and remain silent to mean “no.”

He shows little imagination, seldom acting out adult roles or engaging in fantasy play. In fact, he may insist on lining up an exact number of toys in the same manner over and over or repetitively mimic the actions of someone else.

The autistic child shows characteristically bizarre behavior patterns, such as screaming episodes, rituals, rhythmic rocking, arm flapping, crying without tears, and disturbed sleeping and eating patterns. His behavior may be self-destructive (hand biting, eye gouging, hair pulling, or head banging) or self-stimulating (playing with his own saliva, feces, and urine).

His bizarre responses to his environment include an extreme compulsion for sameness. For example, the slightest change in the arrangement of furniture can cause the child to return it immediately to its original place or, if he's unsuccessful, to fall into a panic state, marked by head banging, screaming, or biting himself.

In response to sensory stimuli, the autistic child may underreact or overreact; he may ignore objects—dropping those he is given or not looking at them—or he may become excessively absorbed in them—continually watching the objects or the movement of his own fingers over the objects. He commonly responds to stimuli by head banging, rocking, whirling, and hand flapping. He appears to rely more on smell, taste, and touch, which don't require him to reach out to the environment, and tends to avoid using sight and hearing to respond to or interact with the environment.

Other pervasive developmental disorders

Although autistic disorder is the most severe and most typical of the pervasive developmental disorders, recent evidence points to other, similar disorders in this class.

For example, the *DSM-IV* category *pervasive developmental disorder not otherwise specified* refers to patients who don't meet the criteria for autistic disorder but who *do* exhibit impaired development of reciprocal social interaction and of verbal and nonverbal communication skills.

Some patients with this diagnosis exhibit a markedly restricted repertoire of activities and interests, but others don't. Research suggests that these disorders are more common than autistic disorder, occurring in 6 to 10 of every 10,000 children.

The autistic child may exhibit additional behavioral abnormalities, such as:

- u cognitive impairment
- u eating, drinking, and sleeping problems; for example, limiting his diet to just a few foods, excessive drinking, or repeatedly waking during the night and rocking
- u mood disorders, including labile mood, giggling or crying without reason, lack of emotional responses, no fear of real danger but excessive fear of harmless objects, and generalized anxiety.

Diagnostic criteria

A diagnosis of autistic disorder is confirmed when the patient meets the criteria set forth in the *DSM-IV*. At least 6 of the following 12 characteristics must be present, including at least two items from the first section, one from the second, and one from the third.

- u Qualitative impairment in social interaction as manifested by the following:
 - marked impairment in the use of multiple nonverbal behaviors (for example, eye contact, facial expression, body posture, and gestures) to regulate social interaction
 - failure to develop peer relationships appropriate to developmental level
 - lack of spontaneous seeking to share enjoyment, interests, or achievements with others
 - lack of social or emotional reciprocity.
- u Qualitative impairments in communication as manifested by the following:
 - delay in or a total lack of development of spoken language (with no attempt to compensate for inadequate language skills nonverbally through gestures or mime)
 - in those with adequate speech, marked impairment in the ability to initiate or sustain conversation with others
 - stereotyped and repetitive use of language or idiosyncratic language
 - lack of varied, spontaneous make-believe play or social imitative play appropriate to developmental level.
- u Restricted repetitive and stereotyped patterns of behavior, interests, and activities as manifested by:
 - encompassing preoccupation with one or more stereotyped and restricted patterns of interest that is abnormal either in intensity or focus
 - apparently inflexible adherence to specific, nonfunctional routines or rituals
 - stereotyped and repetitive motor mannerisms, such as hand or finger flapping or complex whole-body movements
 - persistent preoccupation with parts of objects.

The diagnostic criteria also include delays or abnormal functioning in at least one of the following areas before age 3:

- social interaction and language skills
- symbolic or imaginative play.

Treatment

The difficult and prolonged treatment of autistic disorder must begin early, continue for years (through adolescence), and involve the child, parents, teachers, and therapists in coordinated efforts to encourage social adjustment and speech development and to reduce self-destructive behavior.

Behavioral techniques are used to decrease symptoms and increase the child's ability to respond. Positive reinforcement, using food and other rewards, can enhance language and social skills. Providing pleasurable sensory and motor stimulation (jogging, playing with a ball) encourages appropriate behavior and helps eliminate inappropriate behavior. Pharmacologic intervention may be helpful. Haloperidol often mitigates withdrawn and stereotypical behavior patterns, making the child more amenable to behavior modification therapies.

Treatment may take place in a psychiatric institution, in a specialized school, or in a day-care program, but the current trend is toward home treatment. Helping family members to develop strong one-on-one relationships with the autistic child commonly initiates responsive, imitative behavior. Because family members tend to feel inadequate and guilty, they may need counseling. Until the causes of infantile autism are known, prevention isn't possible.

Nursing diagnoses

u Altered family processes u Altered growth and development u Anxiety u Impaired verbal communication u Ineffective family coping u Risk for injury u Risk for violence: Self-directed u Self-care deficit u Social isolation

Key outcomes

- u Family members will identify and contact available resources as needed.
- u Family members will openly share feelings about the present situation.
- u As much as possible, the patient will demonstrate age-appropriate skills and behaviors.
- u The patient and family members will practice safety measures and take safety precautions in the home.
- u The patient will interact with family or friends.
- u The patient will perform self-care activities independently.

Nursing interventions

- u Reduce self-destructive behaviors. Physically stop the child from harming himself, while firmly saying “no.” When he responds to your voice, first give a primary reward (such as food); later, substitute verbal or physical reinforcement (such as “good” or a hug or a pat on the back).
- u Foster appropriate use of language. Provide positive reinforcement when the child indicates his needs correctly. Give verbal reinforcement at first (such as “good” or “great”); later, give physical reinforcement (such as a hug or a pat on the hand or shoulder).
- u Encourage development of self-esteem. Show the child that he's acceptable as a person. If he sits on the floor, sit on the floor with him.
- u Encourage self-care. For example, place a brush in the child's hand and guide his hand to brush his hair. Similarly, teach him to wash his hands and face.
- u Encourage acceptance of minor environmental changes. Prepare the child for the change by telling him about it. Make the change minor. For example, change the color of his bedspread or the placement of food on his plate. When he has accepted minor changes, move on to bigger ones.
- u Provide emotional support to the parents. Refer them to the Autism Society of America in Washington, D.C., for further assistance.

Patient teaching

- u Teach the parents how to physically care for the child's needs.
- u Teach the parents how to identify signs of excessive stress and coping skills to use under these circumstances. Emphasize that they'll be ineffective caregivers if they don't take the time to meet their own needs in addition to those of their child.
- u Help the parents understand that the cause of this condition is unknown.

BULIMIA NERVOSA

The essential features of bulimia nervosa include eating binges followed by feelings of guilt, humiliation, and self-deprecation. These feelings precipitate the patient's engaging in self-induced vomiting, the use of laxatives or diuretics, or strict dieting or fasting to overcome the effects of the binges. Unless the patient devotes an excessive amount of time to bingeing and purging, bulimia nervosa seldom is incapacitating.

Bulimia nervosa usually begins in adolescence or early adulthood and can occur simultaneously with anorexia nervosa. It affects nine females for every one male. Between 1% and 3% of adolescent and young women meet the diagnostic criteria for bulimia nervosa; 5% to 15% have some symptoms of the disorder.

Causes

The exact cause of bulimia is unknown, but various psychosocial factors are thought to contribute to its development. Such factors include family disturbance or conflict, sexual abuse, maladaptive learned behavior, struggle for control or self-identity, cultural overemphasis on physical appearance, and parental obesity. Bulimia nervosa is strongly associated with depression.

Complications

The repetitive vomiting in bulimia nervosa can result in dental caries, erosion of tooth enamel, parotitis, and gum infections. Electrolyte imbalances (including metabolic alkalosis, hypochloremia, and hypokalemia) or dehydration can occur, increasing the risk of serious physical complications, such as arrhythmias, and even sudden death. Ipecac syrup intoxication can cause cardiac failure in patients who rely on this drug to induce vomiting. Rare complications include esophageal tears and gastric ruptures. If laxatives and enemas are used by the bulimic patient, mucosal damage can occur.

Suicide is a potential psychiatric complication of bulimia nervosa. In addition, bulimic patients are more prone to psychoactive substance use disorders.

Assessment findings

The history of a patient with bulimia nervosa is characterized by episodic binge eating that may occur up to several times a day. The patient commonly reports a binge-eating episode during which she continues eating until abdominal pain, sleep, or the presence of another person interrupts it. The preferred food usually is sweet, soft, and high in calories and carbohydrate content.

The bulimic patient may appear thin or slightly overweight. Typically, however, although the patient's weight frequently fluctuates, it usually stays within the normal range through the use of diuretics, laxatives, vomiting, and exercise. So, unlike the anorexic patient, the bulimic patient usually can keep her eating disorder hidden.

Overt clues to this disorder include hyperactivity, peculiar eating habits or rituals, frequent weighing, and a distorted body image. (See [Recognizing bulimic patients.](#))

The patient may complain of abdominal and epigastric pain caused by acute gastric dilation. Amenorrhea also may be present. Repetitive vomiting may cause

painless swelling of the salivary glands, hoarseness, throat irritation or lacerations, and dental erosion. In addition, the patient may exhibit calluses of the knuckles or abrasions and scars on the dorsum of the hand, resulting from tooth injury during self-induced vomiting.

A bulimic patient commonly is perceived by others as a “perfect” student, mother, or career woman; an adolescent may be distinguished for participation in competitive activities, such as gymnastics, sports, or ballet. However, the patient’s psychosocial history may reveal an exaggerated sense of guilt, symptoms of depression, childhood trauma (especially sexual abuse), parental obesity, or a history of unsatisfactory sexual relationships.

Recognizing bulimic patients

Recognizing a bulimic patient isn't always easy. Unlike anorexic patients, bulimic patients don't deny that their eating habits are abnormal, but they commonly conceal their behavior out of shame and humiliation. If you suspect bulimia nervosa, be on the lookout for these psychological features:

- difficulties with impulse control
- chronic depression
- exaggerated sense of guilt
- low tolerance for frustration
- recurrent anxiety
- feelings of alienation
- self-consciousness
- difficulty expressing feelings such as anger
- impaired social or occupational adjustment
- perfectionism.

Diagnostic criteria

Diagnosis of bulimia nervosa can be confirmed when the patient meets the *DSM-IV* criteria for this disorder: recurrent episodes of binge eating (rapid consumption of a large amount of food in a discrete time) and repeated inappropriate behaviors to prevent weight gain (such as self-induced vomiting, laxative abuse, and fasting) that occur, on average, twice a week for 3 months.

The Beck Depression Inventory may identify coexisting depression. Laboratory tests can help determine the presence and severity of complications. Serum electrolyte studies may show elevated bicarbonate, decreased potassium, and decreased sodium levels. A baseline electrocardiogram may be done if tricyclic antidepressants will be prescribed or if the patient has a severe electrolyte disturbance.

Treatment

Treatment of bulimia nervosa may continue for several years. Interrelated physical and psychological symptoms must be treated simultaneously. Merely promoting weight gain isn't sufficient to guarantee long-term recovery. A patient whose physical status is severely compromised by inadequate or chaotic eating patterns is difficult to engage in the psychotherapeutic process.

Psychotherapy focuses on breaking the binge-purge cycle and helping the patient regain control over eating behavior. Treatment may occur in either an inpatient or outpatient setting. It includes behavior modification therapy, possibly in highly structured psychoeducational group meetings. Individual psychotherapy and family therapy, which address the eating disorder as a symptom of unresolved conflict, may help the patient understand the basis of her behavior and teach her self-control strategies. Antidepressant drugs such as imipramine may be used to supplement psychotherapy.

The patient also may benefit from participation in self-help groups such as Overeaters Anonymous or in a drug rehabilitation program if she has a concurrent substance abuse problem.

Nursing diagnoses

▫ Altered nutrition: Less than body requirements ▫ Anxiety ▫ Body image disturbance ▫ Chronic low self-esteem ▫ Constipation ▫ Fluid volume deficit ▫ Hyperthermia ▫ Ineffective individual coping ▫ Sleep pattern disturbance ▫ Social isolation

Key outcomes

- The patient will acknowledge change in body image.
- The patient will participate in decision-making about his case.
- The patient will express positive feelings about self.
- Fluid balance will remain stable, with intake equal to or greater than output.
- The patient will achieve expected state of wellness.
- The patient will interact with family or friends.

Nursing interventions

- Supervise the patient during mealtimes and for a specified period after meals, usually 1 hour. Set a time limit for each meal. Provide a pleasant, relaxed environment for eating.
- Using behavior modification techniques, reward the patient for satisfactory weight gain.
- Establish a contract with the patient, specifying the amount and type of food to be eaten at each meal.
- Encourage the patient to recognize and verbalize her feelings about her eating behavior. Provide an accepting and nonjudgmental atmosphere, controlling your reactions to her behavior and feelings.

- u Encourage the patient to talk about stressful issues, such as achievement, independence, socialization, sexuality, family problems, and control.
- u Identify the patient's elimination patterns.
- u Assess the patient's suicide potential.
- u Refer the patient and her family to the American Anorexia/Bulimia Association and to Anorexia Nervosa and Related Eating Disorders as sources of additional information and support.

Patient teaching

- u Teach the patient how to keep a food journal to monitor the treatment progress.
- u Outline the risks of laxative, emetic, and diuretic abuse for the patient.
- u Provide assertiveness training to help the patient gain control over her behavior and achieve a realistic and positive self-image.
- u If the patient is taking a prescribed tricyclic antidepressant, instruct her to take the drug with food. Warn her to avoid consuming alcoholic beverages; exposing herself to sunlight, heat lamps, or tanning beds; and discontinuing the medication unless she has notified the doctor.
- u If the patient is taking selective serotonin reuptake inhibitors, instruct her how to recognize signs of central serotonin syndrome (abdominal pain, diarrhea, sweating, fever, myoclonus, irritability and, in some severe cases, hyperpyrexia and cardiovascular shock).

DOWN SYNDROME

The first disorder attributed to a chromosomal aberration, Down syndrome (also known as mongolism and trisomy 21 syndrome) characteristically produces mental retardation, abnormal facial features, and other distinctive physical abnormalities. It's commonly associated with heart defects and other congenital disorders.

Life expectancy and quality for patients with Down syndrome have increased significantly because of improved treatment of related complications and better developmental education programs. Nevertheless, up to 44% of Down syndrome patients who have congenital heart disease die before they're 1 year old.

Overall, Down syndrome occurs in 1 per 800 to 1,000 live births, but the incidence increases with maternal age, especially after age 35. For instance, at age 20, a mother has about one chance in 2,000 of having a child with Down syndrome; by age 49, she has one chance in 12. Although women over age 35 account for fewer than 8% of all births, they bear 20% of all children with Down syndrome.

Causes

Down syndrome usually results from trisomy 21, an aberration in which chromosome 21 has three copies instead of the normal two because of faulty meiosis (nondisjunction) of the ovum or, sometimes, the sperm. This results in a karyotype of 47 chromosomes instead of the normal 46.

Although the incidence of nondisjunction increases with maternal age, the extra chromosome originates from the mother only 80% of the time. Studies suggest that in some cases, the chromosomal abnormality results from deterioration of the oocyte. Such degeneration can be caused by age or the cumulative effects of environmental factors, such as radiation and viruses. About 4% of the time, Down syndrome results from an unbalanced translocation in which the long arm of chromosome 21 breaks and attaches to another chromosome.

Complications

Mortality is high in the fetus and neonate. Early death usually results from complications precipitated by associated congenital heart defects. If the patient survives to adulthood, premature senile dementia, similar to Alzheimer's disease, usually occurs in the 4th decade. An increased incidence of leukemia, acute and chronic infections, diabetes mellitus, and thyroid disorders is common.

Assessment findings

The physical signs of Down syndrome are readily apparent at birth. The neonate is lethargic and a poor feeder. Inspection reveals craniofacial anomalies, such as slanting, almond-shaped eyes (epicanthic folds); a protruding tongue; a small, open mouth; a single transverse palmar crease (simian crease); small white spots (Brushfield's spots) on the iris; a small skull; a flat bridge across the nose; a flattened face; small external ears; and a short neck with excess skin.

Other physical abnormalities include dry, sensitive skin with decreased elasticity, umbilical hernia, short stature, and short extremities with broad, flat, and squarish hands and feet. The patient's hands have a dysplastic middle phalanx of the fifth finger, and his feet have a wide space between the first and second toes. Fingerprints and footprints are abnormal. Hypotonic limb muscles impair reflex development.

Examination reveals an absent Moro reflex and hyperextensible joints. The patient's posture, coordination, and balance are impaired. In many cases, a child with Down syndrome also has congenital heart disease (septal defects or pulmonary or aortic stenosis), duodenal obstruction (from atresia, stenosis, or annular pancreas), clubfoot, imperforate anus, cleft lip and palate, Hirschsprung's disease, meningomyelocele, and pelvic bone abnormalities.

As the child grows, dental development is slow, with abnormal or absent teeth. He also exhibits strabismus and, occasionally, cataracts. The genitalia develop poorly, and puberty is delayed. The female with Down syndrome may menstruate and be fertile. The male is infertile with low serum testosterone levels; in many, the testes fail to descend.

Patients with Down syndrome have an average IQ between 30 and 50 but some have higher IQs; however, social performance usually is beyond that expected for their mental age. Intellectual development slows with age.

Diagnostic tests

A karyotype showing the chromosomal abnormality confirms the diagnosis of Down syndrome. Other tests can reveal Down syndrome before birth. For example, prenatal ultrasonography can suggest Down syndrome if a duodenal obstruction or an atrioventricular canal defect is present. Reduced levels of alpha-fetoprotein may indicate Down syndrome. A simple blood test for alpha-fetoprotein is routinely offered to most pregnant women.

Amniocentesis also allows prenatal diagnosis; 80% of all amniocenteses are done for this purpose and are recommended for pregnant women past age 35. Amniocentesis is indicated for a pregnant woman of any age when either she or the father carries a translocated chromosome.

Additional medical tests confirm the presence of associated conditions. Developmental screening tests, such as the Denver Developmental Screening Test, determine the severity of retardation and chart the patient's progress in response to intervention or education programs.

Treatment

Surgery to correct cardiac defects and other related congenital abnormalities, antibiotic therapy for recurrent infections, and thyroid hormone replacement for hypothyroidism have improved life expectancy considerably for patients with Down syndrome. Plastic surgery may correct the characteristic facial traits, especially the protruding tongue, cleft lip, and cleft palate. Benefits beyond improved appearance may include improved speech, reduced susceptibility to dental caries, and fewer orthodontic problems later.

When possible, parents of Down syndrome children are encouraged to keep their children at home rather than in an institution. Early intervention (such as infant stimulation programs) increases sensory awareness and has proved helpful with some patients. Special education programs, mandated in most communities, permit the child to maximize his potential and promote self-esteem. His physical condition and self-image also can benefit from special athletic programs. As adults, many Down syndrome patients become productive workers at jobs that match their intellectual abilities.

Nursing diagnoses

u Altered growth and development u Altered health maintenance u Bathing and hygiene self-care deficit u Dressing and grooming self-care deficit u Ineffective family coping u Risk for altered parenting

Key outcomes

- u The patient will demonstrate age-appropriate skills and behaviors to the extent possible.
- u The patient will perform health maintenance activities according to level of ability.
- u The patient will participate in developmental stimulation programs to increase skill levels.
- u The patient will express understanding of norms for growth and development.

Nursing interventions

- u Establish a trusting relationship with the child's parents, and encourage communication during the difficult period soon after diagnosis. Recognize signs of grieving.
- u Encourage the parents to hold and nurture their child.
- u Refer the parents and older siblings for genetic and psychological counseling, as appropriate, to help them evaluate future risks and develop coping skills.
- u Refer the parents to national Down syndrome organizations and other community resources.

Patient teaching

- u Emphasize the importance of adequate exercise and maximal environmental stimulation. Refer the parents to infant stimulation classes, which may begin in the early months of life.
- u Assist the parents in setting realistic goals for their child. Although his mental development may seem normal at first, warn the parents not to view this early development as a sign of future progress. By the time the child is 1 year old, his development clearly will lag behind that of normal children. Help the parents view their child's achievements in a positive light.
- u Teach the parents the importance of a balanced diet. Stress the need for patience while feeding their child, who may have more difficulty sucking, be less demanding, and seem less eager to eat than normal babies.
- u Advise the parents to remember the emotional needs of other children in the family.

MENTAL RETARDATION

The American Association on Mental Retardation (AAMR) defines mental retardation as “significantly subaverage general intellectual function existing concurrently with deficits in adaptive behavior manifesting itself during the developmental period (before age 18). An estimated 1% to 3% of the population is mentally retarded, demonstrating an IQ below 70 and an associated deficit in carrying out tasks required for personal independence.

Retardation commonly is accompanied by additional physical and emotional disorders that may constitute handicaps in themselves. Mental retardation places a significant burden on patients and their families, resulting in stress, frustration, and family problems.

Causes

The AAMR has grouped the causes of mental retardation into 10 categories. But a specific cause is identifiable in only 25% of retarded people and, of these, only 10% have the potential for cure through medical or surgical intervention. In the remaining 75%, predisposing factors, such as deficient prenatal or perinatal care, inadequate nutrition, poor social environment, and poor child-rearing practices, contribute significantly to mental retardation. (See [Causes of mental retardation](#).)

Causes of mental retardation
<p>Possible causative factors in mental retardation include:</p> <ul style="list-style-type: none">u chromosomal abnormalities (Down syndrome, Klinefelter syndrome)u disorders resulting from unknown prenatal influences (hydrocephalus, hydranencephaly, microcephaly)u disorders of metabolism or nutrition (phenylketonuria, hypothyroidism, Hurler syndrome, galactosemia, Tay-Sachs disease)u environmental influences (cultural-familial retardation, poor nutrition, lack of medical care)u gestational disorders (prematurity)u gross brain disorders that develop after birth (neurofibromatosis, intracranial neoplasm)u infection and intoxication (congenital rubella, syphilis, lead poisoning, meningitis, encephalitis, insecticides, drugs, maternal viral infection, toxins)u psychiatric disordersu trauma or physical agents (mechanical injury, asphyxia, hyperpyrexia).

It's estimated that 10% to 15% of individuals with mental deficiency have a significant chromosome abnormality. This percentage is greater among individuals who have anatomic malformations. Prenatal screening for genetic defects (such as Tay-Sachs disease) and genetic counseling for families at risk for specific defects have reduced the incidence of genetically transmitted mental retardation.

Complications

Mental retardation poses a risk to patient safety and family integrity. For example, mentally retarded people are vulnerable to physical and mental abuse by others. The birth of a mentally retarded child can precipitate dysfunctional behaviors within the family, depending on the severity of the retardation, the amount of physical care required, and the family's financial resources and coping skills.

Assessment findings

The observable effects of mental retardation are deviations from normal adaptive behaviors, ranging from learning disabilities and uncontrollable behavior to severe cognitive and motor skill impairment. Such deviations may be present during infancy and early childhood or, in mild retardation, not until school age or later. The earlier a child's adaptive deficit is recognized and he's placed in a special learning program, the more likely he is to achieve age-appropriate adaptive behaviors.

If the patient is older, review his adaptation to his environment, especially if he's in a group-living situation.

The family of a mentally retarded patient may report a multitude of problems, stemming from frustration, fear, and exhaustion. These problems, such as financial difficulties, abuse, and divorce, can compromise the child's care. Examination may reveal signs of abuse or neglect.

Mentally retarded people may exhibit signs and symptoms of other disorders, such as cleft lip, congenital heart defects, cerebral palsy, and a lowered resistance to infection.

Diagnostic tests

A score below 70 on a standardized IQ test confirms mental retardation. The recognized levels of mental retardation are as follows:

- u mild retardation, IQ 55 to 69
- u moderate retardation, IQ 40 to 54
- u severe retardation, IQ 25 to 39
- u profound retardation, IQ less than 25.

These ranges of IQ scores may differ slightly, depending on the IQ test used. The IQ test primarily predicts school performance and must be supplemented by other diagnostic evaluations.

For example, the Adaptive Behavior Scale, a test that deals with behaviors important to activities of daily living, determines the patient's adaptive profile. This test evaluates self-help skills (toileting and eating), physical and social development, language, socialization, and time and number concepts. It also examines inappropriate behaviors (such as violent or destructive acts, withdrawal, and self-abusive or sexually aberrant behavior).

Age-appropriate adaptive behaviors are assessed by the use of developmental screening tests such as the Denver Developmental Screening Test. These tests compare the subject's functional level with the normal level for the same chronologic age. The greater the discrepancy between chronologic and developmental age, the more severe the retardation.

In children, the functional level rests on sensory motor skills, self-help skills, and socialization. In adolescents and adults, it rests on academic skills, reasoning and judgment skills, and social skills. Continuing assessment and review of development are essential for effective management.

Treatment

Effective management of a mentally retarded patient requires an interdisciplinary team approach that provides complete, continuous, and coordinated services. A primary goal is to develop the patient's strengths as fully as possible, taking into account his interests, personal experiences, and resources. Another major goal is the development of social adaptive skills to help the patient function as normally as possible.

Mentally retarded children require special education and training, ideally beginning in infancy. An individualized, effective education program can optimize the quality of life for even the profoundly retarded.

The prognosis for people with mental retardation is related more to timing and aggressive treatment, personal motivation, training opportunities, and associated conditions than to the mental retardation itself. With good support systems, many mentally retarded people become productive members of society. Successful management leads to independent functioning and occupational skills for some and a sheltered environment for others.

Nursing diagnoses

u Altered growth and development u Altered health maintenance u Bathing and hygiene self-care deficit u Dressing and grooming self-care deficit u Family coping: Potential for growth u Functional incontinence u Knowledge deficit u Powerlessness u Risk for altered development u Risk for injury u Risk for altered parenting u Self-care deficit

Key outcomes

- u The patient will demonstrate age-appropriate skills and behaviors to the extent possible.
- u The patient will perform health maintenance activities according to level of ability.
- u The patient will demonstrate skills appropriate for age.
- u The patient will participate in developmental stimulation program to increase skill levels.
- u The patient will express understanding of norms for growth and development.

Nursing interventions

- u Support the parents of a child diagnosed with mental retardation. Not only may they be overwhelmed by caretaking and financial concerns, but they also may have difficulty accepting and bonding with their child.
- u Remember that the mentally retarded child has all the ordinary needs of a normal child plus those created by his handicap. The child especially needs affection, acceptance, stimulation, and prudent, consistent discipline; he's less able to cope if rejected, overprotected, or forced beyond his abilities.
- u When caring for a hospitalized retarded patient, promote continuity of care by acting as a liaison for parents and other health care professionals involved in his care.
- u During hospitalization, continue training programs already in place, but remember that illness may bring on some regression in behavior and skills.
- u For the severely retarded child, suggest ways for parents to cope with the guilt, frustration, and exhaustion that often accompany caring for such a child. In particular, parents of a severely retarded child need an extensive teaching and discharge planning program, including physical care procedures, stress reduction techniques, support services, and referral to developmental programs. As needed, request a social service consultation to investigate community resources available to assist the family.

Patient teaching

- u Teach parents how to care for the special needs of the retarded child. Suggest that they contact the AAMR and the Association for Retarded Citizens for more information and referral to sources of community support.
- u Teach retarded adolescents how to deal with physical changes and sexual maturation. Encourage participation in appropriate sex education classes. Keep in mind that the retarded person may experience difficulty in expressing his sexual concerns because of limited verbal skills. In addition, teach socially acceptable expressions of sexuality.

TIC DISORDERS

Tic disorders are a group of three disorders that include Tourette syndrome, chronic motor or vocal tic disorder, and transient tic disorder. Although they're similar pathophysiologically, these disorders differ in severity and prognosis. (For information about related stress disorders, see [Stress disorders with physical manifestations.](#))

All tic disorders, commonly known simply as "tics," are involuntary, spasmodic, recurrent, and purposeless motor movements or vocalizations. These disorders are classified as motor or vocal and as simple or complex. (See [Classifying tics.](#)) Tics begin before age 18. The median age of onset for Tourette syndrome is age 7, but this disorder can occur as early as age 2. All tic disorders are three times more common in males than in females.

Transient tics usually are self-limiting, but Tourette syndrome follows a chronic course characterized by remissions and exacerbations.

Causes

Although their exact cause is unknown, tic disorders occur more frequently in certain families, suggesting a genetic cause. Tics commonly develop when a child experiences overwhelming anxiety, usually associated with normal maturation. Tics may be precipitated or exacerbated by the use of phenothiazines and central nervous system (CNS) stimulants or by head trauma.

Complications

The severe compulsive movements associated with Tourette syndrome can result in physical injury, including blindness subsequent to retinal detachment, orthopedic

disorders, dermatologic complications, and even self-mutilation. The patient also may experience impaired social, academic, or occupational functioning because of rejection by others or anxiety about the tics in social situations.

Assessment findings

Assessment findings vary according to the type of tic disorder. Inspection, coupled with the patient's history, may reveal the specific motor or vocal patterns that characterize the tic, as well as the frequency, complexity, and precipitating causes. The patient or his family may report that the tics occur sporadically many times a day.

Note whether certain situations exacerbate the tics. All tic disorders may be exacerbated by stress, and they usually diminish markedly during sleep. The patient also may report that they occur during activities that require concentration, such as reading or sewing.

Determine if the patient can control the tics. Although he may experience the tic as irresistible, most patients can, with conscious effort, control them for short periods.

Stress disorders with physical manifestations
<p>In addition to tic disorders, other stress-related disorders that produce physical signs in children include stuttering, functional enuresis, functional encopresis, sleepwalking, and sleep terrors.</p> <p>Stuttering</p> <p>Characterized by abnormalities of speech rhythms with repetitions and hesitations at the beginning of words, stuttering also may involve movements of the respiratory muscles, shoulders, and face.</p> <p>Stuttering may be associated with mental dullness, poor social background, and a history of birth trauma. This disorder most commonly occurs in children of average or superior intelligence who fear they can't meet the expectations of socially striving, success-oriented families.</p> <p>Related problems may include low self-esteem, tension, anxiety, humiliation, and withdrawal from social situations because of fear of stuttering.</p> <p>About 80% of stutterers recover after age 16. Evaluation and treatment by a speech pathologist teaches the stutterer to place equal weight on each syllable in a sentence, to breathe properly, and to control anxiety.</p> <p>Functional enuresis</p> <p>Functional enuresis is characterized by intentional or involuntary voiding of urine, usually during the night (nocturnal enuresis).</p> <p>Considered normal in children until age 3 or 4, functional enuresis occurs in about 40% of children at this age and persists in 10% to age 5, in 5% to age 10, and in 1% of males to age 18. The disorder persists longer in males.</p> <p>Causes may be related to stress in the child's life, such as the birth of a sibling, the move to a new home, divorce, separation, hospitalization, faulty toilet training (inconsistent, demanding, or punitive), and unrealistic responsibilities that aren't age-appropriate.</p> <p>Associated problems include low self-esteem, social withdrawal from peers because of ostracism and ridicule, and anger, rejection, and punishment by caregivers.</p> <p>Advise parents to avoid punitive reactions that burden the child with additional stress and guilt. A matter-of-fact attitude helps the child learn to control his bladder function without undue stress.</p> <p>If enuresis persists into late childhood, treatment with imipramine (Tofranil) may help. <i>Caution.</i> Tofranil can cause schizophrenia-like symptoms in young children. Dry-bed therapy may include the use of an alarm apparatus (wet bell pad), social motivation, self-correction of accidents, and positive reinforcement.</p> <p>Functional encopresis</p> <p>Denoted by evacuation of feces into the child's clothes or inappropriate receptacles, functional encopresis is associated with low intelligence, cerebral dysfunction, or other developmental symptoms, such as a lag in language development.</p> <p>Predisposing factors may include psychosocial stress as well as inadequate or inconsistent toilet training.</p> <p>Related problems may include repressed anger, withdrawal from peers in social relationships, and loss of self-esteem.</p> <p>Treatment involves encouraging the child to come to his parents whenever he has an "accident." Encourage the parents to help the child by giving him clean clothes without criticism or punishment. A medical examination should be performed to rule out any physical disorder. Child, adult, and family therapy may be needed to help reduce anger and disappointment over the child's development and to correct parenting techniques.</p> <p>Sleepwalking and sleep terrors</p> <p>In sleepwalking, the child calmly rises from bed in a state of altered consciousness and walks about with no subsequent recollection of any dream content. In sleep terrors, he awakens terrified, in a state of clouded consciousness, often unable to recognize parents and familiar surroundings. Visual hallucinations are common.</p> <p>Sleep terrors are a normal developmental event in 2- and 3-year-old children, usually occurring within 30 minutes to 3½ hours of sleep onset. Tachycardia, tachypnea, diaphoresis, dilated pupils, and piloerection are associated with sleep terrors. The child also may fear being alone.</p> <p>Tell parents to make sure the child has access to them at night. Sleep terrors usually are self-limiting and subside within a few weeks.</p>

Psychosocial assessment may reveal the underlying stressful factors that trigger the tic. In addition, problems with social adjustment, lack of self-esteem, and depression may be identified.

Diagnostic criteria

The diagnosis of a tic disorder is based on fulfillment of the criteria documented in the *DSM-IV*.

For *Tourette syndrome*:

- u Both multiple motor and one or more vocal tics have been present at some time during the illness, although not necessarily concurrently.
- u The tics occur many times over the course of a day (usually in bouts) nearly every day or intermittently for more than 1 year.
- u Onset occurs before age 18.

- u Occurrence isn't exclusively during psychoactive substance intoxication or known CNS disease.

For chronic motor or vocal tic disorder:

- u Either motor or vocal tics, but not both, have been present at some time during the illness.
- u The tics occur many times a day nearly every day or intermittently for more than 1 year.
- u Onset occurs before age 18.
- u Occurrence isn't exclusively during psychoactive substance intoxication or known CNS disease.

For transient tic disorder:

- u Single or multiple motor or vocal tics, or both, are present.
- u The tics occur many times a day nearly every day for at least 4 weeks but for no longer than 12 consecutive months.
- u The patient has no history of Tourette syndrome or chronic motor or vocal tic disorder.
- u Onset occurs before age 18.
- u Occurrence isn't exclusively during psychoactive substance intoxication or known CNS disease.

All tic disorders cause marked distress or significant impairment in social, occupational, or other important areas of functioning.

Treatment

Effective treatment requires correction of the underlying psychopathology by identifying and resolving the sources of the patient's anxiety, stress, and intrapsychic conflict. Without correction of the underlying psychopathology, pressuring the patient to control the tics will be unsuccessful; he can do so only briefly and then only with intense effort. Behavior modification techniques and operant conditioning have been successful when the patient experiences tics that are mild.

No medications are helpful in treating transient tics. Haloperidol is considered the drug of choice if the patient has Tourette syndrome. Pimozide, an oral dopamine-blocking drug, may be substituted in patients who can't tolerate or don't respond well to haloperidol. Alternatively, clonazepam or clonidine may be prescribed.

Nursing diagnoses

- u Anxiety
- u Body image disturbance
- u Chronic low self-esteem
- u Impaired social interaction
- u Ineffective individual coping
- u Powerlessness
- u Social isolation

Classifying tics
According to the <i>DSM-IV</i> , motor and vocal tics are classified as simple or complex. However, the boundaries of these categories remain unclear. In addition, combinations of tics may occur simultaneously.
Motor tics
<i>Simple motor tics</i> include eye blinking, neck jerking, shoulder shrugging, head banging, head turning, tongue protrusion, lip or tongue biting, nail biting, hair pulling, and facial grimacing.
Some examples of <i>complex motor tics</i> are facial gestures, grooming behaviors, hitting or biting oneself, jumping, hopping, touching, squatting, deep knee bends, retracing steps, twirling when walking, stamping, smelling an object, and imitating the movements of someone who's being observed (echopraxia).
Vocal tics
Examples of <i>simple vocal tics</i> include coughing, throat clearing, grunting, sniffing, snorting, hissing, clicking, yelping, and barking.
<i>Complex vocal tics</i> may involve repeating words out of context; using socially unacceptable words, many of which are obscene (coprolalia); or repeating the last-heard sound, word, or phase of another person (echolalia).

Key outcomes

- u The patient will indicate that social relationships have improved and negative feelings have diminished.
- u The patient will voice feelings related to self-esteem.
- u The patient will join gradually in self-care and the decision-making process.
- u The patient will engage in social interactions with others.
- u The patient will demonstrate verbally and behaviorally a decrease in negative self-evaluation.

Nursing interventions

- u Offer emotional support, and help the patient prevent fatigue.
- u Suggest that the patient with Tourette syndrome contact the Tourette Syndrome Association for information and support.

Patient teaching

- u Help the patient to identify and eliminate any avoidable stress and to learn positive new ways to deal with anxiety.
- u Encourage the patient to verbalize his feelings about his illness. Help him understand that the movements are involuntary and that he shouldn't feel guilty or blame himself.

PSYCHOACTIVE SUBSTANCE ABUSE DISORDERS

This section includes alcoholism and psychoactive drug abuse and dependence, disorders that affect the central nervous system and cause physical and mental harm.

ALCOHOLISM

Alcoholism is a chronic disorder most often described as the uncontrolled intake of alcoholic beverages that interferes with physical and mental health, social and familial relationships, and occupational responsibilities. Alcoholism cuts across all social and economic groups, involves both sexes, and occurs at all stages of the life cycle, beginning as early as elementary school age.

Most adults in the United States are light drinkers; a minority—about 10% of the population—account for 50% of all alcohol consumption. About 13% of all adults over age 18 have suffered from alcohol abuse or dependence at some time in their lives. The prevalence of drinking is highest between the ages of 21 and 34, but current statistics show that up to 19% of 12- to 17-year-olds have a serious drinking problem. Males are two to five times more likely to abuse alcohol than are females.

According to some statistics, alcohol abuse is a factor in 60% of all automobile accidents. Alcoholism has no known cure.

Causes

Numerous biological, psychological, and sociocultural factors may cause alcohol addiction, but no clear evidence confirms the influence of any of these factors. Family background may play a significant part: An offspring of one alcoholic parent is seven to eight times more likely to become an alcoholic than is a peer without such a parent. Biological factors may include genetic or biochemical abnormalities, nutritional deficiencies, endocrine imbalances, and allergic responses.

Psychological factors may include the urge to drink alcohol to reduce anxiety or symptoms of mental illness; the desire to avoid responsibility in familial, social, and work relationships; and the need to bolster self-esteem.

Sociocultural factors include the availability of alcoholic beverages, group or peer pressure, an excessively stressful lifestyle, and social attitudes that approve frequent imbibing. Advertising supports society's message that alcohol consumption is part of a healthy lifestyle. Paradoxically, many alcoholics come from families in which alcohol is forbidden.

Complications

Most body tissues can be adversely affected by the heavy intake of alcohol. Death can occur from abrupt withdrawal. For that reason, monitored therapeutic withdrawal is preferred over unmonitored withdrawal. (See [Complications of alcohol use](#).)

Assessment findings

Because alcoholics may hide or deny their addiction and may temporarily manage to maintain a functional life, assessing for alcoholism can be difficult. Note physical and psychosocial symptoms that suggest alcoholism. For example, the patient's history may suggest a need for daily or episodic alcohol use for adequate function, an inability to discontinue or reduce alcohol intake, episodes of anesthesia or amnesia during intoxication (blackouts), episodes of violence during intoxication, and interference with social and familial relationships and occupational responsibilities.

Many minor complaints may be alcohol-related. The patient may report malaise, dyspepsia, mood swings or depression, and an increased incidence of infection. Observe the patient for poor personal hygiene and untreated injuries, such as cigarette burns, fractures, and bruises, that he can't fully explain. Note any evidence of an unusually high tolerance for sedatives and narcotics. Assess the patient for signs of nutritional deficiency, including vitamins and minerals.

Watch for secretive behavior, which may be an attempt to hide the disorder or the patient's stock of alcohol. Suspect alcoholism if the patient buys inordinate amounts of aftershave lotion or mouthwash and doesn't seem to use it in the expected way. Deprived of his usual supply of alcohol, an alcoholic may consume it in any form he can find.

When confronted about his drinking, the patient may deny or rationalize the problem. Alternatively, he may be guarded or hostile in his response and may even sign out of the hospital against medical advice. He also may project his anger or feelings of guilt or inadequacy onto others to avoid confronting his illness.

Complications of alcohol use
<p>Alcohol can damage body tissues by its direct irritating effects, by changes that take place in the body during its metabolism, by aggravation of existing disease, by accidents occurring during intoxication, and by interactions between the substance and drugs. Such tissue damage can cause complications.</p>
<p>Cardiopulmonary complications</p> <ul style="list-style-type: none">u Cardiac arrhythmiasu Cardiomyopathyu Chronic obstructive pulmonary diseaseu Essential hypertensionu Increased risk of tuberculosisu Pneumonia
<p>Hepatic complications</p> <ul style="list-style-type: none">u Alcoholic hepatitisu Cirrhosisu Fatty liver
<p>GI complications</p> <ul style="list-style-type: none">u Chronic diarrheau Esophageal canceru Esophageal varicesu Esophagitisu Gastric ulcersu Gastritisu GI bleedingu Malabsorptionu Pancreatitis
<p>Neurologic complications</p> <ul style="list-style-type: none">u Alcoholic dementiau Alcoholic hallucinosisu Alcohol withdrawal deliriumu Korsakoff's syndromeu Peripheral neuropathyu Seizure disordersu Subdural hematomau Wernicke's encephalopathy
<p>Psychiatric complications</p> <ul style="list-style-type: none">u Amotivational syndromeu Depressionu Fetal alcohol syndromeu Impaired social and occupational functioningu Multiple substance abuseu Suicide

<div><div><div>u Depression</div><div>u Fetal alcohol syndrome</div><div>u Impaired social and occupational functioning</div><div>u Multiple substance abuse</div><div>u Suicide</div></div></div>
<div><div>Other complications</div><div><div><div>u Beriberi</div><div>u Hypoglycemia</div><div>u Leg and foot ulcers</div><div>u Prostatitis</div></div></div></div>

In addition to these progressive signs of psychological deterioration, chronic alcohol abuse brings with it a vast array of physical complications. Assess for these complications in a patient with an alcohol-related disorder.

After abstinence or reduction of alcohol intake, manifestations of withdrawal may vary. Withdrawal signs and symptoms begin shortly after drinking has stopped and last for up to 10 days. The patient initially experiences anorexia, nausea, anxiety, fever, insomnia, diaphoresis, and tremor, progressing to severe tremulousness, agitation and, possibly, hallucinations and violent behavior. Major motor seizures, also known as “rum fits,” can occur during withdrawal. Suspect alcoholism in any patient with unexplained seizure activity. (See [Signs and symptoms of alcohol withdrawal](#).)

Diagnostic criteria

The diagnosis of alcohol dependence is confirmed when the patient meets the following criteria documented in the *DSM-IV*:

- u At least three of the following signs and symptoms must be present:
 - alcohol often taken in larger amounts or for a longer time than the person intended
 - persistent desire or one or more unsuccessful efforts to cut down or control alcohol use
 - excessive time spent in activities necessary to obtain alcohol
 - frequent intoxication or withdrawal symptoms when expected to fulfill major obligations at work, school, or home, or when alcohol consumption is physically hazardous
 - important social, occupational, or recreational activities given up or reduced because of alcohol consumption
 - continued alcohol consumption despite knowledge of having a persistent or recurrent social, psychological, or physical problem that is caused or exacerbated by alcohol use

Signs and symptoms of alcohol withdrawal			
Withdrawal signs and symptoms may vary in degree from mild (morning hangover) to severe (alcohol withdrawal delirium). Alcohol withdrawal delirium, formerly known as delirium tremens (or DTs), is marked by acute distress after drinking cessation in a person with physical dependency on alcohol.			
SIGNS AND SYMPTOMS		MILD WITHDRAWAL	MODERATE WITHDRAWAL
Anxiety	Mild restlessness	Obvious motor restlessness and painful anxiety	Extreme restlessness and agitation with intense fearfulness
			Rejection of all food and fluid except alcohol
Appetite	Impaired appetite	Marked anorexia	Elevated systolic and diastolic
			Marked confusion and disorientation
Blood pressure	Normal or slightly elevated systolic	Usually elevated systolic	Dry heaves and vomiting
Confusion	None	Variable	Visual and occasional auditory hallucinations, usually of fearful or threatening content; misidentification of people and frightening delusions related to hallucinatory experiences
GI symptoms	Nausea	Nausea and vomiting	Gross, uncontrollable bodily shaking
Hallucinations	None	Vague, transient visual and auditory hallucinations and illusions; commonly nocturnal; often with meaning	Pulse rate of 120 to 140 beats/minute
			Common
Motor impairment	Inner tremulousness with hand tremor	Visible tremors	Total wakefulness
			Marked hyperhidrosis
Pulse rate	Tachycardia	Pulse rate 100 to 120 beats/minute	
			Possible
Seizures	None	Marked insomnia and nightmares	
Sleep disturbance	Restless sleep or insomnia	Obvious	
Sweating	Slight		

- marked tolerance: need for markedly increased amounts of alcohol to achieve intoxication or desired effect, or markedly diminished effect with continued use of the same amount
- characteristic withdrawal symptoms
- alcohol often consumed to relieve or avoid withdrawal symptoms
- u Some symptoms must have persisted for at least 1 month or have occurred repeatedly over a longer time.

In addition to a psychiatric examination, laboratory tests can confirm alcohol use and the presence of complications. For example, laboratory data can document recent alcohol ingestion. A blood alcohol level of 0.10% weight/volume (200 mg/dl) is accepted as the level of intoxication. Serum electrolyte levels may identify electrolyte abnormalities (in severe hepatic disease, the blood urea nitrogen level is increased and the serum glucose level is decreased).

Further testing may reveal increased serum ammonia and serum amylase levels. Urine toxicology may help to determine if the alcoholic with alcohol withdrawal

delirium or another acute complication abuses other drugs as well.

Liver function studies, revealing increased levels of serum cholesterol, lactate dehydrogenase, alanine aminotransferase, aspartate aminotransferase, and creatine kinase, may all point to liver damage, and elevated serum amylase and lipase levels point to acute pancreatitis. A hematologic workup can identify anemia, thrombocytopenia, increased prothrombin time, and increased partial thromboplastin time.

Treatment

Total abstinence is the only effective treatment. Supportive programs that offer detoxification, rehabilitation, and aftercare, including continued involvement in Alcoholics Anonymous (AA), may produce long-term results.

Acute intoxication is treated symptomatically by supporting respiration, preventing aspiration of vomitus, replacing fluids, administering I.V. glucose to prevent hypoglycemia, correcting hypothermia or acidosis, and initiating emergency treatment for trauma, infection, or GI bleeding.

Treatment of chronic alcoholism relies on medications to deter alcohol use and treat effects of withdrawal; psychotherapy, using behavior modification techniques, group therapy, and family therapy; and appropriate measures to relieve associated physical problems.

Aversion, or deterrent, therapy uses a daily oral dose of disulfiram to prevent compulsive drinking. This drug interferes with alcohol metabolism and allows toxic levels of acetaldehyde to accumulate in the patient's blood, producing immediate and potentially fatal distress if the patient consumes alcohol up to 2 weeks after taking it.

Disulfiram is contraindicated during pregnancy and in patients with diabetes, heart disease, severe hepatic disease, or any disorder in which such a reaction could be especially dangerous. Another form of aversion therapy attempts to induce aversion by administering alcohol with an emetic.

For long-term success with aversion, or deterrent, therapy, the sober alcoholic must learn to fill the place alcohol once occupied in his life with something constructive. For patients with abnormal dependence or for those who also abuse other drugs, aversion therapy with disulfiram may only substitute one drug dependence for another; so it should be used prudently.

Tranquilizers, particularly benzodiazepines, occasionally are used to relieve overwhelming anxiety during rehabilitation. However, these drugs have addictive potential (substituting one substance abuse problem for another), and they can precipitate coma or even death when combined with alcohol. Naltrexone may be useful as an adjunct to psychotherapy, especially when there are high levels of cravings. Antipsychotics are prescribed to control hyperactivity and psychosis. Anticonvulsants, antiemetics, and antidiarrheals also are used to treat symptoms of alcohol withdrawal.

Supportive counseling or individual, group, or family psychotherapy may improve the alcoholic's ability to cope with stress, anxiety, and frustration and help him gain insight into the personal problems and conflicts that may have led him to alcohol abuse. Ongoing support groups also can help him overcome his dependence on alcohol. In AA, a self-help group with more than a million members worldwide, the alcoholic finds emotional support from others with similar problems. About 40% of AA members stay sober as long as 5 years, and 30% stay sober longer than 5 years.

Nursing diagnoses

u Altered family processes: Alcoholism u Altered nutrition: Less than body requirements u Altered role performance u Altered thought processes u Anxiety u Bathing and hygiene self-care deficit u Dressing and grooming self-care deficit u Hopelessness u Impaired social interaction u Ineffective family coping: Compromised u Ineffective individual coping u Powerlessness u Risk for fluid volume imbalances u Risk for injury u Risk for violence: Directed at others u Self-esteem disturbance

Key outcomes

- u The patient will voice feelings related to self-esteem.
- u The patient will report feeling safe in hospital environment.
- u The patient will join gradually in self-care and the decision-making process.
- u The patient will engage in social interactions with others.
- u The patient will demonstrate verbally and behaviorally a decrease in negative self-evaluation.
- u Family members will identify support systems to assist them and participate in mobilizing these systems.

Nursing interventions

- u During acute intoxication or withdrawal, carefully monitor the patient's mental status, heart rate, breath sounds, blood pressure, and temperature every 30 minutes to 6 hours, depending on the severity of his signs and symptoms.
- u Assess the patient for signs of inadequate nutrition and dehydration. Institute seizure precautions and administer drugs, as ordered, to treat the signs and symptoms of withdrawal in chronic alcohol abuse.
- u During withdrawal in chronic alcohol abuse, orient the patient to reality because he may have hallucinations and may try to harm himself or others. Maintain a calm environment, minimizing noise and shadows to reduce the incidence of delusions and hallucinations. Avoid restraining the patient unless necessary to protect him or others.
- u Approach the patient in a nonthreatening way. Limit sustained eye contact, which can be perceived as threatening. Even if he's verbally abusive, listen attentively and respond with empathy. Explain all procedures.
- u Monitor the patient for signs of depression or impending suicide.
- u In chronic alcoholism, help the patient accept his drinking problem and the necessity for abstinence. Confront his behavior, urging him to examine his actions more realistically.
- u Refer the patient to AA, and offer to arrange a visit from an AA member. Stress how this organization can provide the support he'll need to abstain from alcohol. A concerned religious advisor also can provide the motivation for a personal conversion to sobriety.
- u For alcoholics who have lost all contact with family and friends and who have a long history of unemployment, trouble with the law, or other problems associated with alcohol abuse, rehabilitation may involve job training, sheltered workshops, halfway houses, and other supervised facilities.
- u Refer spouses of alcoholics to Al-Anon and children to Al-Ateen. By participating in these self-help groups, family members learn to relinquish responsibility for the alcoholic's drinking so that they can live meaningful and productive lives. Point out that family involvement in rehabilitation can reduce family tensions.
- u Refer adult children of alcoholics to the National Association for Children of Alcoholics. This organization may provide support in understanding and coping with the past.

Patient teaching

- u Educate the patient and his family about his illness. Warn them that the patient will be tempted to drink again and will be unable to control himself after the first drink. Therefore, he must abstain from alcohol for the rest of his life.
- u Explain to the patient and family that relapses may occur. Help them negotiate a plan to help the patient if he does experience a relapse.
- u If the patient is taking disulfiram (or has taken it within the previous 2 weeks), warn him of the effects of alcohol ingestion, which may last from 30 minutes to 3 hours or longer. The reaction includes nausea, vomiting, facial flushing, headache, shortness of breath, red eyes, blurred vision, sweating, tachycardia, hypotension, and fainting. Emphasize that even a small amount of alcohol induces this adverse reaction and that the longer he takes the drug, the greater his sensitivity to alcohol. Because of this, he must avoid even medicinal sources of alcohol, such as mouthwash, cough syrups, liquid vitamins, and cold remedies.
- u Inform the patient that paraldehyde, a sedative, is chemically similar to alcohol and may provoke a disulfiram-type reaction. Products such as aftershave lotion may be absorbed systemically and cause a severe reaction.
- u Advise the patient that aversion therapy may continue for months or years and that he should remain under medical supervision during that time.

The National Institute on Drug Abuse defines psychoactive drug abuse and dependence as the use of a legal or an illegal drug that causes physical, mental, emotional, or social harm. Examples of commonly abused drugs include narcotics, stimulants, depressants, antianxiety agents, and hallucinogens. Drug abuse is a major public health problem in today's society.

Psychoactive drug abuse can occur at any age. Experimentation with drugs commonly begins in adolescence; recent statistics, however, document a trend toward drug use among preadolescents. Drug abuse often leads to addiction, which may involve physical or psychological dependence or both. The most dangerous form of abuse occurs when users mix several drugs simultaneously, including alcohol. The resultant interactions can complicate assessment, precipitate life-threatening complications, and delay withdrawal.

Causes

Psychoactive drug abuse commonly results from a combination of low self-esteem, peer pressure, inadequate coping skills, and curiosity. Most people who are predisposed to drug abuse have few mental or emotional resources against stress, an excessive dependence on others, and a low tolerance for frustration. Often anxious, angry, or depressed, they demand immediate relief of tension or distress. Taking the drug gives them pleasure by relieving tension, abolishing loneliness, achieving a temporarily peaceful or euphoric state, or simply relieving boredom.

Drug dependence may follow experimentation with drugs in response to peer pressure. It also may follow the use of drugs to relieve physical pain, but this is uncommon.

Complications

Chronic drug abuse, especially I.V. use, can lead to life-threatening complications, such as cardiac and respiratory arrest, intracranial hemorrhage, acquired immunodeficiency syndrome, tetanus, subacute bacterial endocarditis, hepatitis, vasculitis, septicemia, thrombophlebitis, pulmonary emboli, gangrene, malaria, malnutrition and GI disturbances, respiratory infections, musculoskeletal dysfunction, trauma, depression, increased risk of suicide, and psychosis.

Materials used to cut, or dilute, street drugs also can cause toxic or allergic reactions. The specific effects of the street drug vary according to the substance used, its duration of action, and the dosage. (See [Understanding commonly abused substances.](#))

Impaired social and occupational functioning also result from chronic drug use, creating personal, professional, and financial problems. When drug use begins in early adolescence, it may lead to behavioral problems and a failure to complete school.

Assessment findings

The signs and symptoms of acute drug intoxication vary, depending on the drug. The drug user seldom seeks treatment specifically for his drug problem. Instead, he may seek emergency treatment for drug-related injuries or complications, such as a motor vehicle accident, burns from free-basing, an overdose, physical deterioration from illness or malnutrition, or withdrawal. Friends, family members, or law enforcement officials may bring the patient to the hospital because of respiratory depression, unconsciousness, acute injury, or a psychiatric crisis.

Examine the patient for signs and symptoms of drug use or drug-related complications as well as for clues to the type of drug ingested. For example, fever can result from stimulant or hallucinogen intoxication, from withdrawal, or from infection from I.V. drug use.

Inspect the eyes for lacrimation from opiate withdrawal, nystagmus from central nervous system (CNS) depressants and phencyclidine (PCP) intoxication, and drooping eyelids from opiate or CNS depressant use. Constricted pupils occur with opiate use or withdrawal; dilated pupils occur with the use of hallucinogens or amphetamines.

Examine the nose for rhinorrhea from opiate withdrawal and the oral and nasal mucosa for signs of drug-induced irritation. Drug sniffing can cause inflammation, atrophy, or perforation of the nasal mucosa. Dental conditions commonly result from the poor oral hygiene associated with chronic drug use. Also inspect under the tongue for evidence of I.V. drug injection.

Inspect the skin. Sweating, a common sign of intoxication with opiates or CNS stimulants, also accompanies most drug withdrawal syndromes. Drug use may induce a sensation of bugs crawling on the skin, known as formication; as a result, the skin may be excoriated from scratching.

Needle marks or tracks are an obvious sign of I.V. drug abuse. Note that the patient may attempt to conceal or disguise injection sites with tattoos or by selecting an inconspicuous site such as under the nails. In addition, self-injection can sometimes cause cellulitis or abscesses, especially in patients who also are chronic alcoholics. Puffy hands can be a late sign of thrombophlebitis or of fascial infection caused by self-injection on the hands or arms.

Auscultation may disclose bilateral crackles and rhonchi caused by smoking and inhaling drugs or by opiate overdose. Other cardiopulmonary signs of overdose include pulmonary edema, respiratory depression, aspiration pneumonia, and hypotension. CNS stimulants and some hallucinogens may precipitate refractory acute-onset hypertension or cardiac arrhythmias. Withdrawal from opiates or depressants also can provoke arrhythmias and, occasionally, hypotension.

During opiate withdrawal, the patient may report abdominal pain, nausea, or vomiting. Opiate abusers also commonly complain of hemorrhoids, a consequence of the constipating effects of these drugs. Palpation of an enlarged liver, with or without tenderness, may indicate hepatitis.

Neurologic symptoms of drug abuse include tremors, hyperreflexia, hyporeflexia, and seizures. Abrupt withdrawal may precipitate signs of CNS depression ranging from lethargy to coma, hallucinations, or signs of overstimulation, including euphoria and violent behavior.

Carefully review the patient's medical history. Suspect drug abuse if he reports a painful injury or chronic illness but refuses a diagnostic workup. In his attempt to obtain drugs, the dependent patient may feign illnesses, such as migraine headaches, myocardial infarction, and renal colic; claim an allergy to over-the-counter analgesics; or even request a specific medication. Also be alert for a previous history of overdose or a high tolerance to potentially addictive drugs. I.V. drug users may have a history of hepatitis or human immunodeficiency virus (HIV) infection because they often share dirty needles. Female drug users may report a history of amenorrhea.

Understanding commonly abused substances		
Substance	signs and symptoms	Interventions
Stimulants		
<p>Cocaine</p> <ul style="list-style-type: none"> ▫ <i>Street names:</i> coke, flake, snow, nose candy, hits, crack (hardened form), rock, crank ▫ <i>Routes:</i> ingestion, injection, sniffing, smoking ▫ <i>Dependence:</i> psychological ▫ <i>Duration of effect:</i> 15 minutes to 2 hours; with crack, rapid high of short duration followed by down feeling ▫ <i>Medical uses:</i> local anesthetic 	<ul style="list-style-type: none"> ▫ <i>Of use:</i> abdominal pain; alternating euphoria and fear; anorexia; cardiotoxicity, such as ventricular fibrillation or cardiac arrest; coma; confusion, diaphoresis; dilated pupils; excitability; fever; grandiosity; hyperpnea; hypotension or hypertension; insomnia; irritability; nausea and vomiting; pallor or cyanosis; perforated nasal septum with prolonged use; pressured speech; psychotic behavior with large doses; respiratory arrest; seizures; spasms; tachycardia; tachypnea; visual, auditory, and olfactory hallucinations; weight loss ▫ <i>Of withdrawal:</i> anxiety, depression, fatigue 	<ul style="list-style-type: none"> ▫ Place the patient in a quiet room. ▫ If cocaine was ingested, induce vomiting or perform gastric lavage. Follow with activated charcoal and a saline cathartic. ▫ If cocaine was sniffed, remove residual drug from mucous membranes. ▫ Monitor vital signs. ▫ Give propranolol for tachycardia. ▫ Perform cardiopulmonary resuscitation for ventricular fibrillation and cardiac arrest as indicated. ▫ Give a tepid sponge bath for fever. ▫ Administer an anticonvulsant as ordered for seizures.
<p>Amphetamines</p> <ul style="list-style-type: none"> ▫ <i>Street names:</i> for amphetamine sulfate—bennies, grennies, cartwheels; for methamphetamine—speed, meth, crystal; for dextro-amphetamine sulfate—dexies, hearts, oranges ▫ <i>Routes:</i> ingestion, injection ▫ <i>Dependence:</i> psychological ▫ <i>Duration of effect:</i> 1 to 4 hours ▫ <i>Medical uses:</i> hyperkinesis, narcolepsy, weight control 	<ul style="list-style-type: none"> ▫ <i>Of use:</i> altered mental status (from confusion to paranoia), coma, diaphoresis, dilated reactive pupils, dry mouth, exhaustion, hallucinations, hyperactive tendon reflexes, hypertension, hyperthermia, paradoxical reaction in children, psychotic behavior with prolonged use, seizures, shallow respirations, tachycardia, tremors ▫ <i>Of withdrawal:</i> abdominal tenderness, apathy, depression, disorientation, irritability, long periods of sleep, muscle aches, suicide (with sudden withdrawal) 	<ul style="list-style-type: none"> ▫ Place the patient in a quiet room. ▫ If the drug was ingested, induce vomiting or perform gastric lavage; give activated charcoal and a saline or magnesium sulfate cathartic. ▫ Add ammonium chloride or ascorbic acid to the I.V. solution to acidify urine to a pH of 5. Also, administer mannitol to induce diuresis as ordered. ▫ Monitor vital signs. ▫ As ordered, give pentobarbital for seizures, haloperidol for assaultive behavior, phentolamine for hypertension, propranolol for tachyarrhythmias, and lidocaine for ventricular arrhythmias. ▫ Restrain the patient if he's experiencing hallucinations or paranoia. ▫ Give a tepid sponge bath for fever. ▫ Institute suicide and seizure precautions.
Hallucinogens		
<p>Lysergic acid diethylamide (LSD)</p> <ul style="list-style-type: none"> ▫ <i>Street names:</i> acid, microdot, sugar, big D ▫ <i>Routes:</i> ingestion, smoking ▫ <i>Dependence:</i> possibly psychological ▫ <i>Duration of effect:</i> 8 to 12 hours ▫ <i>Medical uses:</i> none 	<ul style="list-style-type: none"> ▫ <i>Of use:</i> abdominal cramps, arrhythmias, chills, depersonalization, diaphoresis, diarrhea, distorted visual perception and perception of time and space, dizziness, dry mouth, fever, grandiosity, hallucinations, hyperpnea, hypertension, illusions, increased salivation, muscle aches, mystical experiences, nausea, palpitations, seizures, tachycardia, vomiting ▫ <i>Of withdrawal:</i> none 	<ul style="list-style-type: none"> ▫ Place the patient in a quiet room. ▫ If the drug was ingested, induce vomiting or perform gastric lavage. Follow with activated charcoal and a cathartic. ▫ Monitor vital signs, and give diazepam for seizures as ordered. ▫ Reorient the patient to time, place, and person, and restrain him as necessary.
<p>Phencyclidine</p> <ul style="list-style-type: none"> ▫ <i>Street names:</i> PCP, hog, angel dust, peace pill, crystal superjoint, elephant tranquilizer, rocket fuel ▫ <i>Routes:</i> ingestion, injection, smoking ▫ <i>Dependence:</i> possibly psychological ▫ <i>Duration of effect:</i> 30 minutes to several days ▫ <i>Medical uses:</i> veterinary anesthetic 	<ul style="list-style-type: none"> ▫ <i>Of use:</i> amnesia; blank stare; cardiac arrest; decreased awareness of surroundings; delusions; distorted body image; distorted sense of sight, hearing, and touch; drooling; euphoria; excitation and psychoses; fever; gait ataxia; hallucinations; hyperactivity; hypertensive crisis; individualized unpredictable effects; muscle rigidity; nystagmus; panic; poor perception of time and distance; possible chromosomal damage; psychotic behavior; recurrent coma; renal failure; seizures; sudden behavioral changes; tachycardia; violent behavior ▫ <i>Of withdrawal:</i> none 	<ul style="list-style-type: none"> ▫ Place the patient in a quiet room. ▫ For ingestion, induce vomiting or perform gastric lavage. Then give activated charcoal. ▫ Add ascorbic acid to the I.V. solution to acidify urine. ▫ Monitor vital signs and urine output. ▫ If ordered, give a diuretic; propranolol for hypertension or tachycardia; nitroprusside for severe hypertensive crisis; diazepam for seizures; diazepam or haloperidol for agitation or psychotic behavior; and physostigmine salicylate, diazepam, chlordiazepoxide, or chlorpromazine for a “bad trip.”
Depressants		
<p>Alcohol</p> <ul style="list-style-type: none"> ▫ <i>Found in:</i> beer, wine, distilled spirits; also contained in cough syrup, aftershave, and mouthwash ▫ <i>Route:</i> ingestion ▫ <i>Dependence:</i> physical, psychological ▫ <i>Duration of effect:</i> varies according to the individual and the amount ingested; metabolized at rate of 10 ml/hour ▫ <i>Medical uses:</i> neurolysis (absolute alcohol), emergency tocolytic, treatment of ethylene glycol and methanol poisoning 	<ul style="list-style-type: none"> ▫ <i>Of acute use:</i> coma, decreased inhibitions, euphoria followed by depression or hostility, impaired judgment, incoordination, respiratory depression, slurred speech, unconsciousness, vomiting ▫ <i>Of withdrawal:</i> acute GI disturbance, arrhythmias, delirium, hallucinations, hypertension, perspiration, seizures, tachycardia, tremors 	<ul style="list-style-type: none"> ▫ Place the patient in a quiet room. ▫ If alcohol was ingested within 4 hours, induce vomiting or perform gastric lavage; give activated charcoal and saline cathartic. ▫ Monitor vital signs. ▫ As ordered, give diazepam for seizures and benzodiazepines or barbiturates for withdrawal. ▫ Institute seizure precautions. ▫ Provide I.V. fluid replacement as well as dextrose, thiamine, B-complex vitamins, and vitamin C to treat dehydration, hypoglycemia, and nutritional deficiencies. ▫ Assess for aspiration pneumonia. ▫ Prepare the patient for dialysis if his vital functions are severely depressed.
<p>Benzodiazepines</p> <p>(alprazolam, chlordiazepoxide,</p>	<ul style="list-style-type: none"> ▫ <i>Of use:</i> ataxia, drowsiness, hypotension, increased self-confidence, relaxation, slurred speech 	<ul style="list-style-type: none"> ▫ If the drug was ingested, induce vomiting or perform gastric lavage. Follow with

Benzodiazepines (alprazolam, chlordiazepoxide, clonazepam, clorazepate, diazepam, flurazepam, halazepam, lorazepam, midazolam, oxazepam, prazepam, quazepam, temazepam, triazolam) u <i>Street names</i> : dolls, green and whites, roaches, yellow jackets u <i>Routes</i> : ingestion, injection u <i>Dependence</i> : physical, psychological u <i>Duration of effect</i> : 4 to 8 hours u <i>Medical uses</i> : antianxiety agent, anticonvulsant, sedative, hypnotic	 u <i>Of use</i> : ataxia, drowsiness, hypotension, increased self-confidence, relaxation, slurred speech u <i>Of overdose</i> : confusion, coma, drowsiness, respiratory depression u <i>Of withdrawal</i> : abdominal cramps, agitation, anxiety, diaphoresis, hypertension, tachycardia, tonic-clonic seizures, tremors, vomiting	 u If the drug was ingested, induce vomiting or perform gastric lavage. Follow with activated charcoal and a cathartic. u Monitor the patient's vital signs. u Give supplemental oxygen for hypoxia-induced seizures. u As ordered, give I.V. fluids for hypertension and physostigmine salicylate for respiratory or central nervous system (CNS) depression.
Barbiturates (amobarbital, phenobarbital, secobarbital) u <i>Street names</i> : for barbiturates—downers, barbs; for amobarbital—blue angels, blue devils; for phenobarbital—purple hearts, goofballs; for secobarbital—reds, red devils u <i>Routes</i> : ingestion, injection u <i>Dependence</i> : physical, psychological u <i>Duration of effect</i> : 1 to 16 hours u <i>Medical uses</i> : anesthetic, anticonvulsant, sedative, hypnotic	 u <i>Of use</i> : absent reflexes, blisters or bullous lesions, cyanosis, depressed level of consciousness (from confusion to coma), fever, flaccid muscles, hypotension, hypothermia, nystagmus, paradoxical reaction in children and elderly people, poor pupil reaction to light, respiratory depression u <i>Of withdrawal</i> : agitation, anxiety, fever, insomnia, orthostatic hypotension, tachycardia, tremors u <i>Of rapid withdrawal</i> : anorexia, apprehension, hallucinations, orthostatic hypotension, tonic-clonic seizures, tremors, weakness	 u If ingestion was recent, induce vomiting or perform gastric lavage. Follow with activated charcoal. u Monitor vital signs, and perform frequent neurologic assessments. u As ordered, give an I.V. fluid bolus for hypotension and alkalinize urine. u Use seizure precautions; relieve withdrawal symptoms as ordered. u Use a hypothermia or hyperthermia blanket for temperature alterations.
Opiates (codeine, heroin, morphine, meperidine, opium) u <i>Street names</i> : for heroin—junk, horse, H, smack; for morphine—morph, M u <i>Routes</i> : for codeine, meperidine, morphine—ingestion, injection, smoking; for heroin—ingestion, injection, inhalation, smoking; for opium—ingestion, smoking u <i>Dependence</i> : physical, psychological u <i>Duration of effect</i> : 3 to 6 hours u <i>Medical uses</i> : for codeine—analgesia, antitussive; for heroin—none; for morphine, meperidine—analgesia; for opium—analgesia, antidiarrheal	 u <i>Of use</i> : anorexia, arrhythmias, clammy skin, constipation, constricted pupils, decreased level of consciousness, detachment from reality, drowsiness, euphoria, hypotension, impaired judgment, increased pigmentation over veins, lack of concern, lethargy, nausea, needle marks, respiratory depression, seizures, shallow or slow respirations, skin lesions or abscesses, slurred speech, swollen or perforated nasal mucosa, thrombosed veins, urine retention, vomiting u <i>Of withdrawal</i> : abdominal cramps, anorexia, chills, diaphoresis, dilated pupils, hyperactive bowel sounds, irritability, nausea, panic, piloerection, runny nose, sweating, tremors, watery eyes, yawning	 u If the drug was ingested, induce vomiting or perform gastric lavage. u As ordered, give naloxone until CNS effects are reversed. u Give I.V. fluids to increase circulatory volume. u Use extra blankets for hypothermia; if ineffective, use a hyperthermia blanket. u Reorient the patient to time, place, and person. u Assess breath sounds to monitor for pulmonary edema. u Monitor for signs and symptoms of withdrawal.

Cannabinoids

Marijuana u <i>Street names</i> : pot, grass, weed, Mary Jane, roach, reefer, joint, THC u <i>Routes</i> : ingestion, smoking u <i>Dependence</i> : psychological u <i>Duration of effect</i> : 2 to 3 hours u <i>Medical uses</i> : antiemetic for chemotherapy	 u <i>Of use</i> : acute psychosis; agitation; anxiety; conjunctival reddening; decreased muscle strength; delusions; distorted sense of time and self-perception; dry mouth; euphoria; hallucinations; impaired cognition, short-term memory, and mood; incoordination; increased hunger; orthostatic hypotension; paranoia; spontaneous laughter; tachycardia u <i>Of withdrawal</i> : chills, decreased appetite, insomnia, irritability, nervousness, restlessness, tremors, weight loss	 u Place the patient in a quiet room. u Monitor vital signs. u Give supplemental oxygen for respiratory depression and I.V. fluids for hypotension. u Give diazepam as ordered for extreme agitation and acute psychosis.
--	--	---

The psychiatric history of a patient who abuses drugs may reveal suggestive behavior patterns or the presence of known risk factors. For example, the patient may give a fictitious name and address, display a reluctance to discuss previous hospitalizations, or seek treatment at a medical facility across town rather than in his own neighborhood. If possible, interview family members to verify his responses.

If the patient admits to drug use, try to determine the extent to which this behavior interferes in his life. Note whether he expresses a desire to overcome his dependence on drugs. If possible, obtain a drug history consisting of substances ingested, amount, frequency, and last dose. Expect incomplete or inaccurate responses. Drug-induced amnesia, a depressed level of consciousness, or ignorance may distort the patient's recollection of the facts; he also may deliberately fabricate answers to avoid arrest or to downplay a suicide attempt.

The hospitalized drug abuser is likely to be uncooperative, disruptive, or even violent. He may experience mood swings, anxiety, impaired memory, sleep disturbances, flashbacks, slurred speech, depression, and thought disorders. Some patients resort to plays on sympathy, bribery, or threats to obtain drugs, or they try to manipulate caregivers by pitting one staff member against another.

Diagnostic criteria

The diagnosis of psychoactive substance dependence is confirmed when the patient meets the criteria documented in the *DSM-IV*.

At least three of the following must be present:

- u substance often taken in larger amounts or for a longer time than the patient intended—persistent desire or one or more unsuccessful efforts to cut down or control substance use
- u excessive time devoted to activities necessary to obtain the substance
- u frequent intoxication or withdrawal symptoms when expected to fulfill major obligations at work, school, or home or when substance use is physically hazardous
- u important social, occupational, or recreational activities given up or reduced because of substance use
- u continued substance use despite the recognition of a persistent or recurrent social, psychological, or physical problem that is caused or exacerbated by the use of the substance
- u marked tolerance: need for markedly increased amounts of the substance to achieve intoxication or the desired effect or markedly diminished effect with continued use of the same amount
- u characteristic withdrawal symptoms
- u substance often taken to relieve or avoid withdrawal symptoms.

Some symptoms must have persisted for at least 1 month or have occurred repeatedly over a longer time.

Additional tests can confirm drug use, determine the amount and type of drug taken, and reveal complications. For example, a serum or urine drug screen can detect substances that were ingested recently. Characteristic findings in other tests include elevated serum globulin levels, hypoglycemia, leukocytosis, liver function abnormalities, positive Venereal Disease Research Laboratories (VDRL) or rapid plasma reagin test results due to elevated protein fractions, elevated mean

corpuscular hemoglobin levels, elevated uric acid levels, and reduced blood urea nitrogen levels.

Treatment

The patient with acute drug intoxication should receive symptomatic treatment based on the drug ingested. Measures include fluid replacement therapy and nutritional and vitamin supplements, if indicated; detoxification with the same drug or a pharmacologically similar drug (exceptions include cocaine, hallucinogens, and marijuana, which aren't used for detoxification); sedatives to induce sleep; anticholinergics and antidiarrheal agents to relieve GI distress; antianxiety drugs for severe agitation, especially in cocaine abusers; and symptomatic treatment of complications. Depending on the dosage and time elapsed before admission, additional treatment may include gastric lavage, induced emesis, activated charcoal, forced diuresis and, possibly, hemoperfusion or hemodialysis.

Treatment of drug dependence commonly involves a triad of care: detoxification, short- and long-term rehabilitation, and aftercare; the latter means a lifetime of abstinence, usually aided by participation in Narcotics Anonymous or a similar self-help group.

Detoxification, the controlled and gradual withdrawal of an abused drug, is achieved through substitution of a drug with similar action. Such gradual replacement of the abused drug controls the effects of withdrawal, reducing the patient's discomfort and associated risks.

Depending on which drug the patient has abused, detoxification may be managed on an inpatient or outpatient basis. For example, withdrawal from depressants can produce hazardous effects, such as generalized tonic-clonic seizures, status epilepticus, and hypotension; the severity of these effects determines whether the patient can be safely treated as an outpatient or requires hospitalization. Withdrawal from depressants usually doesn't require detoxification. Opioid withdrawal causes severe physical discomfort and can even be life-threatening. To minimize these effects, chronic opioid abusers commonly are detoxified with methadone.

To ease withdrawal from opioids, depressants, and other drugs, useful nonchemical measures may include psychotherapy, exercise, relaxation techniques, and nutritional support. Sedatives and tranquilizers may be administered temporarily to help the patient cope with insomnia, anxiety, and depression.

After withdrawal, rehabilitation is needed to prevent recurrence of drug abuse. Rehabilitation programs are available for both inpatients and outpatients; they usually last a month or longer and may include individual, group, and family psychotherapy. During and after rehabilitation, participation in a drug-oriented self-help group may be helpful. The largest such group is Narcotics Anonymous.

Nursing diagnoses

u Altered family processes u Altered nutrition: Less than body requirements u Bathing and hygiene self-care deficit u Dressing and grooming self-care deficit u Self-esteem disturbance u Altered role performance u Altered thought processes u Anxiety u Hopelessness u Impaired social interaction u Ineffective family coping: Compromised u Ineffective individual coping u Powerlessness u Risk for injury u Risk for violence: Directed at others

Key outcomes

- u The patient will voice feelings related to self-esteem.
- u The patient will report feeling safe in hospital environment.
- u The patient will join gradually in self-care and the decision-making process.
- u The patient will engage in social interactions with others.
- u The patient will demonstrate verbally and behaviorally a decrease in negative self-evaluation.
- u Family members will identify support systems to assist them and participate in mobilizing these systems.

Nursing interventions

u Focus on restoring physical health, educating the patient and his family about drug abuse and dependence, providing support, and encouraging participation in drug treatment programs and self-help groups.

During an acute episode:

- u Continuously monitor the patient's vital signs, and observe for complications of overdose and withdrawal, such as cardiopulmonary arrest, seizures, and aspiration.
- u Based on standard hospital policy, institute appropriate measures to prevent suicide attempts.
- u Give medications, as ordered, to decrease withdrawal symptoms; monitor and record their effectiveness.
- u Maintain a quiet, safe environment during withdrawal from any drug because excessive noise may agitate the patient. Remove harmful objects from the room, and use restraints only if you suspect that he might harm himself or others. Institute seizure precautions.

When the acute episode has resolved:

- u Develop self-awareness and an understanding and positive attitude toward the patient; control your reactions to his undesirable behaviors—commonly, psychological dependency, manipulation, anger, frustration, and alienation.
- u Set limits for dealing with demanding, manipulative behavior.
- u Carefully monitor and promote adequate nutrition.
- u Administer medications carefully to prevent hoarding by the patient. Check the patient's mouth to ensure that the medication has been swallowed. Closely monitor visitors who might supply the patient with drugs.
- u Refer the patient for detoxification and rehabilitation as appropriate. Give him a list of available resources.
- u Encourage family members to seek help regardless of whether the abuser seeks it. You can suggest private therapy or community mental health clinics.

Patient teaching

If the patient refuses to participate in a rehabilitation program, teach him how to minimize the risk of drug-related complications, as follows:

- u Review measures for preventing HIV infection and hepatitis. Stress that these infections are readily transmitted by sharing needles with other drug users and by unprotected sexual intercourse.
- u Advise the patient to use a new needle for every injection or to clean needles with a solution of chlorine bleach and water.
- u Emphasize the importance of using a condom during intercourse to prevent disease transmission and pregnancy. If necessary, teach the female drug abuser about other methods of birth control. Explain the devastating effects of drugs on the developing fetus.

SCHIZOPHRENIA AND OTHER PSYCHOTIC DISORDERS

Characterized by disordered thinking, these disorders include delusional disorders and schizophrenia.

DELUSIONAL DISORDERS

According to the *DSM-IV*, delusional disorders are characterized by false beliefs with a plausible basis in reality. Formerly referred to as paranoid disorders, delusional disorders are known to involve erotomanic, grandiose, jealous, or somatic themes as well as persecutory delusions. (See [Delusional disorder or paranoid schizophrenia?](#)) Some patients experience several types of delusions; other patients experience unspecified delusions that have no dominant theme. (See [Delusional themes.](#))

Delusional disorders commonly begin in middle or late adulthood, usually between ages 40 and 55, but they can occur at a younger age. These uncommon illnesses

affect less than 1% of the population; the incidence is about equal in men and women. Typically chronic, these disorders often interfere with social and marital relationships but seldom impair intellectual or occupational functioning significantly.

Causes

Delusional disorders of later life strongly suggest a hereditary predisposition. At least one study has linked the development of delusional disorders to inferiority feelings in the family. Some researchers suggest that delusional disorders are the product of specific early childhood experiences with an authoritarian family structure. Others hold that anyone with a sensitive personality is particularly vulnerable to developing a delusional disorder.

ADVANCED PRACTICE

Delusional disorder or paranoid schizophrenia?

To distinguish between these two disorders, consider the following characteristics.

Delusional disorder

In a delusional disorder, the patient's delusions reflect reality and are arranged into a coherent system. They're based on misinterpretations of or elaborations on reality.

The patient doesn't experience hallucinations, and his affect and behavior are normal.

Paranoid schizophrenia

In paranoid schizophrenia, the patient's delusions are scattered, illogical, and incoherently arranged with no relation to reality.

The patient may have hallucinations, his affect is inappropriate and inconsistent, and his behavior is bizarre.

Certain medical conditions are known to exaggerate the risks of delusional disorders: head injury, chronic alcoholism, deafness, and aging. Predisposing factors linked to aging include isolation, lack of stimulating interpersonal relationships, physical illness, and diminished hearing and vision. In addition, severe stress (such as a move to a foreign country) may precipitate a delusional disorder.

Complications

The delusional patient who acts on his irrational beliefs may pose a threat to himself or others. The more extreme the patient's rage, the greater the risk of violent behavior or suicide.

Assessment findings

The psychiatric history of a delusional patient may be unremarkable, aside from behavior related to his delusions. He's likely to report problems with social and marital relationships, including depressive symptoms or sexual dysfunction. In fact, about one-third of delusional patients are widowed, divorced, or separated at the time of first admission. Others describe a life marked by social isolation or hostility. Such patients may deny feeling lonely, relentlessly criticizing or placing unreasonable demands on others.

Delusional themes

In a patient with a delusional disorder, the delusions are well systematized and follow a predominant theme. Common delusional themes are listed below.

Erotomaniac delusions

A prevalent delusional theme, erotomaniac delusions concern romantic or spiritual love. The patient believes that he shares in an idealized (rather than sexual) relationship with someone of higher status—a superior at work, a celebrity, or an anonymous stranger.

The patient may hold this delusion in secret but more commonly will try to contact the object of his delusion through calls, letters, gifts, or even spying. He may attempt to rescue his beloved from imagined danger. The patient with erotomaniac delusions frequently harasses public figures and often comes to the attention of the police.

Grandiose delusions

The patient with grandiose delusions believes that he has great, unrecognized talent, special insight, or prophetic power or has made an important discovery. To achieve recognition, he may contact government agencies such as the Federal Bureau of Investigation. The patient with a religiously oriented delusion of grandeur may become a cult leader. Less commonly, he believes that he shares a special relationship with some well-known personality, such as a rock star or a world leader. The patient may believe himself to be a famous person, his identity usurped by an imposter.

Jealous delusions

Jealous delusions focus on infidelity. For example, a patient may insist that his spouse or lover has acted unfaithfully and may search for evidence to justify the delusion such as spots on bed sheets. He may confront his partner, try to control her movements, follow her, or track down her suspected lover. He may physically assault her or, less likely, his perceived rival.

Persecutory delusions

The patient suffering from persecutory delusions, the most common delusional theme, believes that he's being followed, harassed, plotted against, poisoned, mocked, or deliberately prevented from achieving his long-term goals. These delusions may evolve into a simple or complex persecution scheme in which even the slightest injustice is interpreted as part of the scheme.

Such a patient may file numerous lawsuits or seek redress from government agencies (querulous paranoia). A patient who becomes resentful and angry may lash out violently against the alleged offender.

Somatic delusions

Somatic delusions center on an imagined physical defect or deformity. The patient may perceive a foul odor coming from his skin, mouth, rectum, or other body part. Other delusions involve skin-crawling insects, internal parasites, or physical illness.

Gathering accurate information from a delusional patient may prove difficult. He may deny his feelings, disregard the circumstances leading to hospitalization, and refuse treatment. However, the patient's responses and behavior during the assessment interview provide clues that can help to identify his disorder. Family members may confirm your observations, often reporting that the patient is chronically jealous or suspicious.

For example, note how effectively the patient communicates. He may be evasive or reluctant to answer questions. Alternatively, he may be overly talkative, explaining events in great detail and emphasizing what he has achieved, prominent people he knows, or places he has traveled. Statements that first seem logical may later prove irrelevant. Some of his answers may be contradictory, jumbled, or irrational.

Be alert for expressions of denial, projection, and rationalization. When delusions become firmly entrenched, the patient no longer seeks to justify his beliefs. However, if he's still struggling to maintain his delusional defenses, he may make statements that reveal his condition, such as "People at work won't talk to me because I'm smarter than them." Accusatory statements are also characteristic of the patient with a delusional disorder. A patient who's chronically late for work, for example, may insist that he lost his job because his supervisor was incompetent. Record pervasive delusional themes (for example, grandiose or persecutory).

Also watch for nonverbal cues, indicating suspiciousness or mistrust, such as excessive vigilance or obvious apprehension on entering the room. During questions, the patient may listen intently, reacting defensively to imagined slights or insults. He may sit at the edge of his seat or fold his arms as if to shield himself. If he carries papers or money, he may clutch them firmly.

Diagnostic criteria

Psychiatric examination confirms the presence of the following diagnostic criteria in the *DSM-IV*:

- u Nonbizarre delusions of at least 1 month's duration are present, involving real-life situations, such as being followed, poisoned, infected, loved at a distance, or deceived by one's spouse or lover.
- u Auditory or visual hallucinations, if present, aren't prominent.
- u Apart from the delusion or its ramifications, behavior isn't obviously odd or bizarre.
- u If a major depressive or manic syndrome has been present during the delusional disturbance, the total duration of all episodes of the mood syndrome has been brief relative to the total duration of the delusional disturbance.
- u The patient has never met diagnostic criteria for schizophrenia (presence of characteristic psychotic symptoms in the active phase for at least 1 week), and it can't be established that an organic factor initiated and maintained the disturbance.
- u In addition, blood and urine tests, psychological tests, and a neurologic evaluation rule out organic causes of the delusions, such as amphetamine-induced psychoses and Alzheimer's disease. Endocrine function tests are performed to rule out hyperadrenalism, pernicious anemia, and thyroid disorders such as

“myxedemic madness.”

Treatment

Effective treatment of delusional disorders, consisting of a combination of drug therapy and psychotherapy, must correct the behavior and mood disturbances that result from the patient's mistaken belief system. Treatment also may include mobilizing a support system for the isolated, aged patient.

Drug treatment with antipsychotic agents is similar to that used in schizophrenic disorders. Antipsychotics appear to work by blocking postsynaptic dopamine receptors. These drugs reduce the incidence of psychotic symptoms, such as hallucinations and delusions, and relieve anxiety and agitation. Other psychiatric drugs, such as antidepressants and anxiolytics, may be prescribed to control associated symptoms.

High-potency antipsychotics include fluphenazine, haloperidol, thiothixene, and trifluoperazine. Loxapine succinate, molindone, and perphenazine are intermediate in potency, and chlorpromazine and thioridazine are low-potency agents. Haloperidol decanoate, fluphenazine decanoate, and fluphenazine enanthate are depot formulations that are implanted I.M. and release the drug gradually over a 30-day period, improving compliance.

Clozapine, which differs chemically from other antipsychotic drugs, may be prescribed for severely ill patients who fail to respond to standard neuroleptic treatment. This agent effectively controls a wider range of psychotic symptoms without the usual adverse effects.

However, clozapine can cause drowsiness, sedation, excessive salivation, tachycardia, dizziness, and seizures, as well as agranulocytosis, a potentially fatal blood disorder characterized by a low white blood cell count and pronounced neutropenia. Routine blood monitoring is essential to detect the estimated 1% to 2% of all patients taking clozapine who develop agranulocytosis. If caught in the early stages, the disorder is reversible.

Nursing diagnoses

- u Altered nutrition: Less than body requirements
- u Altered thought processes
- u Anxiety
- u Fear
- u Impaired home maintenance management
- u Impaired social interaction
- u Ineffective family coping: Disabling
- u Ineffective individual coping
- u Personal identity disturbance
- u Powerlessness
- u Risk for injury
- u Risk for violence: Self-directed or directed at others
- u Sensory or perceptual alterations
- u Social isolation

Key outcomes

- u The patient will identify internal and external factors that trigger delusional episodes.
- u The patient will identify and perform activities that decrease delusions.
- u The patient will consider alternative interpretations of a situation without becoming hostile or anxious.
- u The patient will recognize symptoms and comply with medication regimen.
- u The patient will remain free from injury.
- u The patient and family members will participate in care and prescribed therapies.
- u The patient will demonstrate effective social interaction skills in both one-on-one and group settings.

Nursing interventions

- u In dealing with the patient, be direct, straightforward, and dependable. Whenever possible, elicit his feedback. Move slowly, with a matter-of-fact manner, and respond without anger or defensiveness to his hostile remarks.
- u Respect the patient's privacy and space needs. Avoid touching him unnecessarily.
- u Take steps to reduce social isolation, if the patient allows. Gradually increase social contacts after he has become comfortable with the staff.
- u Watch for refusal of medication or food, resulting from the patient's irrational fear of poisoning.
- u Monitor the patient carefully for adverse effects of neuroleptic drugs: drug-induced parkinsonism, acute dystonia, akathisia, tardive dyskinesia, and malignant neuroleptic syndrome.

Patient teaching

- u If the patient is taking clozapine, stress the importance of returning weekly to the hospital or outpatient setting to have his blood monitored.
- u Emphasize the importance of complying with the prescribed medication treatment. Instruct the patient to report any adverse effects instead of stopping the drug. If he's taking a slow-release formulation, be sure he understands when to return to the doctor for his next dose.
- u Involve family members in treatment. Teach them how to recognize an impending relapse, and suggest ways to manage symptoms. These include tension, nervousness, insomnia, decreased concentration ability, and loss of interest.

SCHIZOPHRENIA

Schizophrenia is characterized by disturbances (for at least 6 months) in thought content and form, perception, affect, language, social activity, sense of self, volition, interpersonal relationships, and psychomotor behavior. The *DSM-IV* recognizes catatonic, paranoid, disorganized, residual, and undifferentiated schizophrenia. (See [Types of schizophrenia](#).)

Schizophrenia affects approximately 0.85% of individuals worldwide, with a lifetime prevalence of 1% to 1.5%. Onset of symptoms usually occurs during late adolescence and has an insidious onset and poor outcome. It can progress to social withdrawal, perceptual distortions, chronic delusions, and hallucinations.

This disorder produces varying degrees of impairment. As many as one-third of schizophrenic patients have just one psychotic episode and no more after that. Some patients have no disability between periods of exacerbation; other patients need continuous institutional care. The prognosis worsens with each acute episode.

Causes and pathophysiology

Schizophrenia may result from a combination of genetic, biological, cultural, and psychological factors with genetic and environmental insults most associated. For example, some evidence supports a genetic predisposition to this disorder. Close relatives of schizophrenic patients are up to 50 times more likely to develop schizophrenia; the closer the degree of biological relatedness, the higher the risk.

The most widely accepted biochemical hypothesis holds that schizophrenia results from excessive activity at dopaminergic synapses. Other neurotransmitter alterations may also contribute to schizophrenic symptoms.

Numerous psychological and sociocultural causes, such as disturbed family and interpersonal patterns, also have been proposed as possible causes. Schizophrenia has a higher incidence among lower socioeconomic groups, possibly related to downward social drift or lack of upward socioeconomic mobility, and to high stress levels, possibly induced by poverty, social failure, illness, and inadequate social resources. Gestational and birth complications, such as Rh factor incompatibility, prenatal exposure to influenza during the second trimester, and prenatal nutritional deficiencies, have been associated.

Types of schizophrenia

The *DSM-IV* recognizes types of schizophrenia based on the patient's signs and symptoms. Here are the distinguishing characteristics.

Catatonic schizophrenia

The catatonic patient may be unable to move around or take care of his personal needs. Commonly, he doesn't feed himself or talk and may show bizarre, stereotypic mannerisms, such as facial grimacing and sucking mouth movements. Extreme changes in motor activity, negativism, and echolalia or echopraxia are dominant. Rarely, he may also exhibit waxy flexibility, in which the body (especially the extremities) will rigidly hold any placed position for prolonged periods.

Diminished sensitivity to painful stimuli and rapid swings between excitement and stupor may be observed. An excitement phase may include extreme psychomotor agitation with excessive, senseless, or incoherent talking or shouting and with increased potential for destructive, violent behavior.

Paranoid schizophrenia

Persecutory or grandiose delusional thought content and possibly delusional jealousy characterize paranoid schizophrenia. This condition may be associated with unfocused anxiety, anger, argumentativeness, and violence. It may also involve gender-identity problems, including fears of being thought of as homosexual or of being approached by homosexuals.

Although the patient frequently experiences auditory hallucinations related to a single theme, he typically doesn't display some of the symptoms common to other types of schizophrenia, including incoherence, marked loosening of associations, flat or grossly inappropriate affect, catatonic behavior, and grossly disorganized behavior.

Paranoid schizophrenia may cause only minimal impairment of function if the patient doesn't act on the delusional thoughts. His affective responsiveness may remain intact, but interactions with others commonly show stilted formality or intensity.

Disorganized schizophrenia

Characteristics of disorganized schizophrenia include marked loosening of associations; grossly disorganized behavior; blunted, silly, flat, or inappropriate affect; incoherence; grimacing; unsystematic delusions; social withdrawal; and hypochondriacal complaints.

This type of schizophrenia may begin early and insidiously with no significant remissions. The patient usually exhibits extreme social impairment.

Residual schizophrenia

Residual schizophrenia is distinguished by emotional blunting, social withdrawal, eccentric behavior, illogical thinking, and mild loosening of associations following resolution of an acute psychotic episode. The patient has no prominent delusions, hallucinations, incoherence, or grossly disorganized behavior.

Undifferentiated schizophrenia

Undifferentiated schizophrenia is characterized by atypical symptoms or a mixture of symptoms associated with several subtypes, such as delusions, incoherence, hallucinations, or grossly disorganized behavior. Schizophreniform disorder patients exhibit symptoms of schizophrenia but don't meet the duration requirements. Schizoaffective disorders include individuals whose symptoms of schizophrenia are independent of associated periods of mood disturbance.

Complications

Because of disordered thought processes, the schizophrenic patient often neglects personal hygiene or ignores health needs. As a result, the patient has a shorter life expectancy than the general population. Ten percent of schizophrenic patients commit suicide.

Assessment findings

Schizophrenia is associated with a wide variety of abnormal behaviors; therefore, assessment findings vary greatly, depending on both the type and phase of the illness. The individual may exhibit a decreased emotional expression, impaired concentration, and decreased social functioning, loss of function, or anhedonia. Individuals with these particular symptoms (present in one-third of the schizophrenic population) are associated with poor response to drug treatment and poor outcome.

Although behaviors and functional deficiencies can vary widely among patients and even in the same patient at different times, watch for the following characteristic signs and symptoms during the assessment interview:

- u ambivalence—coexisting strong positive and negative feelings, leading to emotional conflict
- u apathy
- u clang associations—words that rhyme or sound alike used in an illogical, nonsensical manner—for instance, “It's the rain, train, pain.”
- u concrete thinking—inability to form or understand abstract thoughts
- u delusions—false ideas or beliefs accepted as real by the patient. Delusions of grandeur, persecution, and reference (distorted belief regarding the relation between events and one's self; for example, a belief that television programs address the patient on a personal level) are common in schizophrenia. Also common are feelings of being controlled, somatic illness, and depersonalization.
- u echolalia—meaningless repetition of words or phrases
- u echopraxia—involuntary repetition of movements observed in others
- u flight of ideas—rapid succession of incomplete and poorly connected ideas
- u hallucinations—false sensory perceptions with no basis in reality. Usually visual or auditory, hallucinations also may be olfactory (smell), gustatory (taste), or tactile (touch).
- u illusions—false sensory perceptions with some basis in reality; for example, a car backfiring might be mistaken for a gunshot.
- u loose associations—not connected or related by logic or rationality
- u magical thinking—belief that thoughts or wishes can control other people or events
- u neologisms—bizarre words that have meaning only for the patient
- u poor interpersonal relationships
- u regression—return to an earlier developmental stage
- u thought blocking—sudden interruption in the patient's train of thought
- u withdrawal—disinterest in objects, people, or surroundings
- u word salad—illogical word groupings; for example, “She had a star, barn, plant.” It's the extreme form of loose associations.

Diagnostic criteria

Complete physical and psychiatric examinations rule out an organic cause of schizophrenic symptoms such as an amphetamine-induced psychosis. Diagnosis rests on fulfilling the criteria in the *DSM-IV*. (See [Diagnosing schizophrenia](#).)

Several tests, including brain imaging studies, tissue studies, functional and metabolic studies, and psychological tests, can be helpful in the diagnosis of schizophrenia.

Treatment

In schizophrenia, treatment focuses on meeting both the physical and psychosocial needs of the patient based on his previous level of adjustment and his response to medical and nursing interventions. Treatment typically includes a combination of drug therapy, long-term psychotherapy for the patient and his family, vocational counseling, and the use of community resources.

The primary treatment (for more than 30 years), antipsychotic drugs (sometimes called neuroleptic drugs) appear to work by blocking postsynaptic dopamine receptors. These antipsychotic drugs reduce the incidence of psychotic symptoms, such as hallucinations and delusions, as well as relieve anxiety and agitation. Other psychiatric drugs, such as antidepressants and anxiolytics, may also be prescribed to control associated signs and symptoms.

Some antipsychotic drugs cause numerous adverse reactions, several of which are irreversible. Most experts admit that patients who are withdrawn, isolated, or apathetic show little improvement after this drug treatment. (See [Reviewing adverse effects of antipsychotic drugs.](#))

High-potency antipsychotics include fluphenazine, haloperidol, thiothixene, and trifluoperazine. Loxapine, molindone, and perphenazine are intermediate in potency, and chlorpromazine and thioridazine are low in potency. Haloperidol decanoate, fluphenazine decanoate, and fluphenazine enanthate are depot formulations that are implanted I.M., resulting in gradual release over a 30-day period, thus improving compliance.

Risperidone (Risperdal) and Olanzapine (Zyprexa) are atypical and antipsychotic agents used to treat both the positive and negative symptoms of schizophrenia. Clozapine, which differs chemically from other antipsychotic drugs, may be prescribed for severely ill patients who fail to respond to standard treatment. This agent effectively controls a wider range of signs and symptoms without the usual adverse effects. However, clozapine can cause drowsiness, sedation, excessive salivation, hyperglycemia, tachycardia, dizziness, seizures, and agranulocytosis, a potentially fatal blood disorder characterized by a low white blood cell count and pronounced neutropenia.

Routine blood monitoring is essential to detect the estimated 1% to 2% of all patients taking clozapine who develop agranulocytosis. If the disorder is caught in the early stages, agranulocytosis is reversible.

Clinicians disagree about the effectiveness of psychotherapy in treating schizophrenia. Although a patient who has experienced a single acute psychotic episode may respond, psychotherapy is often futile in a patient with a long history of chronic disease. Nonetheless, some doctors use it as an adjunct to reduce loneliness, isolation, and withdrawal and enhance productivity.

Diagnosing schizophrenia
<p>The following criteria described in the <i>DSM-IV</i> are used to diagnose a person with schizophrenia.</p> <p>Characteristic symptoms</p> <p>A person with schizophrenia has two or more of the following signs and symptoms, each present for a significant portion of time during a 1-month period (or less, if successfully treated):</p> <ul style="list-style-type: none">u delusionsu prominent hallucinations (throughout the day for several days or several times a week for several weeks with each hallucinatory experience lasting more than a few moments)u disorganized speech (for example, frequent derailment or incoherence)u grossly disorganized or catatonic behavioru negative symptoms (for example, flat affect, inability to make decisions, or inability to speak). <p>The diagnosis requires only one of these characteristic signs or symptoms if the person's delusions are bizarre (that is, involving a phenomenon that the person's culture would consider implausible), if hallucinations consist of a voice issuing a running commentary on the person's behavior or thoughts, or if the hallucinations consist of two or more voices conversing with each other.</p> <p>Social and occupational dysfunction</p> <p>For a significant period during the course of the disturbance, one or more major areas of functioning (such as work, interpersonal relationships, or self-care) are markedly below the level achieved before the onset of the disturbance.</p> <p>When the disturbance begins in childhood or adolescence, the dysfunction takes the form of failure to achieve the expected level of interpersonal, academic, or occupational development.</p> <p>Duration</p> <p>Continuous signs and symptoms of the disturbance persist for at least 6 months. The 6-month period must include at least 1 month of symptoms that match the characteristic, active-phase signs and symptoms (or less if signs and symptoms have been successfully treated) and may include periods of prodromal or residual symptoms.</p> <p>During the prodromal or residual periods, signs of the disturbance may be manifested by only negative symptoms or by two or more characteristic symptoms in a less severe form (for example, odd beliefs or unusual perceptual experiences).</p> <p>Schizoaffective and mood disorder exclusion</p> <p>Schizoaffective disorder and mood disorder with psychotic features have been ruled out for these reasons: Either no major depressive, manic, or mixed episodes have occurred concurrently with the active-phase signs and symptoms, or if mood disorder episodes have occurred during active-phase signs and symptoms, their total duration has been relatively brief compared with the duration of the active and residual periods.</p> <p>Substance and general medical condition exclusion</p> <p>The disturbance isn't due to the direct physiologic effects of a substance or a general medical condition.</p> <p>Relationship to a pervasive developmental disorder</p> <p>If the person has a history of autistic disorder or another pervasive developmental disorder, the additional diagnosis of schizophrenia is appropriate only if prominent delusions or hallucinations also are present for at least 1 month (or less if successfully treated).</p>

Other studies suggest that psycho-education and social skills training are more productive approach for the chronic schizophrenic. Besides improving understanding of the disorder, these methods teach the patient and his family coping strategies, effective communication techniques, and social skills such as grocery shopping.

Because schizophrenia is so disruptive to the family, all members may require psychotherapy. Family therapy can reduce guilt and disappointment as well as improve

acceptance of the patient and his bizarre behavior.

Nursing diagnoses

u Altered nutrition: Less than body requirements u Altered role performance u Altered thought processes u Anxiety u Bathing and hygiene self-care deficit u Body image disturbance u Dressing and grooming self-care deficit u Fear u Hopelessness u Impaired home maintenance management u Impaired social interaction u Impaired verbal communication u Ineffective family coping u Ineffective individual coping u Personal identity disturbance u Powerlessness u Risk for injury u Risk for violence: Self-directed or directed at others u Sensory or perceptual alterations u Sleep pattern disturbance u Social isolation

Reviewing adverse effects of antipsychotic drugs

Antipsychotic drugs (sometimes known as neuroleptic drugs) can cause sedative, anticholinergic, or extra-pyramidal effects; orthostatic hypotension; endocrinologic adverse effects; and, rarely, neuroleptic malignant syndrome.

Sedative, anticholinergic, and extrapyramidal effects

High-potency drugs (such as haloperidol) are minimally sedative and minimally anticholinergic but result in a high incidence of extrapyramidal adverse effects. Intermediate-potency agents (such as molindone) are associated with a moderate incidence of adverse effects, whereas low-potency drugs (such as chlorpromazine) are highly sedative and anticholinergic but elicit few extrapyramidal adverse effects.

The most common extrapyramidal effects are dystonia, parkinsonism, and akathisia. Dystonia most frequently occurs in young males, usually within the first few days of treatment. Characterized by anguished tonic contractions of the muscles in the neck, mouth, and tongue, dystonia may be misdiagnosed as a psychotic symptom. Diphenhydramine hydrochloride (Benadryl) or benztropine (Cogentin) administered I.M. or I.V. provides rapid relief.

Drug-induced parkinsonism results in bradykinesia, muscle rigidity, shuffling or propulsive gait, stooped posture, flat facial affect, tremors, and drooling. Parkinsonism may occur from 1 week to several months after the initiation of drug treatment. Drugs prescribed to reverse or prevent this syndrome include benztropine, trihexyphenidyl (Artane), and amantadine (Symmetrel).

Signs and symptoms of akathisia include restlessness, pacing, and an inability to rest or sit still. Propranolol relieves this adverse effect.

Orthostatic hypotension

Low-potency neuroleptics can also cause orthostatic hypotension because they block alpha-adrenergic receptors. If severe, place the patient in a supine position and give I.V. fluids for hypovolemia. If further treatment is necessary, an alpha-adrenergic agonist, such as norepinephrine (Levophed) or metaraminol (Aramine), may be ordered to relieve hypotension. Mixed alpha- and beta-adrenergic drugs such as epinephrine or beta-adrenergic drugs such as isoproterenol shouldn't be given because they can produce further reduction in blood pressure. If less severe, management typically includes the use of elastic hose and avoiding sudden position changes.

Neuroleptic malignant syndrome

In up to 1% of patients, antipsychotic drugs produce this life-threatening syndrome. Signs and symptoms include elevated body temperature, muscle rigidity, and altered consciousness, occurring hours to months after the initiation of drug therapy or increasing the dose. Treatment is symptomatic, largely consisting of dantrolene and other measures to counter muscle rigidity associated with hyperthermia. You'll need to continuously monitor the patient's vital signs and mental status.

Key outcomes

- u The patient will identify internal and external factors that trigger delusional episodes.
- u The patient will identify and perform activities that decrease delusions.
- u The patient will consider an alternative interpretation of a situation without becoming unduly hostile or anxious.
- u The patient will recognize symptoms and comply with medication regimen.
- u The patient will remain free of injury.
- u The patient and family members will participate in care and prescribed therapies.
- u The patient will demonstrate effective social interaction skills in both one-on-one and group settings.

Nursing interventions

- u Assess the patient's ability to carry out the activities of daily living, paying special attention to his nutritional status. Monitor his weight if he isn't eating. If he thinks that his food is poisoned, allow him to fix his own food when possible, or offer him foods in closed containers that he can open. If you give liquid medication in a unit-dose container, allow the patient to open the container.
- u Maintain a safe environment, minimizing stimuli. Administer medication to decrease symptoms and anxiety. Use physical restraints according to your hospital's policy to ensure the patient's safety and that of others.
- u Adopt an accepting and consistent approach with the patient. Don't avoid or overwhelm him. Keep in mind that short, repeated contacts are best until trust has been established.
- u Avoid promoting dependence. Meet the patient's needs, but only do for the patient what he can't do for himself.
- u Reward positive behavior to help the patient improve his level of functioning.
- u Engage the patient in reality-oriented activities that involve human contact: inpatient social skills training groups, outpatient day care, and sheltered workshops. Provide reality-based explanations for distorted body images or hypochondriacal complaints. Clarify private language, autistic inventions, or neologisms, explaining to the patient that what he says isn't understood by others. If necessary, set limits on inappropriate behavior.
- u If the patient is hallucinating, explore the content of the hallucinations. If he has auditory hallucinations, determine if they're command hallucinations that place the client or others at risk. Tell the patient you don't hear the voices but you know they're real to him. Avoid arguing about the hallucinations; if possible, change the subject.
- u Don't tease or joke with the patient. Choose words and phrases that are unambiguous and clearly understood. For instance, a patient who's told, "That procedure will be done on the floor," may become frightened, thinking he is being told to lie down on the floor.
- u If the patient is expressing suicidal thoughts, institute suicide precautions. Document his behavior and your precautions.
- u If the patient is expressing homicidal thoughts (for example, "I have to kill my mother."), institute homicidal precautions. Notify the doctor and the potential victim. Document the patient's comments and who was notified.
- u Don't touch the patient without telling him first exactly what you're going to do. For example, clearly explain to him, "I'm going to put this cuff on your arm so I can take your blood pressure." If necessary, postpone procedures that require physical contact with hospital personnel until the patient is less suspicious or agitated.
- u Remember, institutionalization may produce new symptoms and handicaps in the patient that aren't part of his diagnosed illness, so evaluate symptoms carefully.
- u Mobilize community resources to provide a support system for the patient and reduce his vulnerability to stress. Ongoing support is essential to his mastery of social skills.
- u Encourage compliance with the medication regimen to prevent relapse. Also monitor the patient carefully for adverse effects of drug therapy, including drug-induced parkinsonism, acute dystonia, akathisia, tardive dyskinesia, and malignant neuroleptic syndrome. Make sure you document and report such effects promptly.

In addition, for catatonic schizophrenia:

- u Assess the patient for physical illness. Remember that the mute patient won't complain of pain or physical symptoms; if he's in a bizarre posture, he's at increased

- risk for pressure ulcers or decreased circulation to a body area.
- u Meet physical needs for adequate food, fluid, exercise, and elimination; follow orders with respect to nutrition, urinary catheterization, and enema.
 - u Provide range-of-motion exercises, or ambulate the patient every 2 hours.
 - u Prevent physical exhaustion and injury during periods of hyperactivity.
 - u Tell the patient directly, specifically, and concisely what needs to be done. Don't offer the negativistic patient a choice. For example, you might say, "It's time to go for a walk. Let's go."
 - u Spend some time with the patient even if he's mute and unresponsive. He's acutely aware of his environment even though he seems not to be. Your presence can be calming and reassuring. Avoid mutual withdrawal.
 - u Avoid proceeding as if the client can't hear. Speak to the client and don't talk about the client in his presence.
 - u Verbalize for the patient the message his nonverbal behavior seems to convey, and encourage him to do so as well.
 - u Offer reality orientation. You might say: "The leaves on the trees are turning colors, and the air is cooler. It's fall!" Emphasize reality in all contacts to reduce distorted perceptions.
 - u Stay alert for violent outbursts from the patient; get help promptly to intervene safely for yourself and the patient.

For paranoid schizophrenia:

When the patient is newly admitted, minimize his contact with the staff.

- u Don't crowd the patient physically or psychologically; he may strike out to protect himself.
- u Be flexible; allow the patient some control. Approach him in a calm and unhurried manner. Let him talk about anything he wishes initially, but keep conversation light and social, and avoid entering into power struggles.
- u Respond to the patient's condescending attitudes (arrogance, put-downs, sarcasm, or open hostility) with neutral remarks.
- u Offer simple and matter-of-fact explanations about environmental safeguards, medications, and policies.
- u Don't let the patient put you on the defensive, and don't take his remarks personally. If he tells you to leave him alone, do leave, but make sure you return soon. Brief contacts with the patient may be most useful at first.
- u Anticipate the need for reduced social contact to increase the patient's comfort level.
- u Don't try to combat the patient's delusions with logic. Instead, respond to feelings, themes, or underlying needs—for example, "It seems you feel you've been treated unfairly" (persecution).
- u Build trust; be honest and dependable. Don't threaten, and don't promise what you can't fulfill.
- u Don't tease, joke, argue with, or confront the patient. Remember, his distorted perception will cause him to misinterpret such action in a way that is derogatory to himself.

Patient teaching

- u If the patient is taking clozapine, stress the importance of returning weekly to the hospital or outpatient setting to have his blood monitored.
- u Teach the patient the importance of complying with the medication regimen. Tell him that he should report any adverse effects but that he shouldn't just stop taking the drug. If he takes a slow-release formulation, make sure he understands when to return to the doctor for his next dose of medication.
- u Involve the patient's family in his treatment, particularly because his altered thought processes and sensory and perceptual alterations often make teaching difficult or impossible. Teach family members how to recognize an impending relapse, and suggest ways to manage symptoms, such as tension, nervousness, insomnia, decreased concentration ability, and loss of interest.

MOOD DISORDERS

A mood disorder involves disturbances in the regulation of a person's mood, behavior, and affect. In these disorders, a person's mood becomes so intense and persistent that it interferes with his social and psychological function. Mood disorders include bipolar disorder and major depression.

BIPOLAR DISORDER

Bipolar disorder is an affective disorder marked by severe pathologic mood swings from hyperactivity and euphoria to sadness and depression. Some patients suffer from acute attacks of mania only.

In cyclothymia, a variant of bipolar disorder, numerous episodes of hypomania and depressive symptoms are too mild to meet the criteria for major depression or bipolar illness. In many patients, manic episodes emerge over a period of days to weeks, but onset within hours is possible. Untreated episodes can last weeks or as long as 8 to 12 months, with some having an unremitting course. *Rapid cycling* occurs when four or more episodes of either depression or mania occur in a given year and occurs in 15% of all patients, almost all women. (See [Cyclothymic disorder](#).)

Bipolar disorder is common, affecting 3 million people in the United States, but it's difficult to diagnose. This disorder is equally common in women and men. Women are likely to have more depressive episodes; men experience more manic episodes in a lifetime. Approximately half of all patients with this disorder have difficulties in work performance and psychosocial functioning. Age of onset is usually between 20 and 30, but symptoms have been reported in late childhood and early adolescence.

Causes and pathophysiology

The cause of bipolar disorder is unclear, but hereditary, biological, and psychological factors may play a part. In affected families, autosomal dominant inheritance has been found in genetic studies. There is some support for the theory that bipolar disorder is linked to an X chromosome disorder. For example, the incidence of bipolar disorder among relatives of affected patients is higher than in the general population.

The pathophysiologic mechanisms involving mood swings is unknown for bipolar disorder. Membrane changes in sodium- and potassium-activated adenosine triphosphatase involve disordered intracellular signals. Lithium is thought to help in this respect.

Complications

The impulsive behavior characteristic of manic episodes may have far-reaching emotional and social consequences, such as bankruptcy, child abuse, and divorce. There is an increased incidence of sexually transmitted diseases and unwanted pregnancies. Exhaustion and poor nutrition may result from hyperactivity and sleep disturbances. A patient with bipolar disorder also represents a substantial suicide risk. Suicide can occur impulsively during a manic episode or after the resolution of a depressive episode.

Assessment findings

Widely varying assessment findings depend on whether the patient is experiencing a manic or a depressive episode.

During the assessment interview, the manic patient typically exhibits increased psychomotor activity and excessive social extroversion, describes a decreased need for sleep, expresses impulsivity and impaired judgement, and exhibits expansive, grandiose (and at times irritable) mood. If the mania is severe, the patient may have delusions and paranoid thinking. The patient often overinvolves himself in activities, exhibits limited attention span, and has an increased rate of activity.

The patient often expresses an inflated sense of self-esteem, ranging from uncritical self-confidence to marked grandiosity, which may be delusional.

Accelerated speech, frequent changes of topic, and flight of ideas are common features of the manic phase. The patient may be easily distracted and rapidly

responds to external stimuli, such as background noise or a ringing telephone. The patient may also report sleeping and eating less than usual.

The patient with a bipolar II disorder may not have all the diagnostic criteria for a manic episode. The patient may also experience recurrent depressions, separated by periods of mild activation and increased energy (hypomania).

The patient who experiences a *depressive episode* may report a loss of self-esteem, overwhelming inertia, social withdrawal, and feelings of hopelessness, apathy, or self-reproach.

During the assessment interview, the depressed patient may speak and respond slowly. He may complain of difficulty concentrating or thinking clearly but usually isn't obviously disoriented or intellectually impaired.

Physical examination may reveal psychomotor retardation, lethargy, low muscle tonus, weight loss, slowed gait, and constipation. The patient also may report sleep disturbances (falling asleep, staying asleep, or early morning awakening) and sexual dysfunction.

Diagnostic criteria

A diagnosis of bipolar I or II disorder is confirmed when the patient meets the criteria established in the *DSM-IV* (see [Differentiating bipolar disorder.](#))

Bipolar I disorders can be classified as one of six types: single manic, hypomanic, manic, depressed, mixed, or unspecified. Bipolar II disorder is present when the patient has a history of one or more major depressive and hypomanic episodes but no history of manic episodes.

For a manic or hypomanic episode:

- u The patient experiences a distinct period of abnormally and persistently elevated, expansive, or irritable mood.

ADVANCED PRACTICE

Cyclothymic disorder

A chronic mood disturbance of at least 2 years' duration, cyclothymic disorder involves numerous episodes of hypomania or depressive symptoms that aren't of sufficient severity or duration to qualify as a major depressive episode.

In the hypomanic phase, the patient may experience insomnia; hyperactivity; inflated self-esteem; increased productivity and creativity; overinvolvement in pleasurable activities, including an increased sexual drive; physical restlessness; and rapid speech. Depressive symptoms may include insomnia, feelings of inadequacy, decreased productivity, social withdrawal, loss of libido, loss of interest in pleasurable activities, lethargy, depressed speech, and crying.

A number of medical disorders (for example, endocrinopathies such as Cushing's disease, stroke, brain tumors, head trauma, and drug overdose) can produce a similar pattern of mood alteration. These organic causes must be ruled out before making a diagnosis of cyclothymic disorder.

- u During the mood disturbance, at least three of these symptoms must persist (four, if the mood is only irritable) and be present to a significant degree:
 - inflated self-esteem or grandiosity
 - decreased need for sleep
 - increased talkativeness or pressure to keep talking
 - flight of ideas or subjective experience that thoughts are racing
 - distractibility
 - increased goal-directed activity or psychomotor agitation
 - excessive involvement in pleasurable activities that have a high potential for painful consequences.

For a manic episode only:

- u The mood disturbance is sufficiently severe to cause marked impairment in occupational function, usual social activities, or relations with others, or to require hospitalization to prevent harm to self or others.
- u At no time during the disturbance have delusions or hallucinations persisted for as long as 2 weeks in the absence of prominent mood symptoms.
- u The disturbance isn't superimposed on schizophrenia, schizophreniform disorder, delusional disorder, or psychotic disorder not otherwise specified.
- u No organic factor has initiated and maintained the disturbance.

ADVANCED PRACTICE

Differentiating bipolar disorder

A physical examination and laboratory tests such as endocrine function studies rule out medical causes of mood disturbances such as schizophrenia, mixed mania, and agitated depression. In addition, stimulants and sympathomimetic compounds taken by the patient can cause manic symptoms. Secondary mania, which closely resembles the mania of bipolar disorders, can be caused by hyperthyroidism, acquired immunodeficiency syndrome, neurologic disorders such as Huntington's chorea, or cerebrovascular accidents.

For a depressive episode:

- u At least five of the following symptoms must have been present during the same 2-week period and represent a change from previous function; one of these symptoms must be either a depressed mood or a loss of interest in previously pleasurable activities:
 - depressed mood (irritable mood in children and adolescents) most of the day, nearly every day, as indicated by subjective account or observation by others
 - markedly diminished interest or pleasure in all, or almost all, activities most of the day, nearly every day
 - significant weight loss or weight gain when not dieting or a change in appetite nearly every day—insomnia or hypersomnia nearly every day—psychomotor agitation or retardation nearly every day—fatigue or loss of energy nearly every day
 - feelings of worthlessness and excessive or inappropriate guilt nearly every day
 - diminished ability to think or concentrate or indecisiveness, nearly every day
 - recurrent thoughts of death, recurrent suicidal ideation without a specific plan, or suicide attempt or a specific plan for committing suicide.
- u No organic factor initiated and maintained the disturbance.
- u The disturbance isn't a normal reaction to the death of a loved one.
- u At no time during the disturbance have delusions or hallucinations persisted for as long as 2 weeks in the absence of prominent mood symptoms.
- u The disturbance isn't superimposed on schizophrenia, schizophreniform disorder, delusional disorder, or psychotic disorder not otherwise specified.

For a mixed episode:

- u The current or most recent episode involves the full symptomatic picture of both manic and major depressive episodes intermixed or rapidly alternating every few days.
- u Prominent depressive symptoms last at least a full day

A physical examination and laboratory tests, such as endocrine function studies, rule out medical causes of the mood disturbances, including intra-abdominal neoplasm, hypothyroidism, heart failure, cerebral arteriosclerosis, parkinsonism, psychoactive drug abuse, brain tumor, and uremia. In addition, a review of medications prescribed for other disorders may point to drug-induced depression or mania.

Treatment

Widely used to treat bipolar disorder, lithium proves highly effective in relieving and preventing manic episodes. The drug curbs the accelerated thought processes and hyperactive behavior without the sedating effect of antipsychotic drugs. In addition, it may prevent the recurrence of depressive episodes; however, it's ineffective in treating acute depression.

Lithium has a narrow therapeutic range, so treatment must be initiated cautiously and the dosage adjusted slowly. Therapeutic blood levels must be maintained for 7 to 10 days before effects appear; therefore, antipsychotic drugs often are used in the interim for sedation and symptomatic relief. Because lithium is excreted by the kidneys, any renal impairment necessitates withdrawal of the drug.

Valproic acid is an alternative to lithium for those who don't tolerate it. It's especially helpful in rapid cycling courses of bipolar disorder. Carbamazepine is helpful in the treatment of mania but isn't formally approved by the FDA for bipolar disorder.

Antidepressants occasionally are used to treat depressive symptoms. However, these drugs may trigger a manic episode.

Nursing diagnoses

- u Altered health maintenance
- u Altered role performance
- u Altered thought processes
- u Impaired social interaction
- u Ineffective individual coping
- u Personal identity disturbance
- u Self-esteem disturbance

Key outcomes

- u The patient will identify effective and ineffective coping techniques.
- u The patient will recognize symptoms and comply with medication regimen.
- u The patient will voice feelings related to self-esteem.
- u The patient will join gradually in self-care and the decision-making processes.

Nursing interventions

For the manic patient:

- u Remember the manic patient's physical needs. Involve the patient in activities that require gross motor movements. Encourage him to eat; he may jump up and walk around the room after every mouthful but will sit down again if you remind him. Offer high-calorie finger foods, sandwiches, and cheese and crackers to supplement his diet if he can't remain seated long enough to complete a meal.
- u Suggest short daytime naps, and help with personal hygiene. As the patient's symptoms subside, encourage him to assume responsibility for personal care.
- u Protect the patient from overstimulation, such as large groups, loud noises, and bright colors.
- u Provide emotional support, maintain a calm environment, and set realistic goals for behavior.
- u Provide diversional activities suited to a short attention span; firmly discourage the patient if he tries to overextend himself.
- u When necessary, reorient the patient to reality, and tactfully divert conversations when they become intimately involved with other patients or staff members.
- u In a calm, clear, and self-confident manner, set limits for the manic patient's demanding, hyperactive, manipulative, and acting-out behaviors. Setting limits lets the patient know that you'll provide security and protection by refusing inappropriate and possibly harmful requests. Avoid leaving an opening for the patient to test or argue.
- u Listen to requests attentively and with a neutral attitude, but avoid power struggles if the patient tries to put you on the spot for an immediate answer. Explain that you'll seriously consider the request and will respond later.
- u Collaborate with other staff members to provide consistent responses to the patient's manipulations or acting out. Anticipate the need for excessive verbalization.
- u Watch for early signs of frustration (when the patient's anger escalates from verbal threats to hitting an object). Refrain from reinforcing socially inappropriate or suggestive comments. Tell the patient firmly that threats and hitting are unacceptable and that these behaviors show that he needs help to control his behavior. Then tell him that the staff will help him move to a quiet area and will help him control his behavior so he won't hurt himself or others. Staff members who have practiced as a team can work effectively to prevent acting-out behavior or to remove and confine a patient.
- u Alert the staff team promptly when acting-out behavior escalates. It's safer to have help available before you need it than to try controlling an anxious or frightened patient by yourself.
- u When the incident is over and the patient is calm and in control, discuss his feelings with him and offer suggestions to prevent recurrence.

For the depressed patient:

- u Avoid overwhelming the patient with expectations.
- ASSESSMENT TIP** Expect your patient to have slow psychomotor responses; allow increased time for activities and responses during your assessment.
- u The depressed patient needs continual positive reinforcement to improve his self-esteem. Provide a structured routine, including activities to boost confidence and promote interaction with others (for instance, group therapy), and keep reassuring him that his depression will lift.
- u Assume an active role in communicating. Encourage the patient to talk or to write down his feelings if he's having trouble expressing them. Listen attentively and respectfully, and allow him time to formulate his thoughts if he seems sluggish. Record your observations and conversations to assist in the evaluation of his condition.
- u To prevent possible self-injury or suicide, remove harmful objects from the patient's environment (glass, belts, rope, bobby pins), observe him closely, and strictly supervise his medications. Institute suicide precautions as dictated by hospital policy.
- u Don't forget the patient's physical needs. If he's too depressed to take care of himself, help him with personal hygiene. Encourage him to eat, or feed him, if necessary. If he's constipated, add high-fiber foods to his diet; offer small, frequent meals; and encourage physical activity. To help him sleep, give back rubs or warm milk at bedtime.
- u If the patient is taking an antidepressant, watch for signs of mania.

Patient teaching

- u If the patient is taking lithium, teach him and his family to discontinue the drug and notify the doctor if signs of toxicity occur, including diarrhea, abdominal cramps, vomiting, unsteadiness, drowsiness, muscle weakness, polyuria, and tremors.
- u Advise the patient to take lithium with food or after meals to avoid stomach upset.
- u Because restricting sodium intake increases lithium toxicity, instruct the patient to maintain a normal diet and normal salt and water intake.
- u Lithium may impair mental and physical function; caution against driving or operating dangerous equipment while taking the drug.
- u Teach the patient the importance of continuing his medication regimen even when he doesn't feel a need for it.

MAJOR DEPRESSION

Major depression is defined as a depressed mood on a daily basis for 2 weeks or longer. It's a syndrome of persistent sad, dysphoric mood accompanied by disturbances in sleep and appetite, lethargy, and an inability to experience pleasure (anhedonia). About 15% of the general population experiences a major depression episode at some time in their lives; about 6% to 8% of patients in care settings meet the diagnostic criteria for this disorder. It's often undiagnosed, and patients commonly receive inadequate treatment.

The incidence of depression increases with age; women experience it twice as often as men, regardless of age. Unipolar depressive disorders have an onset in early adulthood with recurrences throughout the patient's lifetime. Recurrences may follow a protracted symptom-free period, or they may occur sporadically, increasing in frequency as the patient grows older, or as clusters of episodes.

Causes and pathophysiology

The relationship between psychological stress, negative life events, and onset of depression is unclear. Genetic, familial, biochemical, physical, psychological, and social causes have been implicated. In many patients, the history identifies a specific personal loss or severe stress that probably interacts with a person's predisposition to provoke major depression. Risk of unipolar depression increases with the number of occurrences. About 50% to 60% of persons who have a first episode experience at least two more episodes.

The neural networks of the prefrontal cortex and the basal ganglia may be the primary sites of defects in unipolar depression. A decreased rate of the brain's glucose metabolism in the caudate nuclei and frontal lobes in depressed patients returns to normal with recovery. In addition, involvement of the serotonin system has been suggested, as has the neuroendocrine systems. Changes in the hypothalamic-pituitary-adrenal regulation system in clinical studies may represent an adaptive deregulation of the stress response. There may also be differences in biological rhythms, as evidenced by changes in the patient's circadian rhythm and various neurochemical and neurohormonal factors.

The practitioner must differentiate major depression from depression that occurs in response to a specific event or has a recognizable organic basis. For example, many physical disorders are associated with secondary depression. Among the most prominent are metabolic disturbances, such as hypoxia and hypercalcemia; endocrine disorders, such as diabetes and Cushing's disease; neurologic diseases, such as Parkinson's and Alzheimer's disease; cancer (especially of the pancreas); viral and bacterial infections, such as influenza and pneumonia; cardiovascular disorders such as heart failure; pulmonary disorders such as chronic obstructive lung disease; musculoskeletal disorders such as degenerative arthritis; GI disorders such as irritable bowel syndrome; genitourinary problems such as incontinence; collagen vascular diseases such as lupus; and anemias.

Drugs prescribed for medical and psychiatric conditions, as well as many commonly abused substances, also can precipitate secondary depression. Examples include antihypertensives, psychotropics, antiparkinsonian drugs, narcotic and nonnarcotic analgesics, numerous cardiovascular medications, oral antidiabetics, antimicrobials, steroids, chemotherapeutic agents, cimetidine, and alcohol.

Complications

Major depression can profoundly alter social, family, and occupational functioning. However, suicide is the most serious complication of major depression, resulting when the patient's feelings of worthlessness, guilt, and hopelessness are so overwhelming that he no longer considers life worth living. (See [Suicide prevention guidelines](#).)

Note: If specific plans for suicide are uncovered or if significant risk factors exist (previous history, profound hopelessness, concurrent medical illness, substance abuse, social isolation), refer the patient to a mental health specialist for immediate care. Nearly 15% of patients with untreated depression commit suicide, and most of these patients sought help from a doctor within 1 month of their deaths.

Assessment findings

Patients with endogenous depression experience a profound loss of pleasure in all enjoyable activities. The duration of an untreated episode can range from a full month to 1 or more years. During the assessment interview, the patient may complain of feeling “down in the dumps,” may express doubts about his self-worth or ability to cope, or may simply appear unhappy and apathetic. The patient often notices that symptoms are worse in the morning. Other common symptoms include difficulty concentrating or thinking clearly, distractibility, and indecisiveness. In severe states of major depression, delusions of persecution or guilt can occur. Severe affective disorder may effectively immobilize the client of all functions. Take special note if the patient reveals suicidal thoughts, a preoccupation with death, or previous suicide attempts.

ASSESSMENT TIP Be alert for signs of suicide. Assess the patient's risk of suicide by using direct questioning. Patients are often reluctant to verbalize these thoughts without prompting.

The psychosocial history may reveal life problems or losses that can account for the depression. Alternatively, the patient's medical history may implicate a physical disorder or the use of prescription, nonprescription, or illegal drugs that can cause depression.

The patient may report an increase or a decrease in appetite, sleep disturbances (for example, insomnia or early awakening), a lack of interest in sex, constipation, or diarrhea. Other signs you may note during a physical examination include agitation (such as hand wringing or restlessness) and psychomotor retardation (for example, slowed speech). In a minority of patients, the severity of depression may progress to psychotic symptoms. There is also a seasonal pattern of depression, seasonal affective disorder, particularly in women, who present with anergy, fatigue, weight gain, hypersomnia, and episode carbohydrate craving. The prevalence increases with distance from the equator. Mood improvement can be accomplished with light exposure therapy. (To distinguish major depression from dysthymia, a disorder with similar symptoms, see [Dysthymia: A chronic affective disorder](#).)

CULTURAL TIP Studies of various cultures show that external manifestations of depression can differ (for example, some individuals become stoic when depressed, whereas others outwardly express their depression); however, the core symptoms remain the same.

Diagnostic criteria

A patient is diagnosed with a major depressive episode when he fulfills the criteria documented in the *DSM-IV*.

u At least five of the following symptoms must have been present during the same 2-week period and represent a change from previous functioning; one of these symptoms must be either depressed mood or loss of interest in previously pleasurable activities (Don't include symptoms that are due to a general medical condition, delusions, or hallucinations):

PREVENTION

Suicide prevention guidelines

To help deter potential suicide in the patient with major depression, keep in mind the following guidelines.

Assess for clues to suicide

Watch for such clues as communicating suicidal thoughts, threats, and messages; hoarding medication; talking about death and feelings of futility; giving away prized possessions; describing a suicide plan; and changing behavior, especially as depression begins to lift.

Provide a safe environment

Check patient areas and correct dangerous conditions, such as exposed pipes, windows without safety glass, and access to the roof or open balconies.

Remove dangerous objects

Remove such objects as belts, razors, suspenders, light cords, glass, knives, nail files, and clippers from the patient's environment.

Consult with staff

Recognize and document both verbal and nonverbal suicidal behaviors, keep the doctor informed, share data with all staff, clarify the patient's specific restrictions, assess risk and plan for observation, and clarify day and night staff responsibilities and frequency of consultation.

Observe the suicidal patient

Be alert when the patient is using a sharp object (shaving), taking medication, or using the bathroom (to prevent hanging or other injury). Assign the patient to a room near the nurses' station and with another patient. Continuously observe the acutely suicidal patient.

Maintain personal contact

Help the suicidal patient feel that he's not alone or without resources or hope. Encourage continuity of care and consistency of primary nurses. Building emotional ties to others is the ultimate technique for preventing suicide.

- depressed mood (irritable mood in children and adolescents) most of the day, nearly every day, as indicated by either subjective account or observation by others
- a markedly diminished interest or pleasure in all, or almost all, activities most of the day, nearly every day
- significant weight loss or weight gain (greater than 5% of the patient's body weight in a month) when not dieting or a change in appetite nearly every day

ADVANCED PRACTICE

Dysthymia: A chronic affective disorder

Dysthymic disorder exists in 5% of primary care patients in which the mood disorder isn't episodic and doesn't cause psychosocial dysfunction or changes from the person's usual life. Formerly known as depressive neurosis, this disorder is characterized by a chronic dysphoric mood (irritable mood in children) that persists at least 2 years. During periods of depression, the patient also may experience poor appetite or overeating, insomnia or hypersomnia, low energy or fatigue, low self-esteem, poor concentration, difficulty making decisions, and feelings of hopelessness.

The symptoms are ongoing and mild and are less severe and disabling than those found in major depression. The two conditions are difficult to separate and at times can occur together, termed *double depression*. Individuals with pessimism, disinterest, and low self-esteem respond to antidepressant treatment.

- insomnia or hypersomnia nearly every day
- psychomotor agitation or retardation nearly every day
- fatigue or loss of energy nearly every day
- feelings of worthlessness and excessive or inappropriate guilt nearly every day
- diminished ability to think or concentrate or indecisiveness, nearly every day
- recurrent thoughts of death, recurrent suicidal ideation without a specific plan, or suicide attempt or a specific plan for committing suicide.
- u The symptoms aren't due to a mixed episode.
- u The symptoms aren't due to a medical condition (such as hypothyroidism) or the effects of a medication or other substance (drug abuse, for example).
- u The symptoms aren't better accounted for by bereavement (for example, symptoms persist for more than 2 months after a loved one's death or are characterized by marked functional impairment, morbid thoughts of worthlessness, suicidal ideation, psychotic symptoms, or psychomotor retardation).

Psychological tests such as the Beck Depression Inventory can be used to determine the onset, severity, duration, and progression of depressive symptoms. The dexamethasone suppression test may show a failure to suppress cortisol secretion; however, this test has a high false-negative rate. Toxicology screening may suggest a drug-induced depression.

Treatment

The primary treatment methods are drug therapy, electroconvulsive therapy, and psychotherapy. They aim to relieve the depressive symptoms. Medication is the most effective intervention for achieving remission and preventing relapse. Improved outcome is achieved with a combination therapy of medication and psychotherapy to help the patient cope with decreased self-esteem and demoralization. There is no ideal antidepressant, so other considerations include the patient's metabolism, adverse effects of the medication, medications that have been effective with other family members, and toxicity (if suicide by overdose is a concern).

Drug therapy that modifies the activity of relevant neurotransmitter pathways includes tricyclic antidepressants (TCAs) such as amitriptyline, selective serotonin reuptake inhibitors such as fluoxetine, and monoamine oxidase (MAO) inhibitors such as isocarboxazid.

TCAs, the most widely used antidepressant drug, prevent the reuptake of norepinephrine or serotonin or both into the presynaptic nerve endings, resulting in increased synaptic concentrations of these neurotransmitters. They also cause a gradual loss in the number of beta-adrenergic receptors.

MAO inhibitors block the enzymatic degradation of norepinephrine and serotonin. These agents often are prescribed for patients with atypical depression (for example, depression marked by an increase in appetite and the need for sleep, rather than anorexia and insomnia) and for some patients who fail to respond to TCAs. The MAO inhibitors are associated with a high risk of toxicity; patients treated with one of these drugs must be able to comply with the necessary dietary restrictions. Conservative doses of a MAO inhibitor may be combined with a TCA for patients refractory to either drug alone

Maprotiline is a potent blocker of norepinephrine uptake, whereas trazodone, fluoxetine, and sertraline are selective serotonin uptake blockers. These drugs are especially useful in patients who are unable to tolerate the adverse effects of TCAs or MAO inhibitors.

Treatment response should be re-evaluated in 2 months and increases or changes made as needed. After remission is achieved, drug treatment should continue for

at least 6 to 9 months or longer.

CULTURAL TIP Look for opportunities to explore alternative treatments. Groups such as Brazilians may be reluctant to take medication because of fear of addiction, and groups such as Cambodians feel that Western medicine is too strong for their bodies so they won't take pills. Alternative therapies should be explored with these patients if they won't comply with medications as treatment.

Electroconvulsive therapy is as effective as medication, but its use is reserved for treatment-resistant cases and patients with delusions.

Short-term psychotherapy also is effective in the treatment of major depression. Many psychiatrists believe that the best results are achieved with a combination of individual, family, or group psychotherapy and medication. After resolution of the acute episode, patients with a history of recurrent depression may be maintained on low doses of antidepressant drugs as a preventive measure.

Nursing diagnoses

⌵ Altered role performance ⌵ Anxiety ⌵ Chronic low self-esteem ⌵ Dysfunctional grieving ⌵ Fatigue ⌵ Impaired social interaction ⌵ Ineffective individual coping ⌵ Risk for violence: Self-directed or directed at others ⌵ Self-esteem disturbance ⌵ Sleep pattern disturbance ⌵ Social isolation ⌵ Spiritual distress

Key outcomes

- ⌵ The patient will voice feelings related to self-esteem.
- ⌵ The patient will make a verbal contract not to harm himself while in the hospital.
- ⌵ The patient will engage in social interactions with others.
- ⌵ The patient will demonstrate verbally and behaviorally a decrease in negative self-evaluation.

Nursing interventions

- ⌵ To prevent the patient from becoming isolated, try to spend some time with him each day. Avoid long periods of silence, which tend to increase anxiety.
- ⌵ Share your observations of the patient's behavior with him. For instance, you might say, "You're sitting all by yourself, looking very sad. Is that how you feel?" Because the patient may think and react sluggishly, try to speak slowly and allow ample time for him to respond. Avoid feigned cheerfulness, but don't hesitate to laugh with the patient and point out the value of humor.

CULTURAL TIP Members of some cultures, such as Arab Americans, don't acknowledge depression. Encourage the patient to discuss his condition, and give the patient permission to feel depressed.

- ⌵ Encourage the patient to talk about and write down his feelings. Show him he's important by listening attentively and respectfully, preventing interruptions, and avoiding judgmental responses.
- ⌵ Provide a structured routine, including noncompetitive activities, to build the patient's self-confidence and encourage interaction with others. Urge him to join group activities and to socialize.
- ⌵ Reassure the patient that he can help ease his depression by expressing his feelings, participating in pleasurable activities, and improving grooming and hygiene.
- ⌵ Ask the patient if he thinks of death or suicide. Such thoughts signal an immediate need for consultation and assessment. Failure to detect suicidal thoughts early may encourage the patient to attempt suicide. The risk of suicide increases as the depression lifts.
- ⌵ Record all observations of and conversations with the patient because they're valuable for evaluating his response to treatment.
- ⌵ While caring for the patient's psychological needs, don't forget his physical needs. If he's too depressed to take care of himself, help him with personal hygiene. Encourage him to eat, or feed him, if necessary. If he's constipated, add high-fiber foods to his diet; offer small, frequent meals; and encourage physical activity and fluid intake. Offer warm milk or back rubs at bedtime to improve sleep.
- ⌵ Assume an active role in initiating communication.
- ⌵ Plan activities for when the patient's energy levels are highest.
- ⌵ If the patient has been prescribed an antidepressant, monitor for evidence of seizures. Some antidepressants significantly lower the seizure threshold.
- ⌵ Recognize that it may take several weeks for the antidepressants to produce an effect.

Patient teaching

- ⌵ Teach the patient about his depression. Emphasize that effective methods are available to relieve his symptoms. Help him to recognize distorted perceptions, and link them to his depression. When the patient learns to recognize depressive thought patterns, he can consciously begin to substitute self-affirming thoughts.
- ⌵ If the patient has been prescribed an antidepressant, stress the need for compliance and review adverse reactions. For drugs that produce strong anticholinergic effects, such as amitriptyline and amoxapine, suggest sugarless gum or hard candy to relieve dry mouth. Many antidepressants are sedating (for example, amitriptyline and trazodone); warn the patient to avoid activities that require alertness, including driving and operating mechanical equipment.
- ⌵ Caution the patient taking a TCA to avoid drinking alcoholic beverages or taking other central nervous system depressants during therapy.
- ⌵ If the patient is taking a MAO inhibitor, emphasize that he must avoid foods that contain tyramine, caffeine, or tryptophan. Emphasize that the ingestion of tyramine can cause a hypertensive crisis. Examples of foods that contain these substances are cheese; sour cream; beer, Chianti, and sherry; pickled herring; liver; canned figs; raisins; bananas; avocados; chocolate; soy sauce; fava beans; yeast extracts; meat tenderizers; coffee; and colas.

ANXIETY DISORDERS

Anxiety is the most prevalent psychiatric illness in the general community. Anxiety is a component of most psychological disorders and many organic disorders, and it affects 15% to 20% of medical clinic patients. The anxiety disorders described below include generalized anxiety disorder, obsessive-compulsive disorder, panic disorder, phobias, and posttraumatic stress disorder.

GENERALIZED ANXIETY DISORDER

Anxiety is a subjective feeling of apprehension caused by a threat to a person or his values. Some describe it as an exaggerated feeling of impending doom, dread, or uneasiness. Unlike fear—a reaction to danger from a specific external source—anxiety is a reaction to an internal threat, such as an unacceptable impulse or a repressed thought that is straining to reach a conscious level or a real, threatened, or imagined threat to the patient's self-esteem.

Occasional anxiety is a rational response to a real threat and is a normal part of life. Overwhelming anxiety, however, can result in a generalized anxiety disorder (GAD)—uncontrollable, unrealistic worry that is persistent. More than 80% of patients with GAD suffer from major depression, arrhythmias, or social phobia. Onset is usually before age 20, and the patient usually has a history of childhood fears. It's equally common in men and women.

Causes and pathophysiology

Anxiety can indicate a primary psychiatric condition, be related to a primary medical disease, or be related to a medication adverse effect. In GAD, an aberration in benzodiazepine receptor regulation is thought to occur. Serotonin changes also appear to play a part in anxiety.

Complications

Anxiety can impair social or occupational functioning; effects can range from mild to severe and incapacitating. GAD patients often abuse substances. Alcohol or sedative and hypnotic abuse is common.

Assessment findings

The patient admits to worrying excessively about minor matters, with life-disrupting effects.

Physical examination of the patient with GAD may reveal symptoms of muscle tension, including trembling, muscle aches and spasms, headaches, and an inability to relax. Autonomic signs and symptoms include shortness of breath, tachycardia, and sweating, and abdominal complaints are rare.

In addition, the patient may startle easily and complain of feeling apprehensive, fearful, or angry and of having difficulty concentrating, eating, and sleeping. The medical, psychiatric, and psychosocial histories fail to identify a specific physical or environmental cause of the anxiety.

Diagnostic criteria

When the patient's symptoms match the following criteria documented in the *DSM-IV*, the diagnosis of GAD is confirmed:

- u The patient has an unrealistic or excessive anxiety and worry about two or more events or activities (such as work or school performance) for 6 months, during which he has been bothered most days by these concerns.
- u The patient finds it difficult to control the worry.
- u The focus of the anxiety and worry doesn't have the features of an Axis I disorder.
- u The disturbance doesn't occur only during the course of a mood disorder, psychotic disorder, or pervasive developmental disorder; nor is it due to direct physiologic effects of a substance (drug abuse or medication) or a general medical condition (such as hyperthyroidism).
- u Anxiety and worry are linked with three or more of the following symptoms present over the past 6 months (only one is required in a child):
 - restlessness or feeling keyed up or on edge
 - being easily fatigued
 - difficulty concentrating or mind going blank
 - irritability
 - muscle tension
 - sleep disturbance.
- u The anxiety, worry, or symptoms cause significant distress or impairment in social, occupational, or other important areas of functioning.

Panic disorder can mimic physiologic disorders; differentiation is necessary. Laboratory tests must exclude organic causes, such as hyperthyroidism, pheochromocytoma, coronary artery disease, supraventricular tachycardia, and Ménière's disease. For example, an electrocardiogram can rule out myocardial ischemia in a patient with chest pain. Blood tests, including complete blood count, white blood cell differential, and serum lactate and calcium levels, can rule out hypocalcemia.

Because anxiety is the central feature of other mental disorders, psychiatric evaluation is necessary to rule out phobias, obsessive-compulsive disorders, depression, and acute schizophrenia.

Treatment

Drug treatment and psychotherapy is most effective in treating a patient with this disorder. Complete symptomatic relief is rare, however. The benzodiazepine antianxiety drugs relieve anxiety but should only be prescribed for 4 to 6 weeks because the patient may develop tolerance to the drugs and because of a potential for abuse. Buspirone, an antianxiety drug, causes less sedation and less risk of physical and psychological dependence than the benzodiazepines. However, it takes several weeks to take effect.

Psychotherapy can help the patient identify and deal with the cause of anxiety, anticipate his reactions, and plan effective response strategies to deal with the anxiety. The patient may also learn relaxation techniques, such as deep breathing, progressive muscle relaxation, focused relaxation, and visualization.

Nursing diagnoses

- u Anxiety
- u Decisional conflict (excessive worry)
- u Impaired social interaction
- u Ineffective individual coping
- u Self-esteem disturbance
- u Social isolation

Key outcomes

- u The patient will experience reduced anxiety by identifying internal precipitating situation.
- u The patient will identify current stressors.
- u The patient will set limits and compromises on behavior when ready.

HOME CARE

Living with generalized anxiety disorder

Follow these guidelines to help your patient live with generalized anxiety disorder:

- u Make sure the patient (or his caregiver) knows the name, dosage, and adverse effects of the prescribed medications.
- u Urge the patient to call the doctor if adverse reactions occur but not to discontinue the drug without his doctor's approval.
- u Advise the patient not to drive or perform other hazardous activities until the drug's effects are known and drug tolerance occurs. Also counsel him to avoid alcohol and other central nervous system depressants.
- u Teach the patient coping techniques, such as distraction, massage, muscle relaxation, breathing exercises, and imagery.
- u Help the patient identify the causes of his anxiety, and review ways to deal with them.
- u Suggest ways the patient can modify his environment to eliminate precipitating factors.

- u The patient will maintain autonomy and independence without handicapping fears and use of phobic behavior.
- u The patient will develop effective coping mechanisms.

Nursing interventions

- u Help the patient develop effective coping mechanisms to manage his anxiety. (See [Living with generalized anxiety disorder.](#))
- u Stay with the patient when he's anxious, and encourage him to discuss his feelings. Reduce environmental stimuli, and remain calm.
- u Suggest activities that distract him from his anxiety.
- u Give antianxiety drugs as prescribed, and evaluate the patient's response.

Patient teaching

- u Warn the patient and his family that antianxiety drugs may cause adverse reactions, such as drowsiness, fatigue, ataxia, blurred vision, slurred speech, tremors, and hypotension.
- u Advise the patient to discontinue medications only with the doctor's approval because abrupt withdrawal could cause severe symptoms.

OBSESSIVE-COMPULSIVE DISORDER

Obsessive-compulsive disorder (OCD) is characterized by obsessive thoughts and compulsive behaviors that impair everyday functioning. Common manifestations include repeated hand washing due to fear of contamination and germs, counting behaviors, and checking and rechecking actions, such as checking and rechecking whether a door is locked.

Obsessions and compulsions may be simple or complex and ritualized. Mild forms of the disorder are relatively common in the general population. It's more common in males and first-born children. Generally, an obsessive-compulsive disorder is chronic, often with remissions and exacerbations. In some cases, patients' psychosocial functioning steadily deteriorates. Tics are sometimes associated with OCD, usually beginning in early adulthood or childhood.

Causes and pathophysiology

In OCD, there is an anatomic-physiologic disturbance that is thought to involve an alteration in the frontal-subcortical neural circuitry of the brain. The orbital frontal cortex, caudate nucleus, and globus pallidus are involved. There seems to be a decrease in caudate nucleus volume; this area of the brain is involved in learning or acquiring and maintaining habits and skills. Interventions that successfully reduce organic brain disease also decrease the caudate glucose metabolic rate, which is elevated in organic brain disease.

Complications

Obsessions and compulsions cause significant distress and may severely impair a person's occupational and social functioning. In some cases, the compulsions may become the patient's major activity.

Compulsive behaviors can also endanger the health and safety of the patient or those around him. For example, a person who compulsively washes his hands may develop severe dermatitis or a skin infection.

Assessment findings

The psychiatric history of a patient with this disorder may reveal the presence of obsessive thoughts, words, or mental images that persistently and involuntarily invade the consciousness. The patient recognizes that the obsessions are a product of his own mind and that they interfere with normal daily activities but feels powerless to stop them. In all cases, obsessive-compulsive behaviors and activities comprise more than 1 hour per day. The activities are done to alleviate anxiety triggered by the patient's core fear.

ASSESSMENT TIP Patients often conceal their symptoms due to embarrassment over the nature of their actions. Ask specific questions about the patient's thoughts and behaviors, especially if there are physical cues, such as chafed or reddened hands or hair loss due to compulsive pulling.

During the assessment interview, determine the patient's personality type. The obsessional personality usually is rigid and conscientious and has great aspirations. He exhibits a formal, reserved manner, with precise and careful movements and posture; he takes responsibility seriously and finds decision making difficult. He lacks creativity and the ability to find alternate solutions to his problems.

Such a person tends to be painfully accurate and complete—carefully qualifying his statements to avoid making a mistake and anticipating every move and gesture of the person to whom he speaks. His affect is flat and unemotional, except for controlled anxiety. Self-awareness is intellectual, without accompanying emotion or feeling.

Also evaluate the impact of obsessive-compulsive phenomena on the patient's normal routine. He'll typically report moderate to severe impairment of social and occupational functioning.

Diagnostic criteria

The diagnosis of obsessive-compulsive disorder is confirmed when the patient's signs and symptoms meet the established criteria in the *DSM-IV*.

For an obsession:

- u The patient experiences, at least initially, recurrent and persistent ideas, thoughts, impulses, or images as intrusive and senseless.
- u For example, a parent has repeated impulses to kill a loved child, or a religious person has recurrent blasphemous thoughts.
- u The patient attempts to ignore or suppress such thoughts or impulses or to neutralize them with some other thought or action.
- u The patient recognizes that the obsessions are the products of his mind, not externally imposed.
- u If another Axis I disorder is present, the content of the obsession is unrelated to it; for example, the ideas, thoughts, or images aren't about food in the presence of an eating disorder, about drugs in the presence of a psychoactive substance use disorder, or about guilt thoughts in a major depressive disorder.

For compulsions:

- u The patient will perform repetitive, purposeful, and intentional behaviors in response to an obsession or according to certain rules or in a stereotypical manner.
- u The patient's behavior is designed to neutralize or prevent discomfort or some dreaded event or situation; however, either the activity isn't connected in a realistic way with what it's designed to neutralize or prevent, or it's clearly excessive.
- u The patient recognizes that his behavior is excessive or unreasonable (this may not be true for young children or for patients whose obsessions have evolved into overvalued ideas).

The obsessions or compulsions, as defined above, must cause marked distress, be time-consuming (take more than an hour a day), or significantly interfere with the person's normal routine, occupational functioning, or usual social activities or relationships.

Treatment

Fluoxetine and fluvoxamine, serotonin reuptake inhibitors, are as effective as clomipramine (a tricyclic antidepressant) and have milder adverse effects. However, only 50% to 60% of OCD patients show improvement solely with pharmacotherapy. In treatment-resistant cases, other serotonergic agents may be beneficial. Long-term maintenance is usually indicated.

ALERT Fluvoxamine inhibits the III A4 isoenzyme specifically and shouldn't be given with other medications that act on III A4 (terfenadine and astemizole); life-threatening cardiac arrhythmias could result.

Behavioral therapies—aversion therapy, thought stopping, thought switching, flooding, implosion therapy, and response prevention—have also been effective. For those with time-consuming obsessive-compulsive behaviors, behavior therapy results in as much improvement as that of medication. Effective techniques include increasing exposure to stressful situations, keeping a diary of daily stressors, and substituting new activities for compulsive behavior. (See [Behavioral therapies](#).)

Nursing diagnoses

- u Altered role performance
- u Anxiety
- u Fear
- u Impaired social interaction
- u Ineffective individual coping
- u Low self-esteem
- u Social isolation

Key outcomes

- u The patient will reduce the amount of time spent each day on obsessing and ritualizing.

Behavioral therapies
<p>The following behavioral therapies may be used to treat the patient with obsessive-compulsive disorder.</p> <p>Aversion therapy</p> <p>In aversion therapy, application of a painful stimulus creates an aversion to the obsession that leads to undesirable behavior (compulsion).</p> <p>Thought stopping</p> <p>Thought stopping breaks the habit of fear-inducing anticipatory thoughts. The patient learns to stop unwanted thoughts by saying the word “stop” and then focusing his attention on achieving calmness and muscle relaxation.</p> <p>Thought replacement or switching</p> <p>To replace fear-inducing self-instructions with competent self-instructions, the patient learns to replace negative thoughts with positive ones until the positive thoughts become strong enough to overcome the anxiety-provoking ones.</p> <p>Flooding</p> <p>Flooding, a frequent full-intensity exposure (through the use of imagery) to an object that triggers a symptom, must be used with caution because it produces extreme discomfort.</p> <p>Implosion therapy</p> <p>A form of desensitization, implosion therapy calls for repeated exposure to a highly feared object. The exposure increases in graduated levels, requiring strong interpersonal support or anxiolytic medication.</p> <p>Response prevention</p> <p>Preventing compulsive behavior by distraction, persuasion, or redirection of activity, response prevention is a form of behavior therapy that may require hospitalization or involvement of the family to be effective.</p>

- u Ritualistic behavior won't produce harmful effects.
- u The patient will express feelings of anxiety as they occur.
- u The patient will cope with stress without excessive obsessive-compulsive behavior.
- u The patient will develop self-esteem.

Nursing interventions

- u Approach the patient unhurriedly.
- u Provide an accepting atmosphere; don't show shock, amusement, or criticism of the ritualistic behavior.
- u Allow the patient time to carry out the ritualistic behavior (unless it's dangerous) until he can be distracted into some other activity. Blocking this behavior raises anxiety to an intolerable level.
- u Keep the patient's physical health in mind. For example, compulsive hand washing may cause skin breakdown, and rituals or preoccupations may cause inadequate food and fluid intake and exhaustion. Provide for basic needs, such as rest, nutrition, and grooming, if the patient becomes involved in ritualistic thoughts and behaviors to the point of self-neglect.
- u Let the patient know you're aware of his behavior. For example, you might say, “I noticed you've made your bed three times today; that must be very tiring for you.” Help the patient explore feelings associated with the behavior. For example, ask him, “What do you think about while you are performing your chores?”
- u Make reasonable demands, and set reasonable limits; make their purpose clear. Avoid creating situations that increase frustration and provoke anger, which may interfere with treatment.
- u Explore patterns leading to the behavior or recurring problems.
- u Listen attentively, offering feedback.
- u Encourage the use of appropriate defense mechanisms to relieve loneliness and isolation.
- u Engage the patient in activities to create positive accomplishments and raise his self-esteem and confidence.
- u Encourage active diversional resources, such as whistling or humming a tune, to divert attention from the unwanted thoughts and to promote a pleasurable experience.
- u Assist the patient with new ways to solve problems and to develop more effective coping skills by setting limits on unacceptable behavior (for example, by limiting the number of times per day he may indulge in obsessive behavior). Gradually shorten the time allowed. Help him focus on other feelings or problems for the remainder of the time.
- u Identify insight and improved behavior (reduced compulsive behavior and fewer obsessive thoughts). Evaluate behavioral changes by your own and the patient's reports.
- u Identify disturbing topics of conversation that reflect underlying anxiety or terror.
- u Observe when interventions don't work; reevaluate and recommend alternative strategies.
- u Monitor effects of pharmacologic therapy.

Patient teaching

- u Help the patient identify progress and set realistic expectations of self and others.
- u Explain how to channel emotional energy to relieve stress (for example, through sports and creative endeavors). In addition, teach the patient relaxation and breathing techniques to help reduce anxiety.

PANIC DISORDER

Characterized by recurrent and unpredictable episodes of intense apprehension, terror, and impending doom, panic disorder represents anxiety in its most severe form. Initially unpredictable, these “panic attacks” may come to be associated with specific situations or tasks. The disorder may exist concurrently with agoraphobia (an irrational fear of being in places where the person may feel trapped or unable to escape), leading to restrictions in the person's lifestyle.

Panic disorder typically has an onset in late adolescence or early adulthood, often in response to a sudden loss. The first attack usually occurs outside the home. It also may be triggered by severe separation anxiety experienced during early childhood. Without treatment, panic disorder can persist for years, with alternating exacerbations and remissions.

Causes and pathophysiology

The etiology of panic disorder is unknown but may have a genetic predisposition, involve autonomic responses, and be related to social learning. Like other anxiety disorders, panic disorder may stem from a combination of physical and psychological factors.

Panic disorder is associated with increased noradrenergic discharge; serotonin has been implicated. The individual appears to have a heightened sensitivity to somatic symptoms, triggering the autonomic system and setting off a panic attack.

Complications

Coexistence of panic disorder with agoraphobia may severely compromise the patient's ability to carry out normal daily activities. If possible, the patient may endure anxiety-provoking situations despite intense discomfort. Ultimately, he may become so fearful that he can no longer leave home alone.

The patient with panic disorder also is at high risk for a psychoactive substance use disorder, resorting to alcohol or anxiolytics in an attempt to relieve his fear.

Assessment findings

The patient with panic disorder typically complains of repeated episodes of unexpected apprehension, fear or, rarely, intense discomfort. These panic attacks may last from a few minutes and usually resolve over an hour. Frequency and severity of attacks vary with the individual. They may occur once a week or as clusters of attacks separated by months of wellness. Because the attacks occur spontaneously, without exposure to a known anxiety-producing situation, the patient often worries between attacks about when the next episode will occur.

Physical examination of the patient during a panic attack may reveal signs of intense anxiety, such as hyperventilation, tachycardia, trembling, and profuse sweating. He may also complain of difficulty breathing, digestive disturbances, and chest pain.

Diagnostic criteria

The diagnosis of panic disorder is based on fulfillment of the following criteria documented in the *DSM-IV*:

- u One or more panic attacks have occurred unexpectedly and weren't triggered by situations in which the person was the focus of other people's attention.
- u Attacks have been followed by a period of at least a month of persistent fear of having another attack.
- u At least four of the following signs and symptoms develop abruptly and reach a peak within 10 minutes:
 - shortness of breath or smothering sensations
 - dizziness or faintness
 - palpitations or tachycardia
 - trembling or shaking
 - sweating
 - feelings of choking
 - nausea or abdominal distress
 - depersonalization (being detached from self) or derealization (feelings of unreality)
 - numbness or tingling sensations (paresthesia)
 - hot flashes or chills
 - chest pain or discomfort
 - fear of dying or going crazy
 - doing something uncontrolled during the attack.
- u It can't be established that an organic factor initiated and maintained the disturbance.

Because many medical conditions can mimic panic disorder, additional tests may be ordered to rule out an organic basis for the symptoms. For example, serum glucose rules out hypoglycemia, urine catecholamines and vanillylmandelic acid rule out pheochromocytoma, and thyroid function tests rule out hyperthyroidism.

Urine and serum toxicology tests reveal the presence of psychoactive substances that can precipitate panic attacks, including barbiturates, caffeine, and amphetamines.

Treatment

Tricyclic antidepressants, imipramine, and clomipramine benefit 75% to 90% of panic disorder patients when given in low doses initially. Selective serotonin reuptake inhibitors are also effective and have fewer adverse effects. Monamine oxidase inhibitors are particularly helpful for individuals with comorbid features of atypical depression (hypersomnia and weight gain). Antianxiety agents take 2 to 6 weeks to become effective. Benzodiazepines such as alprazolam are useful for immediate relief but are dependence-prone.

Early psychotherapeutic intervention (such as deep breathing) and education about physiologic changes enhance the effectiveness of pharmacologic treatments.

Nursing diagnoses

- u Anxiety
- u Impaired social interaction
- u Impaired verbal communication
- u Knowledge deficit about physiologic effects of panic attack
- u Self-esteem disturbance

Key outcomes

- u The patient will experience reduced anxiety by identifying internal precipitating situation.
- u The patient will identify current stressors.
- u The patient will set limits and compromises on behavior when ready.
- u The patient will maintain autonomy and independence without handicapping fears and use of behavior.
- u The patient will develop effective coping behaviors.

Nursing interventions

- u Stay with the patient until the attack subsides. If left alone, he may become even more anxious.
- u Maintain a calm, serene approach. Avoid insincere expressions of reassurance.
- u The patient's perceptual field may be narrowed, and excessive stimuli may cause him to feel overwhelmed. Dim bright lights or raise dim lights as necessary. If the patient loses control, remove him to a smaller, quieter space.
- u Speak in short, simple sentences, and slowly give one direction at a time. Avoid giving lengthy explanations and asking too many questions.
- u Allow the patient to pace around the room (provided he isn't belligerent) to help expend energy.
- u Avoid touching the patient until you've established rapport. Unless he trusts you, he may be too stimulated or frightened to find touch reassuring.
- u Monitor therapeutic and adverse effects of medications.
- u Reduce external stimuli such as groups of people.
- u Provide a safe environment, and prevent harm to the patient or others.

Patient teaching

- u During and after a panic attack, encourage the patient to express his feelings and to cry, if necessary. Discuss his fears, and help him identify situations or events that trigger the attacks.
- u Teach the patient relaxation techniques such as deep-breathing exercises. Point out ways he can use these methods to relieve stress or short-circuit a panic attack.
- u Review with the patient any adverse effects of the drugs he'll be taking. Caution him to notify the doctor before discontinuing the medication because abrupt withdrawal could cause severe symptoms.

PHOBIAS

A phobia is a persistent and irrational fear of a specific object, activity, or situation resulting in an anxiety reaction. A phobia causes a compelling desire to avoid the perceived hazard. This avoidance usually results in an alteration of occupational or social functioning. The patient recognizes that his fear is out of proportion to any actual danger, but he can't control it or explain it away. Panic attacks can be triggered by the phobia.

Common phobias include claustrophobia (fear of enclosed spaces), fear of blood, and fear of flying. Social phobias are specific fears of certain situations and people, such as meeting strangers, using public rest rooms, or talking at a party.

Life-long phobias occur in 10% to 11% of the population; phobias lasting a year occur in 9% of the population. Onset is usually childhood to early adulthood, and there is a familial tendency.

Causes

A phobia develops when anxiety about an object or a situation compels the patient to avoid it. In each case, the patient is aware that the fear is excessive and unreasonable for the situation.

Complications

A phobia can dominate a patient's life, restricting normal activities and even confining the person to home. A patient with social phobia may lose a job promotion because of a fear of speaking in public; or the patient may be continually inconvenienced by fear of using a public lavatory. Patients with social phobias have a high rate of alcohol abuse and other psychiatric conditions (such as eating disorders). The management of each disorder is necessary to reduce anxiety.

Assessment findings

The phobic patient typically reports signs of severe anxiety when confronted with the feared object or situation, or even the threat of it. A patient who routinely avoids the object of his phobia may report a loss of self-esteem and feelings of weakness, cowardice, or ineffectiveness. If he hasn't mastered the phobia, he also may exhibit signs of mild depression.

Diagnostic criteria

Full criteria for a diagnosis is usually present in the adult patient. The history of the patient may reveal behavioral avoidance in infancy of unfamiliar people, situations, or objects. The diagnosis of all three types of phobias is based on fulfillment of the relevant criteria documented in the *DSM-IV*.

For agoraphobia without panic disorder:

The patient has a fear of being in places or situations from which escape might be difficult or embarrassing or in which help might not be available if he suddenly develops symptoms that could be incapacitating or extremely embarrassing. As a result of this fear, he either restricts travel or needs a companion when away from home, or he endures agoraphobic situations despite intense anxiety.

- u The patient has never met the criteria for panic disorder.

For a social phobia:

The patient has a persistent fear of one or more social situations in which he is exposed to possible scrutiny by others and fears that he may do something or act in a way that will be humiliating or embarrassing.

- u The fear isn't related to an Axis III disorder, if present.
- u During some phase of the disturbance, exposure to the specific phobic stimulus almost invariably provokes an immediate anxiety response.
- u The patient avoids the phobic situation or endures it with intense anxiety.
- u The patient's avoidant behavior interferes with occupational functioning or with usual social activities or relationships with others, or the patient experiences marked distress about having the fear.
- u The patient recognizes that his fear is excessive or unreasonable.
- u If the patient is under age 18, the disturbance doesn't meet the criteria for avoidant disorder of childhood or adolescence.

For a specific phobia:

The patient has a persistent fear of an object or a situation other than fear of having a panic attack or of humiliation or embarrassment in certain social situations.

- u During some phase of the disturbance, exposure to the specific phobic stimulus almost invariably provokes an immediate anxiety response.
- u The patient avoids the object or situation or endures it with intense anxiety.
- u The patient's fear or his avoidant behavior significantly interferes with his normal routine or his usual social activities or relationships with others, or the patient experiences marked distress about having the fear.
- u The patient recognizes that his fear is excessive or unreasonable.
- u The phobic stimulus is unrelated to the content of the obsessions of obsessive-compulsive disorder or the trauma of posttraumatic stress disorder.

Treatment

Beta blockers are useful in the treatment of "performance anxiety" but not social phobias because they can prevent the occurrence of perspiration, tachycardia, palpitations, and tremors. Monamine oxidase inhibitors alleviate social phobias independently of their antidepressant activity. Serotonin reuptake inhibitors are also effective. Benzodiazepines are helpful in reducing fearful avoidance but, because of the chronic nature of phobias, are limited.

Relapse rates are high when medication is used alone as treatment. Behaviorally focused psychotherapy is important in treatment. Cognitive-behavioral strategies, individual and group sessions, and desensitization therapy are particularly effective. Systematic desensitization, a behavioral therapy, may be more effective than drugs, especially if it includes encouragement, instruction, and suggestion. Such therapy should help the patient understand that his phobia is symbolic of a more fundamental anxiety and that he must deal with it directly.

In some cities, phobia clinics are available in which people who have recovered from phobias can often help other phobic patients.

Nursing diagnoses

u Anxiety u Fear u Impaired social interaction u Ineffective individual coping u Risk for loneliness u Self-esteem disturbance u Social isolation

Key outcomes

- u The patient will experience reduced anxiety by identifying internal precipitating situation.
- u The patient will identify current stressors.
- u The patient will set limits and compromises on behavior when ready.
- u The patient will maintain autonomy and independence without handicapping fears and use of phobic behavior.
- u The patient will develop effective coping behaviors.

Nursing interventions

- u Provide for the patient's safety and comfort, and monitor fluid and food intake as needed. Certain phobias may inhibit food or fluid intake, disturb hygiene, and disrupt the patient's ability to rest.
- u No matter how illogical the patient's phobia seems, avoid the urge to trivialize his fears. Remember that this behavior represents an essential coping mechanism. A facile pep talk or ridicule may alienate him or increase his loss of self-esteem.
- u Ask the patient how he normally copes with the fear. When he's able to face the fear, encourage him to verbalize and explore his personal strengths and resources with you.
- u Don't let the patient withdraw completely. If he's being treated as an outpatient, suggest small steps to overcome his fears such as planning a brief shopping trip with a supportive family member or friend.
- u In social phobias, the patient fears criticism. Encourage him to interact with others and provide continuous support and positive reinforcement.
- u Support participation in psychotherapy, including desensitization therapy. However, don't force insight. Challenging the patient may aggravate anxiety or lead to panic attacks.

Patient teaching

- u To increase self-esteem and reduce anxiety, explain to the patient that his phobia is a way of coping with anxiety, especially if he perceives his behavior as silly or unreasonable.
- u Teach the patient specific relaxation techniques, such as listening to music and meditating.
- u Suggest ways to channel the patient's energy and relieve stress, such as running and creative activities.
- u If the patient is taking an antidepressant or an anti-anxiety agent, stress the importance of compliance with the prescribed therapy. Teach him to recognize adverse reactions, and instruct him to report such reactions to the doctor.

POSTTRAUMATIC STRESS DISORDER

Patients may develop anxiety after exposure to extreme trauma (such as an actual or threatened death or injury to the patient or another person). If the reaction occurs shortly after the trauma, it's called acute stress disorder, and if the reaction is delayed or recurrent, it's called posttraumatic stress disorder (PTSD).

In PTSD the patient actively avoids stimuli that trigger memory of the event, resulting in increased vigilance, arousal, and startle response. PTSD affects 5% to 10% of Americans at some time in their lives; women are more likely to be affected than men.

CULTURAL TIP PTSD is common among Hmong cultural groups in the United States.

Causes and pathophysiology

Preexisting psychopathology can predispose the patient to this disorder. However, this disorder can develop in anyone, especially if the stressor is extreme. Individuals with a past psychiatric history and neurotic and extroverted characteristics are at increased risk. Genetics are also an influence, but environmental effects aren't.

It's theorized that PTSD impairs the alpha₂-adrenergic receptor response that inhibits a stress-induced release of norepinephrine. This results in a progressive behavioral sensitization to stimulus cues from the original trauma, with responses of increased sympathetic activity.

Complications

Impairment can be mild or severe, affecting nearly every aspect of life. Patients with stress disorders are at increased risk for developing other anxiety, mood, and substance-related disorders. There is frequent substance abuse, especially alcohol abuse.

Assessment findings

The patient experiences symptoms of detachment and loss of emotional response. Feelings of depersonalization and inability to recall specific aspects occur, although flashbacks within dreams or thoughts occur when cues to the event are present. The psychosocial history of a patient with posttraumatic stress disorder may reveal early life experiences, interpersonal factors, military experiences, or other incidents that suggest the precipitating event. Typically, the patient may report that his symptoms began immediately or soon after the trauma, although they may not develop until months or years later. In this case, avoidance symptoms usually have been present during the latency period.

Common symptoms include pangs of painful emotion and unwelcome thoughts; traumatic reexperience of the event; difficulty falling or staying asleep, frequent nightmares of the traumatic event, and aggressive outbursts on awakening; emotional numbing—diminished or constricted response; and chronic anxiety or panic attacks (with physical signs and symptoms).

The patient may display rage and survivor guilt, use of violence to solve problems, depression and suicidal thoughts, phobic avoidance of situations that arouse memories of the trauma (for example, hot weather and tall grasses for the Vietnam veteran), memory impairment, or difficulty concentrating. Feelings of detachment or estrangement may destroy interpersonal relationships. Some patients experience organic symptoms, fantasies of retaliation, and substance abuse.

Diagnostic criteria

The diagnosis of posttraumatic stress disorder is confirmed when the patient's signs and symptoms meet the following criteria documented in the *DSM-IV*:

- u The patient has experienced a traumatic event in which both of the following occurred:
 - actual or threatened death or serious injury or threat to the physical integrity of the patient or others
 - a response of intense fear, helplessness, or horror (or, in a child, a response of disorganization and agitation).
- u The patient persistently reexperiences this traumatic event in at least one of the following ways:
 - recurrent and intrusive distressing recollections of the event (or, in a child, repetitive play that expresses feelings about the event)
 - recurrent distressing dreams of the event (or, in a child, nightmares unrelated to the event)
 - suddenly acting or feeling as if the traumatic event were recurring, including a sense of reliving the experience, illusions, hallucinations, and dissociative episodes (flashbacks), even those that occur when awakening or intoxicated (or, in a child, reenactment of the traumatic event)
 - intense psychological distress at exposure to events that symbolize or resemble an aspect of the traumatic event
 - physiologic reactivity on exposure to events that symbolize or resemble an aspect of the traumatic event.
- u The patient must exhibit persistent avoidance of the stimuli associated with the trauma or numbing of general responsiveness not present before the trauma, as indicated by at least three of the following:

- efforts to avoid thoughts or feelings associated with the trauma
- efforts to avoid activities or situations that arouse recollections of the trauma
- inability to recall an important aspect of the event
- sharply decreased interest in significant activities
- feeling of detachment or estrangement from others
- restricted range of affect, for example, not being able to love others
- sense of foreshortened future, for example, not expecting to be able to have a career, spouse, family, or typical life span.
- u Persistent signs of increased arousal (not previously present) as indicated by two or more of the following:
 - difficulty falling or staying asleep
 - irritability or outbursts of anger
 - difficulty concentrating
 - hypervigilance
 - exaggerated startle response.
- u The disturbance must have lasted at least 1 month.
- u The disturbance must cause significant distress or impairment of social, occupational, or other important areas of functioning.

Treatment

Acute stress reactions are usually self-limiting and may be helped with short-term use of benzodiazepines and supportive/expressive psychotherapy. PTSD is chronic and recurrent and requires drug and behavior therapies. Tricyclic antidepressants, monoamine oxidase inhibitors, phenelzine, and serotonin reuptake inhibitors reduce anxiety, symptoms of intrusion, and avoidance behaviors. Trazodone, a sedating antidepressant, is helpful for insomnia. Symptoms in some patients in uncontrolled trials improved with carbamazepine, valproic acid, and alprazolam.

Psychotherapy is used to overcome avoidance behaviors and demoralization and to help the patient master fears that the trauma will recur. Stepwise focus seems to be most effective in dismantling avoidance behaviors.

Support groups are highly effective and are provided through many Veterans Administration centers and crisis clinics. These groups provide a forum in which victims of this disorder can work through their feelings with others who have had similar conflicts. Some group programs include spouses and families in their treatment processes. Rehabilitation programs in physical, social, and occupational areas also are available for victims of chronic PTSD.

Many patients also need treatment for alcohol or drug abuse.

Nursing diagnoses

u Altered role performance u Altered thought processes u Anxiety u Chronic low self-esteem u Fear u Impaired social interaction u Ineffective individual coping u Personal identity disturbance u Powerlessness u Risk for post-trauma syndrome u Sleep pattern disturbance

Key outcomes

- u The patient will state feelings and fears related to traumatic event.
- u The patient will use available support systems.
- u The patient will use effective coping mechanisms to reduce fear.
- u The patient will maintain or reestablish adaptive social interactions with family members.

Nursing interventions

- u Encourage the patient to express his grief, complete the mourning process, and gain coping skills to relieve anxiety and desensitize him to memories of the event.
- u Practice crisis intervention techniques as needed.
- u Establish trust by accepting the patient's current level of functioning and by assuming a positive, consistent, honest, and nonjudgmental attitude.
- u Deal constructively with the patient's displays of anger. Encourage joint assessment of angry outbursts (identify how anger escalates and explore preventive measures that family members can take to regain control). Provide a safe, staff-monitored room in which the patient can safely deal with urges to commit physical violence or self-abuse by displacement (such as pounding and throwing clay or destroying selected items). Encourage him to move from physical to verbal expressions of anger.
- u Help the patient relieve shame and guilt precipitated by real actions (such as killing and mutilation) that violated a consciously held moral code.
- u Help him put his behaviors into perspective, recognize his isolation and self-destructive behavior as forms of atonement, and accept forgiveness from himself and others.
- u Refer the patient to clergy as appropriate.
- u Provide for or refer the patient to group therapy with other victims for peer support and forgiveness.
- u Evaluate patient's response to drug regimen.

Patient teaching

- u Carefully review the healing process with the patient. Remind him that setbacks shouldn't be equated with treatment failure.
- u Help the patient regain control over angry impulses by identifying situations in which he lost control and by talking about past and precipitating events (conceptual labeling) to help with later problem-solving skills.
- u Teach relaxation and breathing techniques to help reduce anxiety.
- u Educate the patient about prescribed medications and adverse effects. Tell the patient not to discontinue medications without first consulting with the doctor because of possible adverse effects.
- u Refer the patient to appropriate community resources.

SOMATOFORM DISORDERS

The patient with a somatoform disorder complains of physical signs and symptoms and typically travels from doctor to doctor in search of treatment. Physical examinations and laboratory tests fail to uncover an organic basis for the patient's signs and symptoms; nor are the somatic symptoms due to the effects of alcohol or recreational or prescription drugs. They're prevalent in 5% of the primary practice and include a variety of conditions that differ in symptoms and whether they're intentionally produced. Somatoform disorders include conversion disorder, hypochondriasis, pain disorder, and somatization disorder.

CONVERSION DISORDER

Previously called hysterical neurosis, conversion type, a conversion disorder allows a patient to resolve a psychological conflict through the loss of a specific physical function, for example, by paralysis, blindness, or the inability to swallow. Unlike factitious disorders or malingering, the patient's loss of physical function is involuntary. However, laboratory tests and diagnostic procedures don't disclose an organic cause. (See [Factitious disorders](#).)

Conversion disorder can occur in either sex at any age. An uncommon disorder, it usually begins in adolescence or early adulthood. The conversion symptom itself isn't life-threatening and usually has a short duration.

Causes

The patient suddenly develops the conversion symptom soon after experiencing a traumatic conflict that he believes he can't handle. Two theories explain why this

occurs. According to the first, the patient achieves a “primary gap,” when the symptom keeps a psychological conflict out of conscious awareness. For example, a person may experience blindness after witnessing a violent crime.

The second theory suggests that the patient achieves secondary gain from the symptom by avoiding a traumatic activity. For example, a soldier may develop a “paralyzed” hand that prevents him from entering into combat.

Complications

Conversion disorder symptoms can severely impede normal activities. Prolonged loss of function may result in real and serious complications, such as contractures, disuse atrophy, and pressure ulcers; however, in most cases, such complications are curiously absent.

The conversion symptom may encourage the patient with a dependent personality to adopt the role of a chronic invalid. Unnecessary diagnostic or therapeutic medical procedures increase the risk of complications in such a patient.

Assessment findings

The history of a patient with conversion disorder may reveal the sudden onset of a single, debilitating sign or symptom that prevents normal function of the affected body part such as paralysis of a leg. The patient may describe a recent and severe psychologically stressful event that preceded the symptom. Oddly, the patient doesn't show the affect and concern that such a severe symptom usually elicits.

Assessment findings obtained during a physical examination are inconsistent with the primary symptom. For instance, tendon reflexes may be normal in a “paralyzed” part of the body, loss of function fails to follow anatomic patterns of innervation, or normal pupillary responses and evoked potentials are present in a patient who complains of blindness.

Factitious disorders
<p>Marked by the irrational, repetitious simulation of a physical or mental illness for the purpose of obtaining medical treatment, factitious disorders are severely psychopathologic conditions. The symptoms are intentionally produced and can be physical or psychological. These disorders are more common in men than in women.</p>
<p>Chronic factitious disorder with physical symptoms</p> <p>Also called Munchausen syndrome, this is the most common factitious disorder. The patient convincingly presents with intentionally feigned symptoms. These symptoms may be fabricated (acute abdominal pain with no underlying disease), self-inflicted (deliberately infecting an open wound), an exacerbation or exaggeration of a preexisting disorder (taking penicillin despite a known allergy), or a combination of all the above.</p> <p>The history of a patient with Munchausen syndrome may include:</p> <ul style="list-style-type: none">u multiple admissions to various hospitals, typically across a wide geographic areau extensive knowledge of medical terminologyu pathologic lyingu evidence of previous treatment such as surgeryu shifting complaints and signs and symptomsu eagerness to undergo hazardous and painful proceduresu discharge against medical advice to avoid detectionu poor interpersonal relationshipsu refusal of psychiatric examinationu psychoactive substance or analgesic use. <p>Munchausen syndrome by proxy is seen when one person such as a parent produces or causes a physical illness in another person such as a child. Such actions may include injecting toxic substances into the body, tampering with treatments (I.V. or ventilator settings), or even causing harm by biting or mutilating the other person.</p>
<p>Factitious disorder with psychological symptoms</p> <p>Causing severely impaired function, factitious disorder with psychological symptoms is characterized by intentional feigning of symptoms suggestive of a mental disorder. However, the symptoms represent how the patient views the mental disorder and seldom coincide with any of the diagnostic categories documented in the <i>DSM-IV</i>.</p> <p>This disorder almost always coexists with a severe personality disorder. Most patients have a history of psychoactive substance use, often in an attempt to elicit the desired symptoms.</p>

Diagnostic criteria

The diagnosis of conversion disorder is based on fulfillment of the following criteria from the *DSM-IV*:

- u The patient exhibits a loss of or alteration in voluntary motor or sensory function that suggests a physical disorder.
- u Psychological factors are judged to be associated with the symptom because of a temporal relationship between a psychosocial stressor that is apparently related to a psychological conflict or need and the onset or exacerbation of the symptom.
- u The patient isn't intentionally producing or feigning the symptom.
- u The symptom isn't a culturally sanctioned response pattern and can't, after appropriate investigation, be explained by a known physical disorder.
- u The symptom isn't limited to pain or a disturbance in sexual functioning.
- u The symptom causes clinically significant distress or impairment of social, occupational, or other important areas of functioning.

A thorough physical evaluation must rule out any physical cause, especially diseases with vague physical onsets (such as multiple sclerosis or systemic lupus erythematosus).

Treatment

Psychotherapy, family therapy, relaxation therapy, behavior therapy, or hypnosis may be used alone or in combination (two or more) to treat conversion disorder.

Nursing diagnoses

- u Activity intolerance
- u Anxiety
- u Fear
- u Impaired physical mobility
- u Impaired social interaction
- u Ineffective individual coping
- u Dressing and grooming self-care deficit
- u Sensory or perceptual alterations (visual, auditory, kinesthetic, gustatory, tactile, or olfactory)

Key outcomes

- u The patient will connect life events to occurrence of anxiety.
- u The patient will identify current stressors.
- u The patient will develop effective coping behaviors.
- u The patient will maintain autonomy and independence without handicapping fears and use of phobic behavior.
- u The patient will state a sense of satisfaction with each new level of activity attained.
- u The patient will demonstrate skill in conserving energy while carrying out daily activities to tolerance level.

Nursing interventions

- u Help the patient maintain integrity of the affected system. Regularly exercise paralyzed limbs to prevent muscle wasting and contractures.
- u Frequently change the bedridden patient's position to prevent pressure ulcers.
- u Ensure adequate nutrition even if the patient is complaining of GI distress.
- u Provide a supportive environment, and encourage the patient to discuss the stress that provoked the conversion disorder. Don't force the patient to talk, but convey a caring attitude to help him share his feelings.
- u Don't insist that the patient use the affected system. This will only anger him and prevent a therapeutic relationship.
- u Add your support to the recommendation for psychiatric care.
- u Include the patient's family in all care. They may be part of the patient's stress, and they're essential to support the patient and help him regain normal function.

Patient teaching

- u Teach the patient effective coping strategies, such as relaxation and deep-breathing techniques, to help him reduce stress and relieve anxiety.

HYPOCHONDRIASIS

The dominant feature of hypochondriasis (previously referred to as hypochondriacal neurosis) is an unrealistic misinterpretation of the severity and significance of physical signs or sensations as abnormal. This leads to preoccupation with fear of having a serious disease, which persists despite medical reassurance to the contrary. Hypochondriasis causes severe social and occupational impairment. It isn't due to other mental disorders, such as schizophrenia, mood disorder, or somatization disorder.

Hypochondriasis appears to be equally common in men and women. It can begin at any age, but onset most frequently occurs between ages 20 and 30. The course of the disease usually is chronic, although the severity of symptoms may vary.

Causes

Hypochondriasis isn't linked to any specific cause. However, this disorder frequently develops in people or the relatives of those who have experienced an organic disease. It allows the patient to assume a dependent sick role to ensure his needs are met. Such a patient is unaware of these unmet needs and doesn't consciously cause his symptoms. Stress increases the risk of developing hypochondriasis.

Complications

Hypochondriasis entails a danger of overlooking a serious, organic disease, given the patient's previously unfounded complaints. It also has the potential for significant complications or disabilities resulting from multiple evaluations, tests, and invasive procedures.

This disorder may severely impair social and occupational functioning. Possible psychiatric complications include anxiety, depression, and obsessive-compulsive disorder.

Assessment findings

The dominant feature of hypochondriasis is the misinterpretation of symptoms—usually multiple complaints that involve a single organ system—as signs of serious illness. As medical evaluation proceeds, complaints may shift and change. Symptoms can range from specific to general, vague complaints and often are associated with a preoccupation with normal body functions.

The hypochondriacal patient will relate a chronic history of waxing and waning symptoms. Commonly, he will have undergone multiple evaluations for similar symptoms or complaints of serious illness. His past contacts with health care professionals make him quite informed and knowledgeable about illness, diagnosis, and treatment.

Diagnostic criteria

A diagnosis of hypochondriasis is confirmed when the patient's symptoms meet the following criteria established in the *DSM-IV*:

- u The patient exhibits a preoccupation with the fear of having or the belief that he has a serious disease based on his interpretation of physical signs or sensations as evidence of physical illness.
- u Appropriate physical evaluation doesn't support the diagnosis of any physical disorder that can account for the physical signs or sensations or the patient's unwarranted interpretation of them, and the symptoms referred to above aren't just symptoms of panic attacks.
- u The fear of having or the belief that one has a disease persists despite medical reassurance.
- u Duration of the disturbance is at least 6 months.
- u The belief that one has a disease isn't of delusional intensity, as in delusional disorder, somatic type.

Treatment

The goal of treatment is to help the patient continue to lead a productive life despite distressing symptoms and fears. After medical evaluation is complete, the patient should be told clearly that he doesn't have a serious disease but that continued medical follow-up will help control his symptoms. Providing a diagnosis won't make hypochondriasis disappear, but it may ease the patient's anxiety.

Regular outpatient follow-up can help the patient deal with his symptoms and is necessary to detect organic illness. (Up to 30% of these patients develop an organic disease.) Because the patient can be demanding and irritating, consistent follow-up may be difficult.

Most patients don't acknowledge any psychological influence on their symptoms, and they resist psychiatric treatment.

Nursing diagnoses

- u Anxiety u Chronic pain u Impaired adjustment u Impaired social interaction u Ineffective individual coping u Self-esteem disturbance

Key outcomes

- u The patient will maintain current health status.

- u The patient and family members will verbalize feelings and concerns.
- u The patient will establish a firm, positive sense of self and personal identity.
- u The patient will carry out resocialization behavior and activities.
- u The patient will state importance of self-care behaviors or activities.

Nursing interventions

- u Provide a supportive relationship that lets the patient feel cared for and understood. The patient with hypochondriasis feels real pain and distress, so don't deny his symptoms or challenge his behavior.
- u Firmly state that medical test results were negative. Instead of reinforcing his symptoms, encourage him to discuss his other problems, and urge his family to do the same.
- u Recognize that the patient will never be symptom-free, and don't become angry when he won't give up his disease. Such anger can drive the patient away to yet another unnecessary medical evaluation.

Patient teaching

- u Help the patient and family find new ways to deal with stress other than development of physical symptoms. For example, teaching the patient more effective coping strategies can reduce his need to resort to hypochondriacal behavior.
- u If the patient is receiving a tranquilizer, both he and his family should know its dosage, expected effects, and possible adverse effects (for example, drowsiness, fatigue, blurred vision, and hypotension).
- u Warn the patient who's taking tranquilizers to avoid alcohol or other central nervous system depressants because they may potentiate tranquilizer action. Warn him to take the drug only as prescribed (larger or more frequent doses may lead to dependence), to avoid hazardous tasks until he has developed a tolerance to the tranquilizer's sedative effects, and to continue the tranquilizer as his doctor directs because abrupt withdrawal may be hazardous.

PAIN DISORDER

The striking feature of pain disorder is a persistent complaint of pain. The pain is the patient's major complaint, is sufficiently severe to warrant clinical attention, and significantly impairs social, occupational, or other important areas of functioning. Psychological factors play a significant role in the onset, severity, exacerbation, or maintenance of the pain. The patient doesn't intentionally produce or feign the pain. Women experience certain forms of pain such as chronic headaches more than men.

Causes

The pain may be related to psychological factors, medical conditions, or both. When the pain results from a general medical condition, it isn't considered a mental disorder (pain disorder) and is coded on Axis III—general medical conditions.

Complications

The most serious complications of pain disorder are iatrogenic; they include psychoactive substance dependence, multiple surgical interventions, and complications that are associated with extensive diagnostic evaluations.

Assessment findings

The cardinal feature of pain disorder is a history of chronic, consistent complaints of pain. The patient may relate a long history of evaluations and medical procedures at multiple settings without much noticeable pain relief. Because of frequent hospitalizations, the patient may be familiar with pain medications and tranquilizers. He may even ask for a specific medication and know the correct dosage and route of administration.

When a medical condition is a contributing factor to the pain, physical assessment findings are consistent with that medical condition. A psychosocial assessment may reveal that the patient is angry with health care professionals because they've failed to relieve his pain.

Diagnostic criteria

The diagnosis of pain disorder may be difficult to make because the perception of pain is subjective. The diagnosis is based on fulfillment of the following criteria documented in the *DSM-IV*:

- u The patient's chief complaint is pain in one or more anatomic sites, and the pain is sufficient to warrant clinical attention.
- u The pain causes clinically significant distress or impairment of social, occupational, or other important areas of functioning.
- u Psychological factors are judged to have an important role in the onset, severity, exacerbation, or maintenance of the pain.
- u The pain isn't intentionally produced or feigned.
- u The pain isn't accounted for by a mood, anxiety, or psychotic disorder and doesn't meet the criteria for dyspareunia.

Treatment

In pain disorder, treatment aims to ease the pain and help the patient live with it. Treatment at a comprehensive pain center may be helpful. Supportive measures for pain relief may include hot or cold packs, physical therapy, distraction techniques, and cutaneous stimulation with massage or transcutaneous electrical nerve stimulation. Measures to reduce the patient's anxiety also may help.

A continuing, supportive relationship with an understanding health care professional is essential for effective management; regularly scheduled follow-up appointments are helpful.

Analgesics become an issue because the patient believes that he has to “fight to be taken seriously.” The patient should clearly be told which medication he'll receive in addition to supportive pain-relief measures. Regularly scheduled analgesic doses can be more effective than scheduling medication as needed. Regular doses combat pain by reducing the patient's anxiety about asking for medication, and they eliminate unnecessary confrontations. The use of placebos will destroy trust when the patient discovers deceit.

Nursing diagnoses

u Altered health maintenance u Anxiety u Impaired social interaction u Ineffective family coping u Ineffective individual coping: Disabling u Pain u Personal identity disturbance

Key outcomes

- u The patient will maintain current health status.
- u The patient and family members will verbalize feelings and concerns.
- u The patient and family members will participate in a health maintenance program.
- u The patient will use available support systems to assist in coping with fear.
- u The patient will establish a firm, positive sense of self and personal identity.

Nursing interventions

- u Observe and record the characteristics of the patient's pain, including severity, duration, and any precipitating factors.
- u Provide a caring atmosphere in which the patient's complaints are taken seriously and every effort is made to provide relief. This means communicating to the patient that you'll collaborate with him on a treatment plan, clearly stating the limitations. For example, you might say, "I can stay with you now for 15 minutes, but you can't receive another dose of pain medication until 2 p.m."
- u Don't tell the patient that he's imagining the pain or can wait longer for medication that is due. Assess his complaints, and help him understand what is contributing to the pain. To elicit contributing perceptions and fears, you might say, "I've noticed you complain of more pain after your doctor visits. What are his visits like for you?"
- u Provide other, nonpharmacologic comfort measures, such as repositioning, back massage, or heat application, whenever possible.
- u Teach the patient coping strategies to help him deal with the pain. For example, you can teach him to perform progressive muscle relaxation or deep-breathing exercises.
- u Encourage the patient to maintain independence despite his pain.
- u Offer attention at times other than during the patient's complaints of pain, to weaken the link to secondary gain.
- u Consider psychiatric referrals; however, realize that the patient may resist psychiatric intervention, and don't expect psychiatric treatment to replace analgesic measures.

Patient teaching

- u Teach the patient noninvasive, drug-free methods of pain control, such as guided imagery, relaxation techniques, and distraction through reading or writing.

SOMATIZATION DISORDER

In somatization disorder, the patient has unintentional multiple physical complaints from different systems, which is persistent and has onset before age 30. The patient's complaints are often dramatic but inconsistent. Mood and anxiety are common and may be the result of drug interactions of various medication regimens. The typical patient with somatization disorder usually undergoes repeated medical examinations and diagnostic testing that—unlike the symptoms themselves—can be potentially dangerous or debilitating.

In conversion disorder, the patient focuses on defects of motor or sensory function. Psychological factors initiate the condition or seem to worsen it. The defect isn't intentionally produced or simulated.

In hypochondriasis, the patient believes he has a serious medical illness despite reassurance and appropriate medical evaluation. It can be disabling and persistent with waxing and waning symptoms.

In factitious illnesses, the patient consciously produces the physical symptoms of illness. Munchausen syndrome involves dramatic, chronic, or severe factitious illness. The sick role is qualifying in these illnesses; a variety of signs, symptoms, and diseases are simulated. Diagnosis is usually not made until 5 to 10 years after onset, producing significant social and medical costs. In malingering, there is a desire for an external reward, such as narcotic medication or disability reimbursement.

Causes

Both genetic and environmental factors may contribute to the development of somatization disorder. In somatization disorder and hypochondriasis, the patient has a history of poor relationships with doctors. This is because he believes he has been evaluated and treated inappropriately.

Complications

The patient constantly consults with doctors, both in and out of the hospital. As a result, unnecessary surgery may be performed, and an increased risk of substance abuse disorders that involve prescribed medications can also occur. Medication interactions due to taking prescriptions from multiple doctors can occur.

Assessment findings

Examination of a patient with somatization disorder is characterized by physical complaints presented in a dramatic, vague, or exaggerated way, often as part of a complicated medical history in which many physical diagnoses have been considered. An important clue to this disorder is a history of multiple medical evaluations at different institutions, with different doctors sometimes simultaneously—without significant findings. In addition, individuals with somatization disorder may be impulsive and demanding. The person frequently qualifies for a formal comorbid diagnosis.

In factitious illnesses, chronic diarrhea, fever of unknown origin, intestinal bleeding, hematuria, seizures, and hypoglycemia are common.

Common physical complaints include:

- u conversion or pseudoneurologic signs and symptoms (for example, paralysis or blindness)
- u GI discomfort (abdominal pain, nausea, or vomiting)
- u female reproductive difficulties (such as painful menstruation)
- u psychosexual problems (for example, sexual indifference)
- u chronic pain (for example, back pain)
- u cardiopulmonary symptoms (chest pain, dizziness, or palpitations).

The patient with somatization disorder typically relates his current complaints and previous evaluations in great detail. He may be quite knowledgeable about tests, procedures, and medical jargon. He doesn't discuss other aspects of his life without including his many signs and symptoms. In fact, any attempts to explore areas other than his medical history may cause him noticeable anxiety. He tends to disparage previous health care professionals and previous treatment, often with the comment, "No one seems to understand. Everyone thinks I'm imagining these things."

Ongoing assessment should focus on new signs or symptoms or any change in old ones to avoid missing a developing physical disease.

Diagnostic criteria

The diagnosis of somatization disorder is confirmed when the symptoms meet the following criteria that are documented in the *DSM-IV*:

- u The patient has a history of many physical complaints, beginning before age 30 and persisting for several years, that cause him to seek medical treatment or that impair important areas of functioning.
- u The patient will report all of the following at some time during the disturbance:
 - Two GI signs or symptoms: vomiting (other than during pregnancy), abdominal pain (other than during menstruation), nausea (other than motion sickness), bloating, diarrhea, or intolerance of different foods
 - Four pain symptoms: pain in extremities, back pain, joint pain, rectal pain, menstrual pain, pain during urination, pain during sexual intercourse, other pain (excluding headaches)
 - One conversion or pseudoneurologic sign or symptom: amnesia, difficulty swallowing, loss of voice, deafness, double vision, blurred vision, blindness, fainting or loss of consciousness, seizures, difficulty walking, paralysis or muscle weakness, urine retention or difficulty urinating
 - One sexual sign or symptom: burning sensation in sexual organs or rectum (other than during intercourse), sexual indifference, pain during intercourse, impotence, painful menstruation, irregular menstrual periods, excessive menstrual bleeding, vomiting throughout pregnancy

To identify a symptom as significant:

⌞ No organic abnormality or pathophysiologic mechanism exists to account for the patient's sign or symptom. Or, if a related organic abnormality is present, the complaint or resulting social or occupational impairment grossly exceeds what would be expected from the physical findings.

Diagnostic tests rule out physical disorders that cause vague and confusing somatic symptoms, such as hyperparathyroidism, porphyria, multiple sclerosis, and systemic lupus erythematosus. In addition, multiple physical signs and symptoms that become apparent for the first time late in the patient's life usually are the result of physical disease rather than somatization disorder.

Treatment

Behavior modification is most successful, especially if access to a doctor is tightly regulated so that repeated diagnostic testing and exploratory surgeries are limited. After diagnostic evaluation has ruled out organic causes, the patient should be told that although he has no serious illness, he will continue to receive care to ease his signs and symptoms.

Some patients may benefit from antidepressant treatment. Fluoxetine and monoamine oxidase inhibitors may help with patients' obsession with symptoms and preoccupation with multiple somatic complaints. The patient should have regularly scheduled appointments to review his signs and symptoms and the effectiveness of his coping strategies. The patient with somatization disorder seldom acknowledges any psychological aspect of his illness and rejects psychiatric treatment.

Nursing diagnoses

⌞ Altered health maintenance ⌞ Altered role performance ⌞ Altered thought processes ⌞ Anxiety ⌞ Body image disturbance ⌞ Fear ⌞ Impaired social interaction ⌞ Ineffective family coping: Disabling ⌞ Ineffective individual coping ⌞ Pain ⌞ Personal identity disturbance ⌞ Sexual dysfunction

Key outcomes

- ⌞ The patient will maintain current health status.
- ⌞ The patient and family members will verbalize feelings and concerns.
- ⌞ The patient and family members will participate in a health maintenance program.
- ⌞ The patient will use available support systems to assist in coping with fear.
- ⌞ The patient will establish a firm, positive sense of self and personal identity.

Nursing interventions

- ⌞ Acknowledge the patient's symptoms, and support his efforts to function and cope despite his distress. Be careful not to characterize his signs and symptoms as imaginary. Tell him the results and meanings of any tests he undergoes.
- ⌞ Emphasize the patient's strengths (for example, "It's good that you can still work, even though you're in pain. You can be pleased with that accomplishment"). Gently point out to him the time relationship between stress and physical symptoms.
- ⌞ Help the patient manage stress. Typically, his relationships are linked to his signs and symptoms; relieving them can have an impact on his interactions with others.
- ⌞ Negotiate a care plan with input from the patient and, if possible, his family. Encourage and help them to understand the patient's need for troublesome signs and symptoms,
- ⌞ If you develop an attitude that says, "These people don't really want to get better, so why should I waste my time?" acknowledge your feelings honestly. If appropriate, consult a psychiatric clinical nurse specialist to help you develop effective means of dealing with your feelings.

Patient teaching

- ⌞ Teach the patient coping strategies to help him deal with his discomfort. In particular, relaxation and deep-breathing techniques can do much to ease the patient's signs and symptoms by decreasing his anxiety and stress.

DISSOCIATIVE AND PERSONALITY DISORDERS

Dissociation refers to an unconscious defense mechanism that keeps troubling thoughts out of a person's awareness. The patient with a dissociative disorder experiences temporary changes in consciousness, identity, and motor function. The patient with a personality disorder suffers chronic, maladaptive behavior patterns. The disorders included in this section are depersonalization disorder, dissociative amnesia, dissociative fugue, dissociative identity disorder, and personality disorders.

DEPERSONALIZATION DISORDER

Persistent or recurrent episodes of detachment characterize depersonalization disorder. During these episodes, self-awareness is temporarily altered or lost; the patient often perceives this alteration in consciousness as a barrier between himself and the outside world. The sense of depersonalization may be restricted to a single body part such as a limb, or it may encompass the whole self.

Although the patient seldom loses touch with reality completely, the episodes of depersonalization may cause him severe distress.

Depersonalization disorder usually has a sudden onset in adolescence or early in adult life. It follows a chronic course, with periodic exacerbations and remissions, and resolves gradually.

Causes

Depersonalization disorder typically stems from severe stress, including war experiences, accidents, and natural disasters.

Complications

Hypochondriasis and psychoactive substance use may be associated with depersonalization disorder.

Assessment findings

The patient with depersonalization disorder may complain of feeling detached from his entire being and body, as if he were watching himself from a distance or living in a dream. He also may report sensory anesthesia, a loss of self-control, difficulty speaking, and feelings of derealization and losing touch with reality.

Common findings during the assessment interview include symptoms of depression, obsessive rumination, somatic concerns, anxiety, fear of going insane, a disturbed sense of time, a prolonged recall time, and physical complaints such as dizziness.

Diagnostic criteria

The depersonalization disorder diagnosis is confirmed by comparing the patient's symptoms with the following criteria established in the *DSM-IV*:

- u Persistent or recurrent experiences of depersonalization are indicated by a person's feeling detached from his mind or body (as if he were observing himself from the outside) or feeling like an automaton (as if he were in a dream).
- u During the depersonalization experience, reality testing remains intact.
- u The depersonalization is sufficiently severe and persistent to cause marked distress.
- u The depersonalization experience is the predominant disturbance and isn't a symptom of another disorder, such as schizophrenia, panic disorder, or agoraphobia.

Treatment

Psychotherapy aims to establish a trusting therapeutic relationship in which the patient can come to recognize the traumatic event and the anxiety it evoked. The therapist subsequently teaches the patient to use reality-based coping strategies rather than to detach himself from the situation.

Nursing diagnoses

- u Altered family processes
- u Altered role performance
- u Altered thought processes
- u Anxiety
- u Defensive coping
- u Fear
- u Impaired social interaction
- u Ineffective individual coping
- u Personal identity disturbance
- u Powerlessness
- u Risk for posttrauma syndrome

Key outcomes

- u The patient will state feelings and fears related to traumatic event.
- u The patient will express feelings of safety.
- u The patient will use available support systems.
- u The patient will use effective coping mechanisms to reduce fear.
- u The patient will maintain or reestablish adaptive social interactions with family members.

Types of amnesia

The *DSM-IV* recognizes five types of amnesia, based on the time period and the amount of information lost to recall:

- u *continuous amnesia*—failure to recall events subsequent to a specific time up to and including the present
- u *generalized amnesia*—failure to recall all events over the entire life span
- u *localized amnesia*—failure to recall all events that occurred during a circumscribed time period
- u *selective amnesia*—failure to recall some of the events that occurred during a circumscribed time period
- u *systematized amnesia*—failure to recall certain categories of information such as memories of one's family.

Nursing interventions

- u Assist the patient in using reality-based coping strategies under stress rather than strategies that distort reality.
- u Help the patient recognize and deal with anxiety-producing experiences.
- u Establish a therapeutic, nonjudgmental relationship.

Patient teaching

- u Teach the patient effective coping strategies to use in stressful situations rather than strategies that distort reality.

DISSOCIATIVE AMNESIA

The essential feature of dissociative amnesia is a sudden inability to recall important personal information that can't be explained by ordinary forgetfulness. The patient typically can't recall all events that occurred during a specific period, but other types of recall disturbance also are possible. (See [Types of amnesia.](#))

This disorder commonly occurs during war and natural disasters. Although it's more common in adolescents and young women, it also is seen in young men after combat experience. The amnesic event typically ends abruptly, and recovery is complete, with rare recurrences.

Causes

Dissociative amnesia follows severe psychosocial stress, often involving a threat of physical injury or death. Amnesia also may occur after thinking about or engaging in unacceptable behavior such as an extramarital affair.

Complications

Mild to severe social impairment may occur during the amnesic episode.

Assessment findings

During the assessment interview, the amnesic patient may appear perplexed and disoriented, wandering aimlessly. He won't be able to remember the event that precipitated the episode and probably won't recognize his inability to recall information.

After the episode has ended, the patient usually is unaware that he has suffered what is known as a recall disturbance.

Diagnostic criteria

A diagnosis of dissociative amnesia is confirmed when the patient's symptoms meet the following criteria established in the *DSM-IV*:

- u The main disturbance is an episode of sudden inability to recall important personal information that is too extensive to be explained by normal forgetfulness.
- u The disturbance isn't due to dissociative identity disorder or organic mental disorder.
- u The symptoms cause clinically significant distress or impairment of social, occupational, or other areas of functioning.

Treatment

Psychotherapy aims to help the patient recognize the traumatic event that triggered the amnesia and the anxiety it produced. A trusting therapeutic relationship is essential to achieving this goal. The therapist subsequently attempts to teach the patient reality-based coping strategies.

Nursing diagnoses

- u Altered family processes
- u Altered role performance
- u Altered thought processes
- u Anxiety
- u Defensive coping
- u Fear
- u Impaired social interaction
- u Ineffective

individual coping Personal identity disturbance Powerlessness Risk for posttrauma syndrome

Key outcomes

- The patient will state feelings and fears related to traumatic event.
- The patient will express feelings of safety.
- The patient will use available support systems.
- The patient will use effective coping mechanisms to reduce fear.
- The patient will maintain or reestablish adaptive social interactions with family members.

Nursing interventions

- Assist the patient in using reality-based coping strategies under stress rather than strategies that distort reality.
- Help the patient recognize and deal with anxiety-producing experiences.
- Establish a therapeutic, nonjudgmental relationship.

Patient teaching

- Teach the patient effective coping strategies to use in stressful situations rather than strategies that distort reality.

DISSOCIATIVE FUGUE

The patient suffering from dissociative fugue wanders or travels while mentally blocking out a traumatic event. During the fugue state, he usually assumes a different personality; later he can't recall what happened. The degree of impairment varies, depending on the duration of the fugue and the nature of the personality state it invokes. Dissociative fugue may be related to dissociative identity disorder, narcissistic personality disorder, and sleepwalking.

The age of onset varies. Although the fugue state usually is brief (hours to days), it can last for many months and carry the patient far from home. The prognosis for complete recovery is good, and recurrences are rare.

Causes

Dissociative fugue typically follows an extremely stressful event, such as combat experience, a natural disaster, a violent or abusive confrontation, or personal rejection. Heavy alcohol use may constitute a predisposing factor.

Complications

If the patient resorts to violence during the fugue state, he'll have to face the legal, social, and personal consequences of his behavior when he returns to his normal state of mind.

Assessment findings

Psychiatric examination of the patient with dissociative fugue may reveal that he has assumed a new, more uninhibited identity. If the new personality is still evolving, he may avoid social contact. On the other hand, he may have traveled to a distant location, set up a new residence, and developed a well-integrated network of social relationships that don't suggest any mental alteration.

The psychosocial history of such a patient may include episodes of violent behavior. After recovery, he typically can't remember these and other events that took place during the fugue state.

Diagnostic criteria

The diagnosis of dissociative fugue is confirmed if the patient's symptoms meet the following criteria documented in the *DSM-IV*:

- The predominant disturbance is sudden, unexpected travel away from home or the patient's customary place of work, with an inability to recall the past.
- The patient assumes a new partial or complete identity or is confused about his personal identity.
- The disturbance isn't due to dissociative identity disorder or an organic mental disorder.

Treatment

Psychotherapy aims to help the patient recognize the traumatic event that triggered the fugue state and to develop reality-based strategies for coping with anxiety. A trusting, therapeutic relationship is essential for successful therapy.

Nursing diagnoses

▫ Altered family processes Altered role performance Altered thought processes Anxiety Defensive coping Fear Impaired social interaction Ineffective individual coping Personal identity disturbance Risk for posttrauma syndrome Risk for violence: Self-directed or directed at others

Key outcomes

- The patient will state feelings and fears related to traumatic event.
- The patient will express feelings of safety.
- The patient will use available support systems.
- The patient will use effective coping mechanisms to reduce fear.
- The patient will maintain or reestablish adaptive social interactions with family members.

Nursing interventions

- Assist the patient in using reality-based coping strategies under stress rather than strategies that distort reality.
- Help the patient recognize and deal with anxiety-producing experiences.
- Establish a therapeutic, nonjudgmental relationship.

Patient teaching

- Teach the patient effective coping strategies to use in stressful situations rather than strategies that distort reality.

DISSOCIATIVE IDENTITY DISORDER

A complex disturbance of identity and memory, dissociative identity disorder is characterized by the existence of two or more distinct, fully integrated personalities in the same person. The personalities alternate in dominance. Each has unique memories, behavior patterns, and social relationships; rigid and flamboyant personalities

often are combined. Usually, one personality is unaware of the existence of the others.

Dissociative identity disorder usually begins in childhood, but patients seldom seek treatment until much later in life. The disorder is three to nine times more common in women than in men.

Causes

The cause of dissociative identity disorder isn't known. The patient typically has experienced abuse, often sexual, or another form of severe emotional trauma in childhood. Psychiatrists believe that a child exposed to such overwhelming stimuli may evolve multiple personalities to dissociate himself from the traumatic situation. The dissociated contents become linked with one of many possible shaping influences for personality organization.

Complications

Dissociative identity disorder may be complicated by severe social and occupational impairment, depending on the nature of the personalities and their interrelationships. Often, one or more of the personalities have a coexisting mental disorder, such as generalized anxiety disorder, borderline personality disorder, or mood disorder. Suicide attempts, self-mutilation, externally directed violence, and psychoactive drug dependence also may occur.

Assessment findings

The patient with dissociative identity disorder may seek medical treatment for a concurrent psychiatric disorder that is present in one of the personalities. She may have a history of unsuccessful psychiatric treatment, or she may report periods of amnesia and disturbances in time perception. Family members or friends may describe incidents that the patient can't recall, as well as pronounced alterations in facial presentation, voice, and behavior.

The transition from one personality to another often is triggered by stress or idiosyncratically meaningful social or environmental cues. Although usually sudden (seconds to minutes), the transition can occur over hours or days. Hypnosis and amobarbital may facilitate the transition.

Diagnostic criteria

The diagnosis of dissociative identity disorder is based on fulfilling the following criteria from the *DSM-IV*:

- u Two or more distinct personalities or personality states (each with its own relatively enduring pattern of perceiving, relating to, and thinking about the environment and self) exist within the person.
- u At least two of these personalities or personality states recurrently take control of the person's behavior.
- u The person has an inability to recall important personal information that is too extensive to be explained by ordinary forgetfulness.
- u The disturbance isn't due to the physiologic effects of a substance.

Treatment

Psychotherapy is essential to unite the personalities and prevent the personality from splitting again. The treatment's success is linked to the strength of the therapist's relationship with each of the personalities. All of the personalities, whether disagreeable or congenial, require equal respect and empathetic concern.

Nursing diagnoses

- u Altered family processes
- u Altered role performance
- u Altered thought processes
- u Body image disturbance
- u Fear
- u Impaired social interaction
- u Ineffective denial
- u Ineffective individual coping
- u Personal identity disturbance
- u Powerlessness
- u Risk for posttrauma syndrome
- u Risk for violence: Self-directed or directed at others
- u Sexual dysfunction

Key outcomes

- u The patient will state feelings and fears related to traumatic event.
- u The patient will express feelings of safety.
- u The patient will use available support systems.
- u The patient will use effective coping mechanisms to reduce fear.
- u The patient will maintain or reestablish adaptive social interactions with family members.

Nursing interventions

- u Establish an empathetic relationship with each emerging personality
- u Monitor the patient's actions for evidence of self-directed violence or violence directed at others.
- u Recognize even small gains.

Patient teaching

- u Teach the patient more effective defense mechanisms and coping skills, including use of available social support systems.
- u Stress the importance of continuing psychotherapy. Point out that the therapy may be prolonged, with alternating successes and failures, and that one or more of the personalities may resist treatment.

PERSONALITY DISORDERS

Defined as individual traits that reflect chronic, inflexible, and maladaptive patterns of behavior, personality disorders cause social discomfort and impair social and occupational functioning. These behaviors aren't due to a mental disorder, substance abuse, or a medical condition.

Although no statistics exist to quantify personality disorders, they are, nevertheless, widespread. Most patients with personality disorders don't receive treatment; when they do, they're typically managed as outpatients.

Personality disorders fall on Axis II of the *DSM-IV* classification system. Personality notations are appropriate and useful for all patients and help provide a fuller picture of the patient and a more accurate diagnosis. For example, many features that are characteristic of personality disorders are apparent during an episode of another mental disorder (such as a major depressive episode in a patient with compulsive personality features).

The prognosis is variable. Personality disorders typically have an onset before or during adolescence and early adulthood and persist throughout adult life.

Causes

Only recently have personality disorders been categorized in detail, and research continues to identify their causes.

Various theories attempt to explain the origin of personality disorders. Biological theories hold that these disorders may stem from chromosomal and neuronal abnormalities or head trauma. Social theories hold that the disorders reflect learned responses, having much to do with reinforcement, modeling, and aversive stimuli as contributing factors. Psychodynamic theories hold that personality disorders reflect deficiencies in ego and superego development and are related to poor

mother-child relationships that are fraught with unresponsiveness, overprotectiveness, or early separation.

Complications

The patient's maladaptive behavior often leads to social and occupational impairment. Personality disorders also increase the risk of developing mood disturbances, such as anxiety and depression, as well as psychoactive substance use disorders.

Assessment findings

Each specific personality disorder produces characteristic signs and symptoms, which may vary among patients and within the same patient at different times. In general, the history of the patient with a personality disorder will reveal long-standing difficulties in interpersonal relations, ranging from dependency to withdrawal, and in occupational functioning, with effects ranging from compulsive perfectionism to intentional sabotage.

The patient with a personality disorder may show any degree of self-confidence ranging from no self-esteem to arrogance. Convinced that his behavior is normal, he avoids responsibility for the consequences of his behavior, often resorting to projections and blame.

ASSESSMENT TIP Watch for personality changes; they may be the first sign of serious neurologic, endocrine, or medical illness. These causes should be ruled out before settling on the diagnosis of a personality disorder. For example, patients with frontal lobe tumors can present with changes in motivation and personality while results of a neurologic assessment are otherwise negative.

Diagnostic criteria

A patient with one personality disorder may meet the diagnostic criteria for another disorder. Pinpointing a diagnosis and developing an effective treatment plan is especially challenging for this reason. (For diagnostic traits in specific personality disorders, see [Diagnostic criteria for personality disorders.](#))

Treatment

Personality disorders are difficult to treat. Treatment depends on the patient's symptoms but requires a trusting relationship in which the therapist can use a direct approach.

Diagnostic criteria for personality disorders

The diagnosis of each recognized personality disorder is based on fulfillment of the following relevant diagnostic criteria defined in the *DSM-IV*.

General criteria

All types of personality disorders must meet the general diagnostic criteria for personality disorders. These disorders are characterized by an enduring pattern of behaviors and inner experiences that deviates significantly from the norms and expectations of the patient's culture. This pattern affects two or more of the following:

- u cognition (including ways of interpreting and perceiving self, people, and events)
- u affectivity (including the degree, range, lability, and appropriateness of emotional responses)
- u interpersonal functioning
- u impulse control.

This pattern of behaviors and inner experiences is inflexible, extends to a broad range of personal and social situations, and leads to clinically significant distress or impairment of social, occupational, or other important areas of functioning. It's stable and long lasting, with onset that is traceable to early adulthood or even adolescence. The pattern isn't more likely to result from another mental disorder or general medical condition and isn't a direct physiologic effect of a medication or other substance.

The personality disorders are grouped into three clusters that share similar attributes. Cluster A includes paranoid, schizoid, and schizotypal, all of which are odd, eccentric, and emotionally distant. Cluster B includes antisocial, borderline, histrionic, and narcissistic, whose behavior is impulsive, extremely emotional, and erratic. Cluster C incorporates avoidant, dependent, and obsessive-compulsive types; traits of patients in this group are anxious or fearful in nature.

CLUSTER A

Paranoid personality disorder

The patient must exhibit a pervasive and unwarranted tendency, beginning by early adulthood and present in a variety of contexts, to interpret the actions of people as deliberately demeaning or threatening, as indicated by at least four of the following:

- u expects, without sufficient basis, to be exploited or harmed by others
- u questions, without justification, the loyalty and trustworthiness of friends and associates
- u finds hostile or evil meanings in benign remarks or events
- u bears grudges or is unforgiving of insults or slights
- u won't confide in others because of unwarranted fear that the information will be used against him
- u is easily slighted and quick to react with anger or to counterattack
- u questions, without justification, the fidelity of spouse or sexual partner.

These symptoms must not occur exclusively during the course of schizophrenia or a delusional disorder.

Schizoid personality disorder

The patient must exhibit a pervasive pattern of indifference to social relationships and a restricted range of emotional experience and expression, beginning by early adulthood and present in a variety of contexts, as indicated by at least four of the following:

- u neither desires nor enjoys close relationships, including being part of a family
- u almost always chooses solitary activities
- u seldom, if ever, claims or appears to experience strong emotions, such as anger and joy
- u indicates little, if any, desire to have sexual experiences with another person
- u is indifferent to the praise and criticism of others
- u has no close friends or confidants other than first-degree relatives
- u displays constricted affect, coldness, or detachment.

These symptoms must not occur exclusively during the course of schizophrenia or a delusional disorder.

Schizotypal personality disorder

These symptoms must not occur exclusively during the course of schizophrenia or a delusional disorder.

Schizotypal personality disorder

The patient must exhibit a pervasive pattern of deficits in interpersonal relatedness and peculiarities of ideation, appearance, and behavior, beginning by early adulthood and present in a variety of contexts, as indicated by at least five of the following:

- u ideas of reference (excluding delusions of reference)
- u excessive social anxiety
- u odd beliefs or magical thinking, influencing behavior and inconsistent with subcultural norms
- u unusual perceptual experiences
- u odd or eccentric behavior or appearance
- u absence of close friends or confidants (or only one) other than first-degree relatives
- u odd speech and thinking
- u inappropriate or constricted affect
- u suspiciousness or paranoid ideation.

These symptoms must not occur exclusively during the course of schizophrenia or a pervasive developmental disorder.

CLUSTER B

Antisocial personality disorder

The patient must be at least 18 years old and must have displayed a pervasive pattern of disregard for and violation of the rights of others since age 15, as indicated by a history of three or more of the following:

- u failure to conform to social norms with respect to lawful behaviors, as shown by repeatedly performing acts that are grounds for arrest
- u deceitfulness, as shown by repeatedly lying, using aliases, or conning others for personal profit or pleasure
- u impulsivity or failure to plan ahead
- u irritability and aggressiveness, as indicated by repeated physical fights or assaults
- u reckless disregard for own safety or the safety of others
- u consistent irresponsibility, as demonstrated by repeated failure to sustain consistent work or honor financial obligations to others
- u lack of remorse, as demonstrated by indifference to or rationalization of hurting, mistreating, or stealing from another.

None of these symptoms of antisocial behavior should have occurred exclusively during the course of schizophrenia or manic episodes.

The patient must also display some signs of conduct disorder before age 15. The patient with conduct disorder consistently behaves in ways that violate the basic rights of others or major age-appropriate societal norms or rules. Signs and symptoms of conduct disorder include the following:

- u aggression toward people and animals
 - bullies, threatens, or intimidates others
 - frequently initiates physical fights
 - has used a weapon that can seriously harm others
 - has been physically cruel to people or animals
 - has stolen while confronting a victim (for example, mugging, purse snatching, extortion)
 - has forced someone into sexual activity
- u property destruction
 - has deliberately set fires with the intention of causing serious property damage
 - has deliberately destroyed others' property in different ways such as vandalism
- u theft or deceitfulness
 - has broken into a house, building, or car
 - frequently lies to obtain goods or favors or to avoid obligations (conning behavior)
 - has stolen items of value without confronting a victim (for instance, by shoplifting or forgery)
- u serious rule violations
 - frequently stays out at night despite parental prohibitions, beginning before age 13
 - has run away from home at least twice while living in parental or parental surrogate home (or once with returning for a lengthy period)
 - is often truant from school, beginning before age 13.

Patients with conduct disorder also display clinically significant impairment of social, academic, or occupational functioning because of behavior disturbances.

Borderline personality disorder

The patient must exhibit a pervasive pattern of instability of mood, interpersonal relationships, and self-image, beginning by early adulthood and present in a variety of contexts, as indicated by at least five of the following:

- u pattern of unstable and intense interpersonal relationships characterized by alternating between extremes overidealization and devaluation
- u impulsiveness in at least two areas that are potentially self-damaging, such as spending, sex, substance abuse, shoplifting, reckless driving, and binge eating (excluding suicidal or self-mutilating behavior)
- u affective instability—marked shifts from baseline mood to depression, irritability, or anxiety, lasting usually a few hours and seldom more than a few days
- u inappropriate, intense anger or lack of control of anger
- u recurrent suicidal threats, gestures, or behavior, or self-mutilating behavior
- u persistent identity disturbance manifested by uncertainty about at least two of the following: self-image, sexual orientation, long-term goals or career choice, type of friends desired, and preferred values
- u chronic feelings of emptiness or boredom
- u frantic efforts to avoid real or imagined abandonment.

Histrionic personality disorder

The patient must exhibit a pervasive pattern of excessive emotionality and attention-seeking, beginning by early adulthood and present in a variety of contexts, as indicated by at least five of the following:

- u constantly seeks or demands reassurance, approval, or praise
- u is inappropriately sexually seductive in appearance or behavior
- u consistently uses physical appearance to draw attention to self
- u expresses emotion with inappropriate exaggeration
- u is uncomfortable not being the center of attention
- u displays rapidly shifting and shallow expression of emotions
- u is easily influenced by others
- u has a style of speech that is excessively impressionistic and lacking in detail
- u considers relationships to be more intimate than they actually are.

Narcissistic personality disorder

The patient must exhibit a pervasive pattern of grandiosity, lack of empathy, and hypersensitivity to the evaluation of others, beginning by early adulthood and present in a variety of contexts, as indicated by at least five of the following:

Narcissistic personality disorder

The patient must exhibit a pervasive pattern of grandiosity, lack of empathy, and hypersensitivity to the evaluation of others, beginning by early adulthood and present in a variety of contexts, as indicated by at least five of the following:

- displays arrogant, haughty behaviors or attitudes
- is interpersonally exploitative—takes advantage of others to achieve his own ends
- has a grandiose sense of self-importance
- believes that his problems are unique and can be understood only by other special people
- is preoccupied with fantasies of unlimited success, power, brilliance, beauty or ideal love
- has a sense of entitlement—unreasonable expectation of especially favorable treatment
- requires constant attention and admiration
- lacks empathy—is unable to recognize and experience how others feel
- is preoccupied with feelings of envy.

CLUSTER C

Avoidant personality disorder

The patient must display a pervasive pattern of social discomfort, fear of negative evaluation, and timidity, beginning by early adulthood and present in a variety of contexts, as indicated by at least four of the following:

- avoids occupational activities that involve significant interpersonal contact because of fears of criticism, disapproval, or rejection
- is unwilling to become involved with people unless certain of being liked
- shows restraint in intimate relationships because of the fear of being shamed or ridiculed
- is preoccupied with being criticized or rejected in social situations
- is inhibited in new interpersonal situations because of feelings of inadequacy
- views self as socially inept, personally unappealing, or inferior to others
- is unusually reluctant to take personal risks or engage in new activities because they may prove embarrassing.

Dependent personality disorder

The patient must demonstrate a pervasive pattern of dependent and submissive behavior, beginning by early adulthood and present in a variety of contexts, as indicated by at least five of the following:

- is unable to make everyday decisions without an excessive amount of advice or reassurance from others
- allows others to make most of his important decisions
- agree with people even when he believes that they're wrong because of fear of being rejected
- has difficulty initiating projects or doing things on his own
- volunteers to do things that are unpleasant or demeaning to get other people to like him
- feels uncomfortable or helpless when alone or goes to great lengths to avoid being alone
- feels devastated and helpless when close relationships end
- is frequently preoccupied with fears of being abandoned
- is easily hurt by criticism or disapproval.

Obsessive-compulsive personality disorder

The patient must display a pervasive pattern of perfectionism and inflexibility, beginning by early adulthood and present in a variety of contexts, as indicated by at least five of the following:

- perfectionism that interferes with task completion
- preoccupation with details, rules, lists, order, organization, or schedules until the major point of the activity is lost
- unreasonable insistence that others submit to exactly his way of doing things or unreasonable reluctance to allow others to do things because of the conviction that they won't do them correctly
- excessive devotion to work and productivity to the exclusion of leisure activities and friendships (not accounted for by obvious economic need)
- overconscientiousness, scrupulousness, and inflexibility about matters of morality, ethics, or values (not accounted for by cultural or religious identification)
- lack of generosity in giving time, money, or gifts when no personal gain is likely
- inability to discard worn-out or worthless objects even when they have no sentimental value.

Passive-aggressive personality disorder

The patient must display a pervasive pattern of negative attitudes and passive resistance to demands for adequate social and occupational performance, beginning by early adulthood and present in a variety of contexts, as indicated by at least four of the following:

- passively resists accomplishing and fulfilling routine occupational and social tasks
- complains of being unappreciated and misunderstood by others
- is argumentative and sullen
- expresses resentment and envy of those who are apparently more fortunate
- voices persistent and exaggerated complaints of personal misfortune
- alternates between contrition and hostile defiance.

These signs and symptoms don't occur exclusively during a major depressive episode and aren't better accounted for by dysthymic disorder.

Traditionally, long-term psychotherapy was used to treat patients with personality disorders. Because of the biological implications, clusters may be treated with drugs to relieve specific symptoms. Patients with cluster A personality disorders benefit from antidepressants and low-dose antipsychotic medications. Anticonvulsant mood-stabilizing agents and mono-amine oxidase inhibitors may be used on cluster B patients who show marked mood reactivity, behavioral drug control, or rejection hypersensitivity. Cluster C patients may be treated with antianxiety agents or drugs used to treat Axis I anxiety disorders. Positive effects may be subtle at first, and it may take time for the patient to see beneficial effects.

Nursing diagnoses

- Altered role performance
- Anxiety
- Chronic low self-esteem
- Fear
- Impaired adjustment
- Impaired social interaction
- Ineffective individual coping
- Powerlessness
- Social isolation

Key outcomes

- The patient will identify effective and ineffective coping techniques.
- The patient will voice feelings related to self-esteem.
- The patient will join gradually in self-care and the decision-making process.
- The patient will verbally express comfort with surroundings.
- The patient will indicate that social relationships have improved and negative feelings have diminished.

Nursing interventions

- u Know your own feelings and reactions as the basis for assessing the patient's overt responses.
- u Offer patient, persistent, consistent, and flexible care. Take a direct, involved approach to ensure the patient's trust. Keep in mind that many of these patients don't respond well to interviewing, whereas others are charming and convincing.
- u Teach the patient social skills, and reinforce appropriate behavior.
- u Encourage expression of feelings, self-analysis of behavior, and accountability for actions.
- u Recognize the client's need for physical and emotional distance.
- u Avoid defensiveness and arguing.

Specific care measures vary with the particular personality disorder.

For paranoid personality disorder:

- u Avoid situations that threaten the patient's autonomy.
- u Approach the patient in a straightforward and candid manner, adopting a professional, rather than a casual or friendly, attitude. Remember that remarks intended to be humorous are easily misinterpreted by the paranoid patient.
- u Provide a supportive and nonjudgmental environment in which the patient can safely explore and verbalize his feelings.

For schizoid personality disorder:

- u Remember that the schizoid patient needs close human contact but is easily overwhelmed.
- u Respect his need for privacy, and slowly build a trusting therapeutic relationship so that he finds more pleasure than fear in relating to you.
- u Give the patient plenty of time to express his feelings. Keep in mind that if you push him to do so before he's ready, he may retreat.

For schizotypal personality disorder:

- u Recognize that this type of patient is easily overwhelmed by stress. Allow him plenty of time to make difficult decisions.
- u Be aware that the patient may relate unusually well to certain staff members and not at all to others.

For antisocial personality disorder:

- u Be clear about your expectations and the consequences of failing to meet them.
- u Anticipate manipulative efforts.
- u Plan for staff consistencies in approaching the patient.
- u Use a straightforward, matter-of-fact approach to set limits on unacceptable behavior. Encourage and reinforce positive behavior.
- u Expect the patient to refuse to cooperate so that he can gain control.

For borderline personality disorder:

- u Encourage the patient to take responsibility for himself. Don't attempt to rescue him from the consequences of his actions.
- u Don't try to solve problems that the patient can solve himself.
- u Maintain a consistent approach in all interactions with the patient; ensure that other team members use the same approach.
- u Recognize that the patient may idolize some staff members and devalue others.
- u Don't take sides in the patient's disputes with other staff members.
- u Avoid sympathetic, nurturing responses.

For histrionic personality disorder:

- u Recognize that this patient usually functions well as long as he receives attention, flattery, and admiration. As a result, he may never receive appropriate treatment.
- u Give the patient choices in care strategies, and incorporate his wishes into the treatment plan as much as possible. By increasing his sense of self-control, you'll reduce anxiety.
- u Approach the patient formally. He may be uncomfortable with a casual approach.

For narcissistic personality disorder:

- u Recognize the patient's sense of entitlement and matter-of-factly inform him of the unreasonableness of certain expectations. A critical attitude may cause him to become even more demanding and difficult.
- u Focus on positive traits or on his feelings of pain, loss, or rejection.

For avoidant personality disorder:

- u Assess for signs of depression. Social impairment increases the risk of affective disorders in these patients.
- u Establish a trusting interpersonal relationship with the patient. Be aware that he may become dependent on the few staff members whom he believes he can trust.
- u Be sure that all upcoming procedures are known to the patient in plenty of time for him to adjust. This patient is unable to handle surprises well.
- u Inform the patient when you will and won't be available if he needs assistance.

For dependent personality disorder:

- u Initially, give the patient explicit directives rather than ask him to make decisions. Then encourage him to make easy decisions, such as what to wear or which television program to watch. Continue to provide support and reassurance as his decision-making ability improves.
- u Avoid actions that foster dependency.

For obsessive-compulsive personality disorder:

- u Allow the patient to control his own treatment plan by offering choices whenever possible.
- u Adopt a professional approach in your interactions with the patient. Avoid informality; this patient wants strict attention to detail.

For passive-aggressive personality disorder:

- u Avoid power struggles with the patient.
- u Provide the patient with as much opportunity to control his treatment as possible. Offer options and allow the patient to choose, even if he chooses all of them. Verify his approval before initiating specific treatment.

Patient teaching

- u When providing care for any patient with a personality disorder, assess the patient's coping skills. As necessary, teach him more effective strategies to alleviate

stress and reduce anxiety.

SEXUAL DISORDERS

The disorders in this section affect a person's sexual ability or response, gender identity, or sexual behavior.

DYSPAREUNIA

The term *dyspareunia* refers to pain associated with intercourse. It may be mild or severe enough to restrict the enjoyment of intercourse. Dyspareunia may be associated with physical disorders or, less commonly, with psychologically based sexual dysfunctions.

Occurring almost exclusively in women, this disorder typically occurs in the late 20s and early 30s, a few years after the establishment of a sustained sexual relationship. The prognosis is good if the underlying disorder can be treated successfully.

Causes

Physical causes of dyspareunia include an intact hymen; deformities or lesions of the introitus or vagina; retroversion of the uterus; genital, rectal, or pelvic scar tissue; acute or chronic infections of the genitourinary tract; and disorders of the surrounding viscera (including residual effects of pelvic inflammatory disease or disease of the adnexal and broad ligaments).

Among the many other possible physical causes are:

- u endometriosis
- u benign and malignant growths and tumors
- u insufficient lubrication, often due to use of drugs, such as antihistamines, decongestants, and nonsteroidal anti-inflammatory drugs, or to estrogen loss associated with menopause
- u radiation to the genital area
- u allergic reactions to diaphragms, condoms, or other contraceptives.

Acute onset of dyspareunia is a classic sign of pelvic inflammatory disease caused by *Neisseria gonorrhoeae* or *Chlamydia trachomatis*.

Psychological causes include fear of pain or injury during intercourse, recollection of a previous painful experience, guilty feelings about sex, fear of pregnancy or of injury to the fetus during pregnancy, anxiety caused by a new sexual partner or technique, and mental or physical fatigue.

Complications

Dyspareunia can impair marital or other sexual relationships.

Assessment findings

The patient with dyspareunia usually complains of discomfort ranging from mild aches to severe pain before, during, or after intercourse. Vaginal itching or burning also may be present.

Diagnostic criteria

The diagnosis of dyspareunia is confirmed when symptoms meet the following criteria established in the *DSM-IV*:

- u Genital pain is recurrent or persistent before, during, or after sexual intercourse.
- u The disturbance isn't exclusively caused by tack of lubrication or vaginismus.
- u The disturbance causes marked distress or interpersonal difficulty.

Physical examination and laboratory tests help determine the underlying disorder.

Treatment

The treatment of physical causes of dyspareunia may include creams and water-soluble jellies for inadequate lubrication, appropriate medications for infections, excision of hymenal scars, and gentle stretching of painful scars at the vaginal opening with a medium-sized Graves speculum. The patient may be advised to change her coital position to reduce pain on deep penetration.

Methods for treating psychologically based dyspareunia vary. Psychotherapy may uncover hidden conflicts that are creating fears concerning intercourse. Sensate focus exercises de-emphasize intercourse itself and teach appropriate foreplay techniques. Information about appropriate methods of contraception can reduce fear of pregnancy; education concerning sexual activity during pregnancy can relieve fears of harming the fetus.

Nursing diagnoses

- u Altered family processes
- u Altered sexuality patterns
- u Anxiety
- u Body image disturbance
- u Self-esteem disturbance
- u Sexual dysfunction

Key outcomes

- u The patient will acknowledge a problem in sexual function.
- u The patient will voluntarily discuss the problem.
- u The patient and partner will discuss their feelings and perceptions about changes in sexual performance.
- u The patient will agree to obtain sexual evaluation and therapy if needed.
- u The patient will develop and maintain a positive attitude toward sexuality and sexual performance.

Nursing interventions

- u Communicate an open, nonjudgmental attitude in caring for a patient with dyspareunia.
- u Listen empathetically to the patient's complaints of sex-related pain, and encourage her to express her feelings freely.
- u As needed, refer the patient to a doctor, nurse, psychologist, social worker, or counselor trained in sex therapy.

Patient teaching

- u Provide instruction concerning anatomy and physiology of the reproductive system, contraception, and the human sexual response cycle.
- u When appropriate, give advice and information on drugs that may affect the patient's sexual response and on lubricating jellies and creams.
- u As a helpful guideline, inform the patient that a therapist's certification by the American Association of Sex Educators, Counselors, and Therapists or by the American Society for Sex Therapy and Research usually assures quality treatment. If the therapist isn't certified by one of these organizations, advise the patient to

inquire about the therapist's training in sex counseling and therapy.

FEMALE AROUSAL AND ORGASMIC DISORDER

Arousal disorder (an inability to experience sexual pleasure) is one of the severest forms of female sexual dysfunction. Orgasmic disorder, the most common type of female sexual dysfunction, is an inability to achieve orgasm. Unlike the woman with arousal disorder, the woman with orgasmic disorder may desire sexual activity and become aroused but feels inhibited as she approaches orgasm.

Arousal and orgasmic disorder are considered primary if they exist in a woman who has never experienced sexual arousal or orgasm; they're considered secondary when some physical, mental, or environmental condition inhibits or obliterates previously normal sexual functioning.

The prognosis is good for temporary or mild dysfunction that results from misinformation or situational stress but guarded for dysfunction that results from intense anxiety, chronically discordant relationships, psychological disturbances, or drug or alcohol abuse in either partner.

Causes

One or more of the following factors may cause arousal or orgasmic disorder:

- u drug use—central nervous system depressants, antidepressants, alcohol, illegal drugs and, rarely, oral contraceptives
- u disease—general systemic illness, diseases of the endocrine or nervous system, and diseases that impair muscle tone or contractility
- u gynecologic factors—chronic vaginal or pelvic infection or pain (from endometriosis), congenital anomalies, and genital cancers
- u stress and fatigue
- u inadequate or ineffective stimulation
- u psychological factors—performance anxiety, guilt, depression, unconscious conflicts about sexuality, or fear of losing control of feelings or behavior
- u discordant relationships—poor communication, hostility or ambivalence toward the partner, fear of abandonment or of asserting independence, or boredom with sex.

The likelihood of sexual dysfunction and the type of dysfunction depend on how well the woman copes with the pressures imposed by these factors.

Complications

Sexual dysfunction may impair marital or other sexual relationships.

Assessment findings

The woman with arousal disorder usually reports limited or absent sexual desire and experiences little or no pleasure from sexual stimulation. The patient's history may include:

- u a high level of family stress or fatigue, as occurs in many working mothers with children under age 5 who are too exhausted to care about sex
- u misinformation about sex and sexuality
- u a pattern of dysfunctional sexual response
- u conceptual problems in childhood and adolescence about sex in general and, specifically, about masturbation, incest, rape, sexual fantasies, and homosexual or heterosexual practices
- u concerns about contraception and reproductive ability
- u interpersonal problems in the current sexual relationship, including the partner's attitude toward sex
- u poor self-esteem and body image.

Physical signs of arousal disorder include a lack of vaginal lubrication and the absence of signs of genital vasocongestion.

The woman with orgasmic disorder may report an inability to achieve orgasm, either totally or under certain circumstances. Many women experience orgasm through masturbation or other means but not through intercourse alone. Others achieve orgasm with some partners but not with others.

Diagnostic criteria

The diagnosis of sexual dysfunction is based on fulfillment of the criteria established in the *DSM-IV*.

For female arousal disorder:

- u Persistent or recurrent, partial or complete failure to attain or maintain the lubrication-swelling response of sexual excitement until completion of sexual activity
- u Marked distress or interpersonal difficulty as a result of the disturbance.

In addition, the disorder doesn't occur exclusively during the course of another Axis I disorder such as major depression.

For female orgasmic disorder:

- u Persistent or recurrent delay in or absence of orgasm after a normal sexual excitement phase during sexual activity that the clinician judges to be adequate in focus, intensity, and duration. Some women can experience orgasm during noncoital clitoral stimulation but can't experience it during coitus in the absence of manual clitoral stimulation. In most of these women, this represents a normal variation of the female sexual response and doesn't justify the diagnosis. In some, however, this represents a psychological inhibition that does justify the diagnosis. This difficult judgment is assisted by a thorough sexual evaluation, which may require a trial of treatment.
- u Marked distress or interpersonal difficulty as a result of the disturbance.

In addition, the disorder doesn't occur exclusively during the course of another Axis I disorder such as major depression.

A thorough physical examination, laboratory tests, and the medical history rule out physical causes of arousal or orgasmic disorder.

Treatment

Arousal disorder is difficult to treat, especially when the woman has never experienced sexual pleasure. Therapy is designed to help the patient relax, become aware of her feelings about sex, and eliminate guilt and fear of rejection.

Specific measures usually include sensate focus exercises similar to those developed by Masters and Johnson, which emphasize touching and awareness of sensual feelings over the entire body—not just genital sensations—and minimize the importance of intercourse and orgasm.

Psychoanalytic treatment consists of free association, dream analysis, and discussion of life patterns to achieve greater sexual awareness. One behavioral approach attempts to correct maladaptive patterns through systematic desensitization to situations that provoke anxiety, partially by encouraging the patient to fantasize about these situations.

The goal in treating orgasmic disorder is to decrease or eliminate involuntary inhibition of the orgasmic reflex. Treatment may include experiential therapy,

psychoanalysis, and behavior modification.

Treatment of primary orgasmic disorder may involve teaching the patient self-stimulation. Also, the therapist may teach distraction techniques, such as focusing attention on fantasies, breathing patterns, or muscle contractions to relieve anxiety. Thus, the patient learns new behavior through exercises she does in the privacy of her home between sessions. The therapist gradually involves the patient's sexual partner in the treatment sessions, although some therapists treat the couple as a unit from the outset.

Treatment of secondary orgasmic disorder aims to decrease anxiety and promote the factors necessary for the patient to experience orgasm. The therapist should communicate an accepting and permissive attitude and help the patient understand that satisfactory sexual experiences don't always require coital orgasm.

Nursing diagnoses

- u Altered family processes
- u Altered sexuality patterns
- u Anxiety
- u Body image disturbance
- u Self-esteem disturbance
- u Sexual dysfunction

Key outcomes

- u The patient will acknowledge a problem in sexual function.
- u The patient will voluntarily discuss the problem.
- u The patient and partner will discuss their feelings and perceptions about changes in sexual performance.
- u The patient will agree to obtain sexual evaluation and therapy if needed.
- u The patient will develop and maintain a positive attitude toward her sexuality and sexual performance.

Nursing interventions

- u Communicate an open, nonjudgmental attitude when caring for a patient with a sexual dysfunction.
- u Listen empathetically to the patient's problems empathetically.
- u Refer the patient to doctors, nurses, psychologists, social workers, or counselors trained in sex therapy.

Patient teaching

- u Provide accurate information regarding sexual anatomy and physiology and sexual response patterns.
- u As a helpful guideline, inform the patient that the therapist's certification by the American Association of Sex Educators, Counselors, and Therapists or by the American Society for Sex Therapy and Research usually ensures quality treatment. If the therapist isn't certified by one of these organizations, advise the patient to inquire about the therapist's training in sex counseling and therapy.

GENDER IDENTITY DISORDERS

Sexual disorders that involve gender identity produce persistent feelings of gender discomfort and dissatisfaction. Defined as the intimate personal feeling one has about being male or female, gender identity includes three components: self-concept, perception of an ideal partner, and external presentation of masculinity and femininity through behavior, dress, and mannerisms.

Patients with these disorders typically behave and present themselves as people of the opposite sex, which they intensely desire to become. The disorder affects more men than women and usually begins in childhood. Rare in both children and adults, gender identity disorders shouldn't be confused with the far more common phenomenon of feeling inadequate in fulfilling the expectations normally associated with a particular sex.

Causes

Current theories about the causes of gender identity disorders suggest a combination of predisposing factors: chromosomal anomaly, hormonal imbalance (particularly in utero during brain formation), and pathologic defects in early parent-child bonding and child-rearing practices. For example, parents who deliberately treat their child as a member of the opposite sex significantly contribute to gender identity disorder.

Complications

Many children, particularly boys, are rejected by their peer group; this social conflict may be reflected in poor academic performance. Girls may not experience social difficulties until early adolescence.

Transsexualism may seriously impair social and occupational functioning, partly because of psychopathology and partly because of problems in attempting to live in the desired gender role. Anxiety and depression are common and can lead to suicide attempts. Rarely, men may mutilate their genitalia.

The onset of gender identity disorder after marriage may significantly disrupt the marital relationship.

Assessment findings

During the assessment interview, a child with a gender identity disorder may express the desire to be—or insist that he or she is—the opposite sex. Such a child may express disgust with his genitalia and the belief, often expressed as an ardent hope, that when he grows up, he will become the opposite sex.

Men with a gender identity disorder may describe a lifelong history of feeling feminine and pursuing feminine activities. Women exhibit similar propensities for opposite sex activities and discomfort with the female role. In both instances, the crisis seems especially acute during puberty. Development of secondary sex characteristics (breasts and pubic hair in the female; enlarged penis and testes in the male) may precipitate intense distress or intensify the feeling that one is a misfit.

Diagnostic criteria

The diagnosis of gender identity disorder is confirmed when the patient's signs and symptoms meet the criteria established in the *DSM-IV*.

For gender identity disorder, both a strong and persistent cross-gender identification (not just a desire for perceived cultural advantages of being the other sex) as well as a persistent discomfort with his or her sex or sense of inappropriateness in the gender role of that sex must be present.

In children, this cross-gender identification is manifested by at least four of the following:

- u a repeatedly stated desire to be, or insistence that he or she is, the other sex
- u in boys, a preference for cross-dressing or simulating female attire; in girls, insistence on wearing only stereotypically masculine clothing
- u a strong and persistent preference for cross-sex roles in make-believe play or persistent fantasies of being the other sex
- u an intense desire to participate in the stereotypical games of the other sex
- u a strong preference for playmates of the other sex.

In adolescents and adults, this cross-gender identification is manifested by such symptoms as a stated desire to be the other sex, frequently posing as the other sex, a desire to live or be treated as the other sex, or the conviction that he or she has the typical feelings and reactions of the other sex.

Discomfort with his or her own sex is manifested by any of the following:

- in boys, an assertion that his penis or testes are disgusting or will disappear or an assertion that it would be better not to have a penis, or an aversion toward rough play and rejection of stereotypically male toys, games, and activities
- in girls, rejection of urinating in a sitting position, an assertion that she wants to grow a penis, an assertion that she doesn't want to grow breasts or menstruate, or a marked aversion toward normative feminine clothing
- in adolescents and adults, a preoccupation with getting rid of primary and secondary sex characteristics (asking for hormone therapy, surgery, or other procedures to alter sexual characteristics to simulate the other sex) or a belief that he or she was born the wrong sex.

Diagnostic criteria for gender identity disorder also includes the following:

- The disturbance isn't concurrent with a physical intersex disorder.
- The disturbance causes clinically significant distress or impairment of social, occupational, or other areas of functioning.

Treatment

Individual and family therapy are indicated for treatment of childhood gender identity disorders. Ideally, a therapist of the same sex may be useful for role modeling purposes. The earlier this problem is diagnosed and treatment begins, the more hopeful the prognosis for the child.

In an adult, individual and couples therapy may help the patient to cope with the decision to live as the opposite sex or to cope with the knowledge that he or she won't be able to live as the opposite sex.

Sex reassignment through hormonal and surgical treatment may be an option; however, surgical sex reassignment hasn't been as beneficial as first hoped. Severe psychological problems may persist after sex reassignment and sometimes lead to suicide. Furthermore, these patients may have gender disorders as part of a larger pattern of depression and personality disorders such as a borderline personality disorder.

With or without treatment, female transsexuals have shown stabler patterns of adjustment than male transsexuals have demonstrated.

Appropriate psychiatric management, including hospitalization, may be necessary if the patient displays evidence of the potential for violent behavior, such as suicidal ideation and fantasies of self-mutilation.

Nursing diagnoses

- Altered family processes
- Altered growth and development
- Altered role performance
- Anxiety
- Body image disturbance
- Chronic low self-esteem
- Impaired social interaction
- Ineffective family coping: Compromised
- Ineffective individual coping
- Personal identity disturbance
- Powerlessness
- Sexual dysfunction
- Social isolation

Key outcomes

- The patient will express positive feelings about self.
- The patient will voluntarily discuss the problem.
- The patient will agree to obtain sexual evaluation and therapy if needed.
- The patient will interact with family or friends.
- The patient will indicate that social relationships have improved and negative feelings have diminished.
- The patient will achieve expected state of wellness.

Nursing interventions

- Use a nonjudgmental approach in facial expression, tone of voice, and choice of words to convey your acceptance of the person's choices. By gaining the patient's trust, you'll lessen his discomfort about discussing his sexuality.
- Realize that treating such a patient with empathy doesn't threaten your own sexuality.
- Respect the patient's privacy and sense of modesty, particularly during procedures or examinations.
- Monitor for related or compounded problems, such as suicidal thought or intent, depression, and anxiety.
- As needed, refer the patient to a doctor, nurse, psychologist, social worker, or counselor trained in sex therapy.

Patient teaching

As a helpful guideline, inform the patient that the therapist's certification by the American Association of Sex Educators, Counselors, and Therapists or by the American Society for Sex Therapy and Research usually assures quality treatment. If the therapist isn't certified by one of these organizations, advise the patient to inquire about the therapist's training in sex counseling and therapy.

MALE ERECTILE DISORDER

Erectile dysfunction (or impotence) refers to the inability of a man to attain or maintain penile erection long enough to complete intercourse. Erectile dysfunction is characterized as primary or secondary. The patient with primary impotence has never achieved sufficient erection. Secondary impotence, which is more common and less serious than the primary form, implies that, despite the current inability, the patient has succeeded in completing intercourse in the past. Transient periods of impotence aren't considered dysfunctional and probably occur in 50% of men.

Three types of secondary erectile disorder occur:

- Partial—The patient is unable to achieve a full erection or to keep his erection long enough to penetrate his partner.
- Intermittent—The patient sometimes is potent with the same partner.
- Selective—The patient is potent only with certain partners.

Erectile disorder affects all age-groups but increases in frequency with age. The prognosis depends on the severity and duration of impotence and on the underlying cause.

Causes

Psychogenic factors are responsible for 50% to 60% of cases of erectile disorder; the rest can be attributed to organic factors. In some patients, psychogenic and organic factors coexist, making isolation of the primary cause difficult.

Psychogenic causes may be intrapersonal, reflecting personal sexual anxieties, or interpersonal, reflecting a disturbed sexual relationship. Intrapersonal factors include guilt, fear, depression, and feelings of inadequacy resulting from a previous traumatic sexual experience, rejection by parents or peers, exaggerated religious orthodoxy, abnormal mother-son intimacy, or homosexual experiences or fantasies.

Interpersonal factors may stem from differences in sexual preferences between partners, lack of communication, insufficient knowledge of sexual function, or

nonsexual personal conflicts.

Situational impotence, a temporary condition, may develop in response to stress. Organic causes include chronic diseases, such as cardiopulmonary disease, diabetes mellitus, multiple sclerosis, and renal failure; spinal cord trauma; complications of surgery; drug- or alcohol-induced dysfunction; and, rarely, genital anomalies or central nervous system defects.

Complications

Erectile disorder may seriously disrupt marital or other sexual relationships.

Assessment findings

The history of a patient with erectile disorder may reveal a long-standing inability to achieve erection, a sudden loss of erectile function, or a gradual decline in function. In addition, the patient may describe a history of medical disorders, drug therapy, or psychological trauma that may contribute to erectile disorder.

If the cause is psychogenic rather than organic, the patient may report that he can achieve erection through masturbation but not with a partner. He may display characteristic signs of anxiety when discussing his condition, such as sweating and palpitations, or appear disinterested. Depression, another common complaint, may be either a cause or a result of the impotence.

Diagnostic criteria

A diagnosis of male erectile disorder is confirmed when the patient's symptoms meet either of the following two criteria, established in the *DSM-IV*:

- u The patient experiences a persistent or recurrent partial or complete failure to attain or maintain erection until completion of sexual activity.
- u The disturbance causes marked distress or interpersonal difficulty.

In addition, the disorder shouldn't occur exclusively during the course of another Axis I disorder such as major depression.

Laboratory tests are ordered to rule out chronic diseases, such as diabetes, and other vascular, neurologic, or urogenital problems.

Treatment

Sex therapy, which is designed to reduce performance anxiety, may effectively cure psychogenic impotence. To be most effective, such therapy should include both partners.

The course and content of sex therapy for male erectile disorder depend on the specific cause of the disorder and the nature of the male-female relationship. Treatment usually includes sensate focus therapy, which restricts the couple's sexual activity and encourages them to become more attuned to the physical sensations of touching. Other measures include improving verbal communication skills, eliminating unreasonable guilt, and re-evaluating attitudes toward sex and sexual roles.

Treatment of organic impotence focuses on eliminating the cause, if possible. If the cause can't be eliminated, psychological counseling may help the couple deal realistically with their situation and explore alternatives for sexual expression. Some patients with organic impotence may benefit from a surgically inserted inflatable or semirigid penile prosthesis. Others may be treated with medication such as sildenafil (Viagra).

Nursing diagnoses

- u Altered family processes
- u Altered sexuality patterns
- u Anxiety
- u Ineffective individual coping
- u Self-esteem disturbance
- u Sexual dysfunction

Key outcomes

- u The patient will acknowledge a problem in sexual function.
- u The patient will voluntarily discuss the problem.
- u The patient and partner will discuss their feelings and perceptions about changes in sexual performance.
- u The patient will agree to obtain sexual evaluation and therapy if needed.
- u The patient will develop and maintain a positive attitude toward sexuality and sexual performance.

Nursing interventions

- u Help the patient feel comfortable about discussing his sexuality.
- u As needed, refer the patient to a doctor, nurse, psychologist, social worker, or counselor trained in sex therapy.

After penile prosthesis surgery:

- u Apply ice packs to the penis for 24 hours.
- u Empty the drainage device when it's full.
- u If the patient has an inflatable prosthesis, instruct him to pull the scrotal pump downward to ensure proper alignment.
- u When ordered, have the patient practice inflating and deflating the device.

Patient teaching

- u Provide instruction concerning anatomy and physiology of the reproductive system and the human sexual response cycle as needed.
- u After penile implant surgery, instruct the patient to avoid intercourse until the incision heals, usually in 6 weeks. Advise him to report signs of infection to the doctor.
- u As a helpful guideline, inform the patient that the therapist's certification by the American Association of Sex Educators, Counselors, and Therapists or by the American Society for Sex Therapy and Research usually assures quality treatment. If the therapist isn't certified by one of these organizations, advise the patient to inquire about the therapist's training in sex counseling and therapy.

PARAPHILIAS

Characterized by a dependence on unusual behaviors or fantasies to achieve sexual excitement, paraphilias are complex psychosexual disorders. The imagery or acts may involve the use of inanimate objects (especially clothing), repetitive sexual activity that includes suffering or humiliation, or sexual behavior with nonconsenting partners. The *DSM-IV* recognizes eight types of paraphilias: exhibitionism, fetishism, frotteurism, pedophilia, sexual masochism, sexual sadism, transvestic fetishism, and voyeurism. (See [Types of paraphilias](#).)

Some paraphilias that violate social mores or norms are considered sex offenses or sex crimes. However, everyone has sexual fantasies, and sexual behavior between two consenting adults that isn't physically or psychologically harmful isn't considered a paraphilia.

Little data exist on the prevalence of paraphilias in our society. Most people with paraphilias come to the mental health care system not because of their own distress but at the behest of their partners or legal authorities.

Causes

The specific cause of paraphilias isn't known, although several contributing factors have been identified. Many patients with these disorders come from dysfunctional families, characterized by isolation and sexual, emotional, or physical abuse. Others suffer from other mental disorders, such as psychoactive substance use disorders or a personality disorder.

Complications

Sexual masochism may sometimes result in serious physical injury. Paraphilias that involve another person, particularly voyeurism, exhibitionism, frotteurism, pedophilia, and sexual sadism, commonly lead to arrest and incarceration. Exhibitionists, pedophiles, and voyeurs make up the majority of apprehended sex offenders, and sexual offenses against children constitute a significant proportion of all reported criminal sex acts.

Assessment findings

The patient's history will reveal the particular pattern of abnormal sexual behaviors associated with one of the eight recognized paraphilias.

Diagnostic criteria

The diagnosis of paraphilia is confirmed when the patient's symptoms meet the criteria established in the *DSM-IV*.

For exhibitionism:

- u Over a period of at least 6 months, the patient has experienced recurrent, intense sexual urges and sexually arousing fantasies involving the exposure of his genitalia to an unsuspecting stranger.
- u The patient's fantasies, urges, or behaviors cause clinically significant distress or impairment of social, occupational, or other areas of functioning.
- u Over a period of 6 months, the patient has experienced recurrent, intense sexual urges and sexually arousing fantasies involving the use of nonliving objects by himself.
- u The fantasies, sexual urges, or behaviors cause clinically significant distress.
- u The fetishes aren't restricted to articles of female clothing used in cross-dressing or devices designed for the purpose of tactile genital stimulation.

For frotteurism:

- u Over a period of at least 6 months, the patient has experienced recurrent, intense sexual urges and sexually arousing fantasies involving touching or rubbing against a nonconsenting person.
- u The fantasies, urges, or behaviors cause clinically significant distress.

For pedophilia:

- u Over a period of at least 6 months, the patient has experienced recurrent, intense sexual urges and sexually arousing fantasies involving sexual activity with a prepubescent child or children (generally age 13 or younger).
- u The fantasies, urges, or behaviors cause clinically significant distress.
- u The patient is at least 16 years old and at least 5 years older than the child or children involved. The late adolescent involved in an ongoing sexual relationship with a 12- or 13-year-old child shouldn't be included in this group.

Types of paraphilias

Some people derive sexual excitement through behaviors or fantasies known as paraphilias. Eight paraphilias, including exhibitionism, fetishism, frotteurism, pedophilia, sexual masochism, sexual sadism, transvestic fetishism, and voyeurism, are described below.

Exhibitionism

The patient with exhibitionism obtains sexual gratification from publicly exposing his genitals to others, principally female passersby. The problem is most common in men (who often achieve erection while exposing themselves). Some masturbate to orgasm at the time.

Fetishism

The term *fetish* describes a recurrent and intense sexual arousal to an inanimate object (most often an article of women's clothing, such as panties or boots) or body parts that are neither primary nor secondary sexual organs. The patient frequently masturbates while holding, rubbing, or smelling the fetish object or may ask his partner to wear the object during their sexual encounters. Fetishism occurs primarily in men and typically follows a chronic course.

Frotteurism

The patient with frotteurism achieves sexual arousal by touching or rubbing a nonconsenting person. For example, he may rub his genitals against a woman's thigh or fondle her breasts. The behavior frequently occurs in crowded places, where it's easier to avoid detection. It's most common between ages 15 and 25.

Pedophilia

A pedophile (almost always a man) is erotically aroused by and seeks sexual gratification from children. This urge forms his preferred or exclusive sexual activity. Prepubertal children are the most common targets, and attraction to girls is almost twice as common as attraction to boys. The pedophile may sexually abuse his own children or those of a friend or relative or, rarely, he may even abduct a child. He may be quite attentive to all of the child's needs to gain the child's loyalty and prevent the child from reporting the encounters. Some pedophiles also are attracted to adults.

Sexual masochism

Sexual masochism refers to the urge to submit to physical or psychological pain, such as being humiliated, beaten, bound, or tortured, to achieve sexual gratification. This disorder is chronic.

Infantilism, a form of sexual masochism, is a desire to be treated as a helpless infant, including wearing diapers. One dangerous form of this paraphilia, sexual hypoxiphilia, relies on oxygen deprivation to induce sexual arousal. The patient uses a noose, mask, plastic bag, or chemical to induce a temporary decrease in brain oxygenation. Equipment malfunction or other mistakes can cause accidental death.

Sexual sadism

The converse of sexual masochism, sadism refers to recurrent, intense sexual urges and fantasies that involve inflicting physical or psychological suffering. The sadist derives sexual gratification from this behavior.

Transvestic fetishism

The transvestite is a heterosexual man who obtains sexual pleasure from cross-dressing (dressing in women's clothing). He may select a single article of apparel, such as a garter or stockings, or he may dress entirely as a woman, with a well made-up face and an immaculate feminine coiffure. This behavior often is accompanied by masturbation and mental images of other men being attracted to him as a “woman.”

Voyeurism

The voyeur derives sexual pleasure from looking at sexual objects or sexually arousing situations such as an unsuspecting couple engaged in sexual intercourse. No sexual orgasm may occur during the voyeuristic activity or later in response to the memory of what the person witnessed. Onset of this disorder is before age 15, and it tends to be chronic.

For sexual masochism:

- u Over a period of at least 6 months, the patient has experienced recurrent, intense sexual urges, sexually arousing fantasies, or behaviors involving the act of being humiliated, beaten, bound, or otherwise made to suffer.
- u The fantasies, urges, or behaviors cause clinically significant distress.

For sexual sadism:

- u Over a period of at least 6 months, the patient has experienced recurrent, intense sexual urges, sexually arousing fantasies, or behaviors involving acts in which the psychological or physical suffering of the victim is sexually exciting to the patient.
- u The fantasies, urges, or behaviors cause clinically significant distress.

For transvestic fetishism:

- u Over a period of at least 6 months, the patient (a heterosexual man) has experienced recurrent, intense sexual urges, sexually arousing fantasies, or behaviors involving cross-dressing.
- u The fantasies, urges, or behaviors cause clinically significant distress.
- u The patient doesn't meet the *DSM-IV* criteria for gender identity disorder.

For voyeurism:

- u Over a period of at least 6 months, the patient has experienced recurrent, intense sexual urges, sexually arousing fantasies, or behaviors involving the act of observing an unsuspecting person disrobing or engaging in sexual activity.
- u The fantasies, urges, or behaviors cause clinically significant distress.

Treatment

Paraphilias require mandatory treatment when the patient's sexual preferences result in socially unacceptable or harmful behavior. Depending on the paraphilia, treatment may include a combination of psychotherapy, behavior therapy, pharmacotherapy, and surgery. The effectiveness of treatment varies.

Nursing diagnoses

- u Altered role performance
- u Altered sexuality patterns
- u Anxiety
- u Chronic low self-esteem
- u Impaired social interaction
- u Personal identity disturbance
- u Risk for violence: Directed at others
- u Sexual dysfunction

Key outcomes

- u The patient will express positive feelings about self.
- u The patient will voluntarily discuss the problem.
- u The patient will agree to obtain sexual evaluation and therapy if needed.
- u The patient will interact with family or friends.
- u The patient will indicate that social relationships have improved and negative feelings have diminished.
- u The patient will achieve expected state of wellness.

Nursing interventions

- u Use a nonjudgmental approach in facial expression, tone of voice, and choice of words to convey your acceptance of the patient's choices.
- u Realize that treating such a patient with empathy doesn't threaten your own sexuality.
- u Encourage the patient to express his sexual preferences as well as his feelings about them.
- u As needed, refer the patient to a doctor, nurse, psychologist, social worker, or counselor trained in sex therapy.

Patient teaching

u As a helpful guideline, inform the patient that a therapist's certification by the American Association of Sex Educators, Counselors, and Therapists or by the American Society for Sex Therapy and Research usually ensures quality treatment. If the therapist isn't certified by one of these organizations, advise the patient to inquire about the therapist's training in sex counseling and therapy.

PREMATURE EJACULATION

One of the most common types of male sexual dysfunction, premature ejaculation is an inability to control the ejaculatory reflex during intercourse. As a result, ejaculation occurs before or immediately after penetration or before the wishes of both partners. This disorder affects men of all ages.

Causes

Premature ejaculation may result from anxiety and may be linked to immature sexual experiences. Other psychological factors include ambivalence toward or unconscious hatred of women, a negative sexual relationship in which the patient unconsciously denies his partner sexual fulfillment, and guilt feelings about sex.

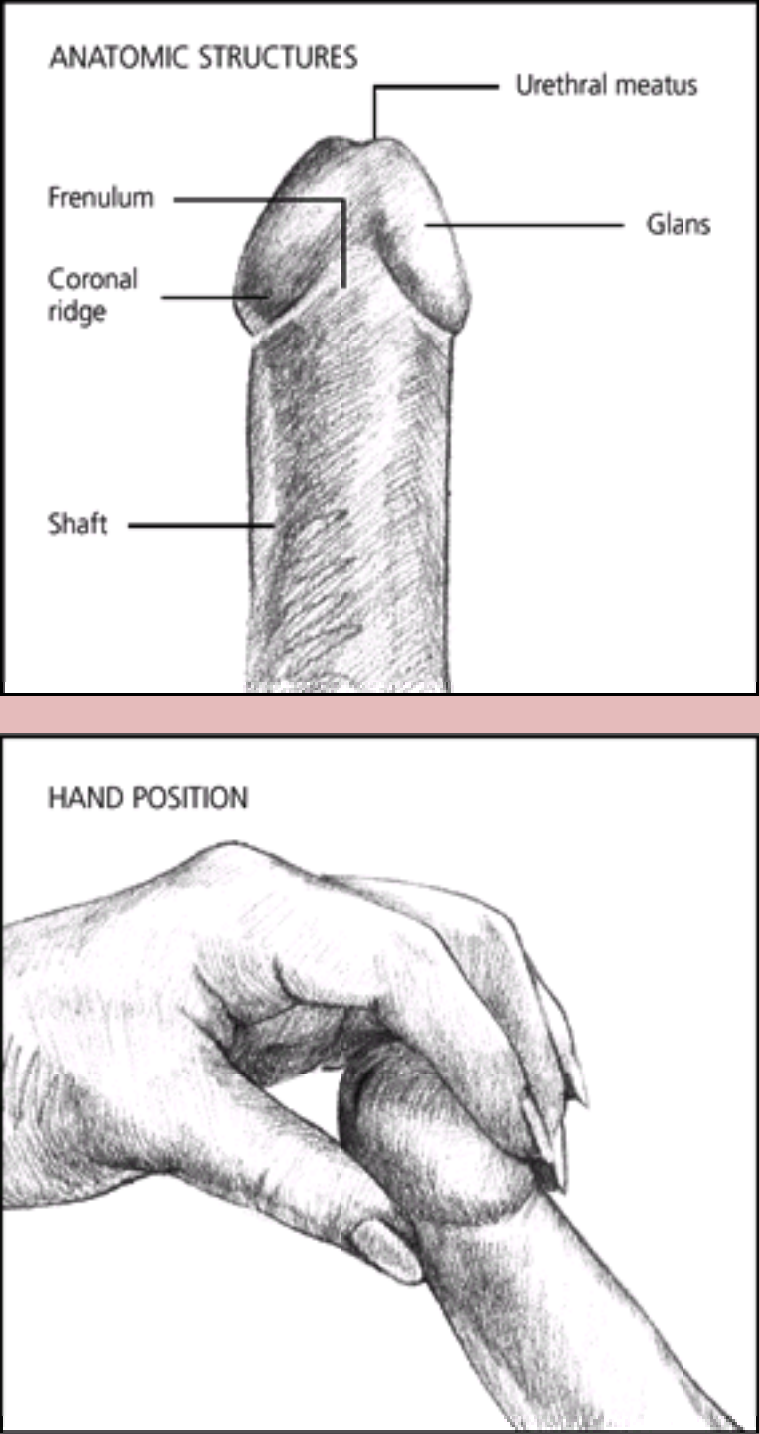

Psychological factors aren't the only cause of premature ejaculation; this disorder can also occur in emotionally healthy men with stable, positive relationships. Rarely, premature ejaculation may be linked to an underlying degenerative neurologic disorder such as multiple sclerosis or an inflammatory process such as posterior urethritis or prostatitis.

Complications

Premature ejaculation can seriously disrupt marital or other sexual relationships. In addition, the disorder can lead to generalized anxiety disorder as well as to pervasive feelings of inadequacy, guilt, and self-doubt.

The squeeze technique: Position and pressure

To delay ejaculation using the squeeze technique, the patient's partner must position the fingers correctly around the penis and apply the right amount of pressure. When the patient feels the urge to ejaculate, the partner should place a thumb on the frenulum of the penis and the index and middle fingers above and below the coronal ridge, as shown here. Then the penis is squeezed from front to back. The penis should be squeezed more firmly for an erect penis and less firmly for a partially flaccid one. The patient will feel pressure but no pain.

Assessment findings

The patient's history may reveal that he can't prolong foreplay or that he can prolong foreplay but ejaculates as soon as intromission occurs. In some cases, the patient's partner may seek psychiatric treatment, complaining that the patient is indifferent to her sexual needs.

Diagnostic criteria

The diagnosis of premature ejaculation is based on the criterion established in the *DSM-IV*: persistent or recurrent ejaculation with minimal sexual stimulation before, during, or shortly after penetration and before the person wishes it to occur.

The clinician may take into account factors that affect duration of the excitement phase, such as age, novelty of the sexual partner or situation, and frequency of sexual activity.

Treatment

Masters and Johnson have developed a highly successful, intensive treatment program for premature ejaculation. The program combines insight therapy, behavioral techniques, and experiential sessions that involve both sexual partners. The program is designed to help the patient focus on sensations of impending orgasm. The therapy sessions, which continue for 2 weeks or longer, typically include:

- mutual physical examination, which increases the couple's awareness of anatomy and physiology while reducing shameful feelings about sexual parts of the body
- sensate focus, which allows each partner, in turn, to caress the other's body without intercourse and to focus on the pleasurable sensations of touch
- the squeeze technique, which helps the patient gain control of ejaculatory tension by having the woman squeeze his penis, with her thumb on the frenulum and her forefinger and middle finger on the dorsal surface, near the coronal ridge. At the patient's direction, she applies and releases pressure every few minutes during a touching exercise to delay ejaculation by keeping him at an earlier phase of the sexual response cycle. (See [The squeeze technique: Position and pressure.](#))

The stop-and-start technique also helps delay ejaculation. With the woman in the superior position, this method involves pelvic thrusting until orgasmic sensations start and then stopping and restarting to aid control of ejaculation. The couple eventually is allowed to achieve orgasm.

Nursing diagnoses

- Altered family processes
- Altered sexuality patterns
- Anxiety
- Ineffective individual coping
- Self-esteem disturbance
- Sexual dysfunction

Key outcomes

- The patient will acknowledge a problem in sexual function.
- The patient will voluntarily discuss the problem.
- The patient and partner will discuss their feelings and perceptions about changes in sexual performance.
- The patient will agree to obtain sexual evaluation and therapy if needed.
- The patient will develop and maintain a positive attitude toward sexuality and sexual performance.

Nursing interventions

- Convey sympathy and a nonjudgmental attitude when caring for a patient with premature ejaculation.
- Provide expert teaching in a comfortable environment that encourages open discussion of sexuality.
- As needed, refer the patient to a doctor, nurse, psychologist, social worker, or counselor trained in sex therapy.

Patient teaching

- Provide instruction concerning anatomy and physiology of the reproductive system and the human sexual response cycle as needed.
- Encourage a positive self-image by explaining that premature ejaculation is a common disorder that doesn't reflect on the patient's masculinity.
- Assure the patient that the condition is reversible.
- As a helpful guideline, inform the patient that a therapist's certification by the American Association of Sex Educators, Counselors, and Therapists or by the American Society for Sex Therapy and Research usually assures quality treatment. If the therapist isn't certified by one of these organizations, advise the patient to inquire about the therapist's training in sex counseling and therapy.

VAGINISMUS

Vaginismus is an involuntary spastic constriction of the lower vaginal muscles. It usually stems from a fear of vaginal penetration. If severe, it may prevent intercourse. Vaginismus affects women of all ages and backgrounds. The prognosis is excellent for a motivated patient who has no untreatable organic abnormalities.

Causes

Vaginismus may be physical or psychological in origin. It may occur spontaneously as a protective reflex to pain, or it may result from organic causes, such as abnormalities of the hymen, genital herpes, obstetric trauma, and atrophic vaginitis.

Psychological causes of vaginismus include:

- childhood and adolescent exposure to rigid, punitive, and guilt-ridden attitudes toward sex
- fears resulting from painful or traumatic sexual experiences, such as incest or rape
- early traumatic experience with pelvic examinations
- phobias of pregnancy, venereal disease, or cancer
- dysfunctional childhood experiences and family attitudes toward sex
- concern about contraception and potential pregnancy
- conflicts with the sexual partner.

Complications

Vaginismus can impair marital or other sexual relationships.

Assessment findings

The patient with vaginismus may report muscle spasm with constriction and pain on insertion of any object into the vagina, such as a vaginal tampon, diaphragm, or speculum. She may profess a lack of sexual interest or a normal level of sexual desire (typically characterized by sexual activity without intercourse).

Diagnostic criteria

The diagnosis of vaginismus is based on fulfillment of the following criteria established in the *DSM-IV*:

- u The patient experiences recurrent or persistent involuntary spasm of the musculature of the outer third of the vagina, which interferes with coitus.
- u The disturbance causes marked distress or interpersonal difficulty.
- u The disturbance isn't caused exclusively by a physical disorder and isn't due to another Axis I disorder.

A carefully performed pelvic examination confirms the diagnosis by demonstrating involuntary constriction of the musculature surrounding the outer portion of the vagina.

Treatment

Appropriate treatment is designed to eliminate maladaptive muscle constriction and underlying psychological problems. In Masters and Johnson therapy, the patient uses a graduated series of plastic dilators, which she inserts into her vagina while tensing and relaxing her pelvic muscles. The patient controls the time the dilator is left in place (if possible, she retains it for several hours) and the movement of the dilator. Together with her sexual partner, she begins sensate focus and counseling therapy to increase sexual responsiveness, improve communications skills, and resolve any underlying conflicts.

Kaplan therapy also uses progressive insertion of dilators or fingers (in vivo desensitization therapy), with behavior therapy (imagining vaginal penetration until it can be tolerated) and, if necessary, psychoanalysis and hypnosis. Both Masters and Johnson and Kaplan report a 100% cure rate; however, Kaplan states that the patient and her partner may show other sexual dysfunctions that necessitate additional therapy.

Nursing diagnoses

- u Altered family processes u Altered sexuality patterns u Anxiety u Body image disturbance u Self-esteem disturbance u Sexual dysfunction

Key outcomes

- u The patient will acknowledge a problem in sexual function.
- u The patient will voluntarily discuss the problem.
- u The patient and partner will discuss their feelings and perceptions about changes in sexual performance.
- u The patient will agree to obtain sexual evaluation and therapy if needed.
- u The patient will develop and maintain a positive attitude toward sexuality and sexual performance.

Nursing interventions

- u Communicate an open, nonjudgmental attitude in caring for a patient with vaginismus.
- u Listen empathetically to the patient's complaints of sex-related pain, and encourage her to express her feelings.
- u Because a pelvic examination may be painful for the patient, proceed gradually, at the patient's own pace. Support her throughout the pelvic examination, explaining each step beforehand. Encourage her to verbalize her feelings, and take plenty of time to answer her questions.
- u As needed, refer the patient to a doctor, nurse, psychologist, social worker, or counselor trained in sex therapy.

Patient teaching

- u Provide instruction concerning anatomy and physiology of the reproductive system, contraception, and the human sexual response cycle.
- u When appropriate, advise the patient about drugs that may affect sexual response and about lubricating jellies and creams.
- u As a helpful guideline, inform the patient that the therapist's certification by the American Association of Sex Educators, Counselors, and Therapists or by the American Society for Sex Therapy and Research usually assures quality treatment. If the therapist isn't certified by one of these organizations, advise the patient to inquire about the therapist's training in sex counseling and therapy.

INTRODUCTION

Despite improved methods of treating and preventing infection—potent antibiotics, rigorous immunizations, and modern sanitation—infection still accounts for much serious illness, even in highly industrialized countries. In developing countries, infection remains one of the most pressing health problems.

What is infection?

Infection is the invasion and multiplication of microorganisms in or on body tissues that produce signs and symptoms as well as an immune response. Such reproduction injures the host by causing cellular damage from microorganism-produced toxins or intracellular multiplication or by competing with host metabolism. The host's own immune response may compound the tissue damage. The damage may be localized (as in infected pressure ulcers) or systemic. The infection's severity varies with the pathogenicity and number of the invading microorganisms and the strength of host defenses. The very young and the very old are especially susceptible to infections.

Why are the microorganisms that cause infectious diseases so hard to overcome? Many complex reasons exist:

- u Some bacteria—especially gram-negative bacilli—develop resistance to antibiotics.
- u Some microorganisms—the influenza virus, for example—have so many strains that a single vaccine can't provide protection against them all.
- u Most viruses resist antiviral drugs.
- u Some microorganisms localize in areas that make treatment difficult, such as the central nervous system or bone.

Moreover, certain factors contribute to increase the risk of infection. For example, travel can expose people to diseases for which they have little natural immunity. In addition, the expanded use of immunosuppressants, surgery, and other invasive procedures increases the risk of infection. (See [Reportable infectious diseases.](#))

Kinds of infections

A laboratory-verified infection that causes no signs and symptoms is called a *subclinical*, *silent*, or *asymptomatic infection*. A multiplication of microbes that produces no signs, symptoms, or immune responses is called a *colonization*. A person with a subclinical infection or a colonization may be a carrier and transmit infection to others.

A *latent infection* occurs after a microorganism has been dormant in the host, sometimes for years. An exogenous infection results from environmental pathogens; an endogenous infection, from the host's normal flora (for instance, *Escherichia coli* displaced from the colon, which may cause urinary tract infection).

The varied forms of microorganisms responsible for infectious diseases include bacteria, spirochetes (a type of bacteria), viruses, rickettsiae, chlamydiae, fungi, and protozoa. Larger organisms, such as helminths (worms), also may cause disease.

Bacteria

Single-cell microorganisms with well-defined cell walls, bacteria can multiply independently on artificial media without the need for other cells. In developing countries, where poor sanitation heightens the risk of infection, bacterial diseases commonly cause death and disability. Even in industrialized countries, they're still the most common fatal infectious diseases. (See [How bacteria damage tissue.](#))

Bacteria can be classified by shape. Spherical bacterial cells are called *cocci*; rod-shaped bacteria, *bacilli*; and spiral-shaped bacteria, *spirilla*. They also can be classified by their response to staining (gram-positive, gram-negative, or acid-fast bacteria), their motility (motile or nonmotile bacteria), their tendency toward capsulation (encapsulated or nonencapsulated bacteria), their capacity to form spores (sporulating or nonsporulating bacteria), and their oxygen requirements (aerobic bacteria need oxygen to grow; anaerobic bacteria don't).

Spirochetes

A type of bacteria, spirochetes are flexible, slender, undulating spiral rods that have cell walls. Most are anaerobic. The three forms pathogenic in humans include *Treponema*, *Leptospira*, and *Borrelia*.

Viruses

Viruses are subcellular organisms made up of only a ribonucleic acid (RNA) or a deoxyribonucleic acid (DNA) nucleus covered with proteins. They are the smallest known organisms, so tiny that they're visible only through an electron microscope. Viruses can't replicate independent of host cells. Rather, they invade a host cell and stimulate it to participate in the formation of additional virus particles. The estimated 400 viruses that infect humans are classified according to their size, shape (spherical, rod-shaped, or cubic), or means of transmission (respiratory, fecal, oral, or sexual).

Reportable infectious diseases

Disease reporting laws vary from state to state. Local agencies report specified diseases to state health departments, which determine which diseases are reported to the Centers for Disease Control and Prevention. Reportable infectious diseases include:

- u acquired immunodeficiency syndrome
- u amebiasis
- u animal bites
- u anthrax (cutaneous or pulmonary)
- u arbovirus
- u aseptic meningitis
- u botulism
- u brucellosis
- u campylobacteriosis
- u chancroid
- u chlamydial infections
- u cholera
- u congenital rubella syndrome
- u diarrhea of the newborn (epidemic)
- u diphtheria (cutaneous or pharyngeal)
- u encephalitis (postinfectious or primary)
- u food poisoning
- u gastroenteritis (hospital outbreak)
- u giardiasis
- u gonococcal infections
- u gonorrhea
- u group A beta-hemolytic streptococcal infection (including scarlet fever)
- u Guillain-Barré syndrome
- u hepatitis (types A, B, C, and unspecified)
- u histoplasmosis
- u influenza
- u Kawasaki disease
- u lead poisoning
- u *Legionella* infections (Legionnaires' disease)
- u leprosy
- u leptospirosis
- u listeriosis
- u Lyme disease
- u lymphogranuloma
- u malaria
- u measles
- u meningitis
- u meningococcal disease
- u mumps
- u neonatal hypothyroidism
- u pertussis
- u phenylketonuria
- u plague
- u poliomyelitis
- u psittacosis
- u rabies
- u Reye's syndrome
- u rheumatic fever
- u rickettsial diseases (including Rocky Mountain spotted fever)
- u rubella and congenital rubella syndrome
- u salmonellosis (excluding typhoid fever)
- u shigellosis
- u smallpox
- u staphylococcal infections (neonatal)
- u syphilis (congenital)
- u syphilis (primary or secondary)
- u tetanus
- u toxic shock syndrome
- u toxoplasmosis
- u trichinosis
- u tuberculosis
- u tularemia, typhoid, and paratyphoid fever
- u typhus
- u varicella
- u yellow fever.

Rickettsiae

Relatively uncommon in the United States, these small, gram-negative bacteria-like organisms frequently induce life-threatening infections. Like viruses, they require a host cell for replication. Three genera of rickettsiae include *Rickettsia*, *Coxiella*, and *Rochalimaea*.

Chlamydiae

Larger than viruses, chlamydiae have recently been found to be intracellular obligate bacteria. Unlike other bacteria, they depend on host cells for replication; unlike viruses, they're susceptible to antibiotics.

Fungi

These single-cell organisms have nuclei enveloped by nuclear membranes. They have rigid cell walls like plant cells but lack chlorophyll, the green matter necessary for photosynthesis. They also show relatively little cellular specialization. Fungi occur as yeasts (single-cell, oval-shaped organisms) or molds (organisms with hyphae or branching filaments). Depending on the environment, some fungi may occur in both forms. Fungal diseases in humans are called mycoses.

PATHOPHYSIOLOGY

How bacteria damage tissue

Bacteria and other infectious organisms constantly infect the human body. Some are beneficial, such as the intestinal bacteria that produce vitamins. Others are harmful, causing illnesses ranging from the common cold to life-threatening septic shock.

To infect a host, bacteria must first enter it. They do this either by adhering to the mucosal surface and directly invading the host cell or by attaching to epithelial cells and producing toxins that invade host cells. To survive and multiply within a host, bacteria or their toxins adversely affect biochemical reactions in cells. The result is a disruption of normal cell function or cell death. (See [figure 1.](#)) For example, the diphtheria toxin damages heart muscle by inhibiting protein synthesis. In addition, as some organisms multiply, they extend into deeper tissue and eventually enter the bloodstream.

FIGURE 1

Some toxins cause blood to clot in small blood vessels. The tissues supplied by these vessels may be deprived of blood and damaged. (See [figure 2.](#))

FIGURE 2

Other toxins can damage the cell walls of small blood vessels, causing leakage. This fluid loss results in decreased blood pressure, which in turn impairs the heart's ability to pump enough blood to vital organs. (See [figure 3.](#))

FIGURE 3

Protozoa

Protozoa are the simplest single-cell organisms of the animal kingdom, but they show a high level of cellular specialization. Like other animal cells, they have cell membranes rather than cell walls, and their nuclei are surrounded by nuclear membranes.

Helminths

The three groups of helminths that invade humans include nematodes, cestodes, and trematodes. Nematodes are cylindrical, unsegmented, elongated helminths that taper at each end; this shape has earned them the designation *roundworm*. Cestodes, better known as *tapeworms*, have bodies that are flattened front to back with distinct, regular segments. Tapeworms also have heads with suckers or sucking grooves. Trematodes have flattened, unsegmented bodies. They are called *blood*, *intestinal*, *lung*, or *liver flukes*, depending on their infection site.

Modes of transmission

Most infectious diseases are transmitted in one of four ways.

In *contact transmission*, the susceptible host comes into direct contact (as in sexually transmitted diseases) or indirect contact (contaminated inanimate objects or the close-range spread of respiratory droplets) with the source.

Airborne transmission results from inhalation of contaminated evaporated saliva droplets (as in pulmonary tuberculosis), which sometimes are suspended in airborne

dust particles or vapors.

In *enteric* (fecal-oral) *transmission*, the organisms are found in feces and are ingested by susceptible victims, often through fecally contaminated food or water.

Vector-borne transmission occurs when an intermediate carrier (vector), such as a flea or a mosquito, transfers an organism.

Prevention of contagion

The following measures can be taken to prevent the transmission of infectious diseases:

- u drug prophylaxis
- u standard precautions
- u hand washing between patients
- u comprehensive immunization (including immunization of travelers to or emigrants from endemic areas)
- u improved nutrition, living conditions, and sanitation
- u correction of environmental factors.

Although prophylactic antibiotic therapy may prevent certain diseases, the risk of superinfection and the emergence of drug-resistant strains may outweigh the benefits. So prophylactic antibiotics usually are reserved for patients at high risk for exposure to dangerous infection.

Appropriate immunization can now prevent many diseases, including diphtheria, tetanus, pertussis, measles, rubella, some forms of meningitis, poliomyelitis, hepatitis B, pneumococcal pneumonia, influenza, rabies, and tetanus. Smallpox (variola), which killed and disfigured millions, is believed to have been eradicated by a comprehensive World Health Organization program of surveillance and immunization.

Vaccines, which contain live but attenuated (weakened) or killed microorganisms, and toxoids, which contain bacterial exotoxins, induce immunity against bacterial and viral diseases by stimulating the recipient's antibody formation. Natural active immunity is produced by a patient who has the disease and forms antibodies against it, thus preventing recurrence of disease.

Immune globulins, which contain previously formed antibodies from hyperimmunized donors or pooled plasma, provide temporary passive immunity. Antitoxins provide immunity to various toxins. Passive immunization is used only when active immunization is perilous or impossible or when complete protection requires both active and passive immunization. Maternal passive immunity crosses the placental barrier from mother to fetus and is also provided to the infant by antibodies present in breast milk. (See [Immunization schedule](#).)

Nosocomial infections

A nosocomial infection is one that develops while a patient is in a hospital or another institution. Most infections of this type result from group A *Streptococcus pyogenes*, *Staphylococcus*, *E. coli*, *Klebsiella*, *Proteus*, *Pseudomonas*, *Haemophilus influenzae*, *Candida albicans*, and hepatitis viruses.

Nosocomial infections usually are transmitted by direct contact. Less often, they're transmitted by inhalation of or wound invasion by airborne organisms or by contaminated equipment and solutions.

Despite facility infection-control programs that include surveillance, prevention, and education, an estimated 5% of patients who enter facilities each year contract a nosocomial infection. Since the 1960s, staphylococcal infections have been declining; however, fungal infections and infections caused by gram-negative bacilli have been steadily increasing.

Nosocomial infections continue to pose a problem because most facility patients are older and more debilitated than in the past. The advances in treatment that increase longevity in patients with diseases that alter immune defenses also create a population at high risk for infection. Moreover, the growing use of invasive and surgical procedures, immunosuppressants, and antibiotics predisposes patients to infection and superinfection and helps create new strains of antibiotic-resistant bacteria. The growing number of facility personnel that come in contact with each patient increases the risk of exposure. (See [Preventing nosocomial infections](#), and [Revised CDC isolation precautions](#).)

Immunization schedule	
Before an immunization, obtain the child's medication, illness, and allergy history. Instruct the parents to report a severe reaction to the vaccine to the doctor. Childhood immunizations are usually given on a fixed schedule, as follows.	
AGE	IMMUNIZATIONS
Birth to 2 months	First dose: Hepatitis B vaccine (HBV) Second dose: HBV ¹
1 to 4 months	First dose: diphtheria-tetanus acellular-pertussis (DTaP) vaccine, inactivated polio vaccine (IPV), <i>Haemophilus influenzae</i> type b conjugate (Hib) vaccine
2 months	Second dose: DTaP, IPV, and Hib
4 months	Third dose: DTaP and Hib
6 months	Third dose: HBV and IPV
6 to 18 months	First dose: Measles-mumps-rubella (MMR) vaccine. Fourth dose: Hib
12 to 15 months	First dose: varicella zoster virus vaccine
12 to 18 months	Fourth dose: DTaP ² .
15 to 18 months	First dose: Hepatitis A ³ . Second dose: 6 to 12 months after first dose
24 months	Fifth dose: DTaP. Fourth dose: IPV. Second dose: MMR
4 to 6 years	HBV (if dose missed); MMR (if not given at age 4 to 6); varicella zoster (catch-up vaccination ⁴)
11 to 12 years	Tetanus (booster every 10 years)
11 to 16 years	
<div></div>	
<div><div>¹ The second dose of HBV is given at least 1 month after the first dose. The third dose is given at least 6 months after the second dose.</div><div>² A fourth dose of DTaP may be given as early as age 12 months through 18 months provided that 6 months have elapsed since the third dose. The acellular form of the vaccine is now used for all doses in the vaccination series, even for children who started the series with standard whole-cell D vaccine.</div><div>³ The hepatitis A vaccination is now recommended for use in selected areas of the U.S. with high rates of hepatitis A, starting no sooner than age 2.</div><div>⁴ Nonvaccinated children with no history of chickenpox should be vaccinated at age 11 to 12.</div></div>	

Standard precautions

The Centers for Disease Control and Prevention recommends that the following standard blood and body fluid precautions be used for *all* patients. This is especially important in emergency care settings where the risk of blood exposure is increased and the patient's infection status is usually unknown. Implementing standard

precautions doesn't eliminate the need for other transmission-based precautions, such as airborne, droplet, and contact precautions.

Sources of potential exposure

Standard precautions apply to blood, semen, vaginal secretions, cerebrospinal fluid, synovial fluid, pleural fluid, peritoneal fluid, pericardial fluid, and amniotic fluid. These fluids are most likely to transmit human immunodeficiency virus (HIV). Standard precautions also apply to other body fluids—including feces, nasal secretions, saliva, sputum, tears, vomitus, and breast milk.

Barrier precautions

- u Wear gloves when touching blood and body fluids, mucous membranes, or broken skin of all patients; when handling items or touching surfaces soiled with blood or body fluids; and when performing venipuncture and other vascular access procedures.
- u Change gloves and wash hands after contact with each patient.
- u Wear a mask and protective eyewear or a face shield to protect mucous membranes of the mouth, nose, and eyes during procedures that may generate drops of blood or other body fluids.
- u In addition to a mask and protective eyewear or a face shield, wear a gown or an apron during procedures that are likely to generate splashing of blood or other body fluids.
- u After removing gloves, thoroughly wash hands and other skin surfaces that may be contaminated with blood or other body fluids.

PREVENTION

Preventing nosocomial infections

Here is how you can help prevent nosocomial infections:

- u Follow strict infection-control procedures.
- u Document hospital infections as they occur.
- u Identify outbreaks early, and take steps to prevent their spread.
- u Eliminate unnecessary procedures that contribute to infection.
- u Strictly follow necessary isolation techniques.
- u Observe all patients for signs of infection, especially patients who are at high risk for infection.
- u Follow good hand-washing techniques, and encourage other staff members to do the same.
- u Keep staff members and visitors with obvious infection, as well as known carriers, away from susceptible patients.

Precautions for invasive procedures

- u During all invasive procedures, wear gloves. Also wear a surgical mask and goggles or a face shield.
- u During procedures that commonly generate droplets or splashes of blood or other body fluids, or that generate bone chips, wear protective eyewear and a mask or a face shield.
- u During invasive procedures that are likely to cause splashing or splattering of blood or other body fluids, wear a gown or an impervious apron.
- u If you perform or assist in vaginal or cesarean deliveries, wear gloves and gown when handling the placenta or the infant and during umbilical cord care.

Work practice precautions

- u Prevent injuries caused by needles, scalpels, and other sharp instruments or devices when cleaning used instruments, when disposing of used needles, and when handling sharp instruments after procedures.
- u To prevent needle-stick injuries, don't recap used needles, bend or break needles, remove them from disposable syringes, or manipulate them.
- u Place disposable syringes and needles, scalpel blades, and other sharp items in puncture-resistant containers for disposal, making sure these containers are located near the area of use.
- u Place large-bore reusable needles in a puncture-resistant container for transport to the reprocessing area.
- u If the glove tears or a needle-stick or other injury occurs, remove the gloves, wash your hands, and wash the site of the needle stick thoroughly; then put on new gloves as quickly as patient safety permits. Remove the needle or instrument involved in the incident from the sterile field. Promptly report injuries and mucous-membrane exposure to the appropriate infection-control officer.

Additional precautions

- u Make sure mouthpieces, one-way valve masks, resuscitation bags, or other ventilation devices are available in areas where the need for resuscitation is likely. *Note:* Saliva hasn't been implicated in HIV transmission.
- u If you have exudative lesions or weeping dermatitis, refrain from direct patient care and handling patient-care equipment until the condition resolves.

Need for accurate assessment

Accurate assessment helps identify infectious diseases and prevents avoidable complications. Complete assessment consists of a patient history, a physical examination, and diagnostic tests.

The history should include the patient's sex, age, address, occupation, and place of work; known exposure to infection; and date of disease onset. It also should detail information about recent hospitalization, blood transfusions, blood donation denial by the Red Cross or other agencies, vaccination, travel or camping trips, and exposure to animals.

If applicable, ask the patient about possible exposure to sexually transmitted diseases and about drug abuse. Also ask him about his usual dietary patterns, unusual fatigue, and factors that may predispose the patient to infection, such as neoplastic disease and alcoholism. Notice if the patient is listless or uneasy, lacks concentration, or has any obvious abnormality of mood or affect.

In suspected infection, a physical examination includes assessment of the skin, mucous membranes, liver, spleen, and lymph nodes. Check for and note the location and type of drainage from skin lesions. Record skin color, temperature, and turgor; ask if the patient has pruritus. Take his temperature, using the same route consistently, and watch for a fever, the best indicator of many infections. Note and record the pattern of temperature change and the effect of antipyretics. Be aware that certain analgesics may contain antipyretics. In a high fever, especially in children, watch for seizures.

Revised CDC isolation precautions

To help facilities maintain up-to-date isolation practices, the Centers for Disease Control and Prevention (CDC) and the Hospital Infection Control Practices Advisory Committee recently revised the CDC's *Guidelines for Isolation Precautions in Hospitals*.

Standard precautions

The revised guidelines contain two tiers of precautions. The first—called *standard precautions*—are those designated for the care of all facility patients regardless of their diagnosis or presumed infection. Standard precautions are the primary strategy for preventing nosocomial infection and take the place of universal precautions. These precautions apply to:

- u blood
- u all body fluids, secretions, and excretions, except sweat, regardless of whether or not they contain visible blood
- u skin that isn't intact
- u mucous membranes.

Transmission-based precautions

The second tier of precautions are known as *transmission-based precautions*. These precautions are instituted for patients who are known to be or suspected of being infected with a highly transmissible infection— one that needs precautions beyond those set forth in the standard precautions. There are three types of transmission-based precautions: airborne precautions, droplet precautions, and contact precautions.

Airborne precautions. These precautions are designed to reduce the risk of airborne transmission of infectious agents. Microorganisms carried through the air can be dispersed widely by air currents, making them available for inhalation or deposit on a susceptible host in the same room or a longer distance away from the infected patient. Airborne precautions include special air handling and ventilation procedures to prevent the spread of infection. They require the use of respiratory protection such as a mask—in addition to standard precautions—when entering an infected patient's room.

Droplet precautions. These precautions are designed to reduce the risk of transmitting infectious agents through large-particle (exceeding 5 micrometers) droplets. Such transmission involves contact of infectious agents to the conjunctivae or to the nasal or oral mucous membranes of a susceptible person. Large-particle droplets don't remain in the air and generally travel short distances of 3' (1 m) or less. They require the use of a mask—in addition to standard precautions—to protect the mucous membranes.

Contact precautions. These precautions are designed to reduce the risk of transmitting infectious agents by direct or indirect contact. Direct-contact transmission can occur through patient-care activities that require physical contact. Indirect-contact transmission involves a susceptible host coming in contact with a contaminated object, usually inanimate, in the patient's environment. Contact precautions require the use of gloves, a mask, and a gown—in addition to standard precautions—to avoid contact with the infectious agent. Stringent hand washing is also necessary after removal of the protective items. The following chart sets forth the different types of precautions and provides examples of infections for which specific precautions would be used.

PRECAUTIONS	INDICATIONS
Standard precautions	Designated for all patients regardless of diagnosis or presumed infection.
Airborne precautions (used in addition to standard precautions)	Patients known to have or suspected of having a serious illness transmitted by airborne droplet nuclei, such as: <ul style="list-style-type: none">u measlesu tuberculosisu varicella.
Droplet precautions (used in addition to standard precautions)	Patients known to have or suspected of having a serious illness transmitted by large-particle droplets, such as: <ul style="list-style-type: none">u invasive <i>Haemophilus influenzae</i> type b disease, including meningitis, pneumonia, epiglottitis, and sepsisu invasive <i>Neisseria meningitides</i> disease, including meningitis, pneumonia, and sepsisu other serious bacterial respiratory infections spread by droplets, such as:<ul style="list-style-type: none">–diphtheria–<i>Mycoplasma pneumonia</i>–pertussis–pneumonic plague–streptococcal pharyngitis, pneumonia, or scarlet fever in infants and young childrenu other serious viral infections spread by droplets, including:<ul style="list-style-type: none">–adenovirus–influenza–mumps–parvovirus B19 (with most serious risk to fetuses)–rubella.
Contact precautions (used in addition to standard precautions)	Patients known to have or suspected of having a serious illness easily transmitted by direct patient contact or by contact with items in the patient's environment. Examples of such illnesses include: <ul style="list-style-type: none">u GI, respiratory, skin or wound infections or colonization with multidrug-resistant bacteria judged by the infection control program (based on current state, regional, or national recommendations) to be of special clinical and epidemiologic significanceu enteric infections with a low infectious dose or prolonged environmental survival, including:<ul style="list-style-type: none">–<i>Clostridium difficile</i>–for diapered or incontinent patients, enterohemorrhagic <i>Escherichia coli</i> O157:H7, <i>Shigella</i>, hepatitis A, or rotavirusu respiratory syncytial virus, parainfluenza virus, or enteroviral infections in infants and young childrenu skin infections that are highly contagious or that may occur on dry skin, including:<ul style="list-style-type: none">–diphtheria (cutaneous)–herpes simplex virus (neonatal or mucocutaneous)–impetigo–major (noncontained) abscesses, cellulitis, or decubiti–pediculosis–scabies–staphylococcal furunculosis in infants and young children–viral or hemorrhagic conjunctivitis–zoster (disseminated or in an immunocompromised host)u viral hemorrhagic infections (Ebola, Lassa, or Marburg).

Check the patient's pulse rate. Infection commonly increases the pulse rate, but some infections, such as typhoid fever, may decrease it. In severe infection or when complications are possible, monitor the patient for hypotension, hematuria, oliguria, hepatomegaly, jaundice, palpable and painful lymph nodes, bleeding from gums or into joints, and altered level of consciousness. Obtain diagnostic tests and appropriate cultures, as ordered. (See [How to collect culture specimens.](#))

How to collect culture specimens

Proper identification of the causative organism requires proper culture collection. Label culture specimens with the date, time, patient's name, suspected diagnosis, and source of culture. Always try to obtain cultures before the first dose of antibiotics. If antibiotics are given before specimen collection, obtain the specimen as soon as possible. Don't withhold treatment to wait for specimen collection if delay may be prolonged or may increase risk for the patient.		
CULTURE SITE	SPECIMEN SOURCE	SPECIAL CONSIDERATIONS
Infected wound	<ul style="list-style-type: none"> Aspiration of exudate with syringe (preferred technique) Applicator swab 	<ul style="list-style-type: none"> Use only a sterile syringe. A pungent odor suggests the presence of anaerobes. Use oxygen-free collection tubes if available. Firmly but gently insert the swab deep into the wound, and saturate it with exudate from the infected site. If the surface is dry, moisten the swab with sterile saline solution before taking the culture.
Skin lesions	<ul style="list-style-type: none"> Excision or puncture 	<ul style="list-style-type: none"> Thoroughly clean the skin before excision or puncture, and follow the procedure for an infected wound.
Upper respiratory tract	<ul style="list-style-type: none"> Nasopharyngeal swab (generally used to detect carriers of <i>Staphylococcus aureus</i> and viral infections) Throat swab 	<ul style="list-style-type: none"> Gently pass the swab through the nose into the nasopharynx. Send the specimen to the laboratory for culture immediately. Under adequate light, swab the area of inflammation or exudation.
Lower respiratory tract	<ul style="list-style-type: none"> Expectorated sputum Induced sputum (used when patient can't expectorate sputum) Nasotracheal suction Pleural tap 	<ul style="list-style-type: none"> Instruct the patient to cough deeply and to expectorate into a cup. Culture requires expectorated sputum, not just saliva. The best time to obtain a sputum specimen is first thing in the morning, before eating. Use aerosol mist spray of saline solution or water to induce sputum production. Perform cupping and postural drainage if needed. Measure the approximate distance from the patient's nose to his ear. Note the distance; then insert a sterile suction catheter this length, with a collection vial attached, into his nose. Maintain suction during catheter withdrawal. Warn the patient that he may feel discomfort even though his skin will be anesthetized before this procedure. After the tap, check the site often for local swelling, and report dyspnea and other adverse reactions.
Lower intestinal tract	<ul style="list-style-type: none"> Rectal swab Stool specimen 	<ul style="list-style-type: none"> A lesion on the colon or rectal wall may require a colonoscopy or sigmoidoscopy to obtain the specimen. If so, explain the procedure. Help the patient to assume a left lateral decubitus or knee-chest position. The specimen should contain any pus or blood present in stool and a sampling of the first, middle, and last portion of stool. Urine with stool can invalidate results. Send the specimen to the laboratory at once in a clean, tightly covered container, especially stool being examined for ova and parasites.
Eye	<ul style="list-style-type: none"> Cotton swab Corneal scrapings 	<ul style="list-style-type: none"> Carefully retract the lower lid, and gently swab the conjunctiva. The doctor uses a swab loop to scrape the specimen from the site of corneal infection. Reassure the patient that the procedure is short and discomfort is minimal.
Genital tract	<ul style="list-style-type: none"> Swab specimen 	<ul style="list-style-type: none"> A specimen from a male should contain urethral discharge or prostatic fluid; from a female, the specimen should contain urethral or cervical specimens. Always collect specimens on two swabs simultaneously.
Urinary tract	<ul style="list-style-type: none"> Midstream clean-catch urine (avoids specimen contamination with microorganisms commonly found in the lower urethra and perineum) Indwelling urinary catheter specimen 	<ul style="list-style-type: none"> A midstream clean-catch specimen in an infected person should contain fewer than 10,000 bacteria/ml. Teach the patient how to collect the specimen or supervise collection. In males, retract the foreskin and clean the glans penis; in females, clean and separate the labia so the urinary meatus is clearly visible; then clean the meatus. Tell the patient to void 25 to 30 ml first; then, without stopping the urine stream, collect the specimen. In infants, apply the collection bag carefully and check it frequently to avoid mechanical urethral obstruction. Send the urine specimen to the laboratory immediately, or refrigerate it to retard growth. Clean the specimen port of the catheter with povidone-iodine, and aspirate urine with a sterile needle, or from a latex catheter, at a point distal to the "Y" branch.
Body fluids	<ul style="list-style-type: none"> Needle aspiration 	<ul style="list-style-type: none"> Send peritoneal and synovial fluid and cerebrospinal fluid (CSF) to the laboratory at once. Don't retard the growth of CSF organisms by refrigerating the specimen. After pericardial and pleural fluid aspiration, observe the patient carefully and check vital signs often. Watch for signs of pneumothorax or cardiac tamponade.
Blood	<ul style="list-style-type: none"> Venous or arterial aspiration 	<ul style="list-style-type: none"> Prepare the skin according to your facility's policy. Using a sterile syringe, collect 12 to 15 ml of blood, changing needles before injecting blood into the aerobic and anaerobic collection bottles. Continue the procedure according to your facility's policy. If the patient is receiving antibiotics, note this on the laboratory slip because the laboratory may add enzymes or resins to the culture to inactivate the drug.

Gram-positive cocci

Although most gram-positive cocci cause organ-specific disorders, *Staphylococcus aureus* and group A beta-hemolytic streptococci cause systemic disorders.

METHICILLIN-RESISTANT *STAPHYLOCOCCUS AUREUS*

Methicillin-resistant *S taphylococcus aureus* (MRSA) is a mutation of a very common bacterium that is spread easily by direct person-to-person contact. Once limited to large teaching facilities and tertiary care centers, MRSA is now endemic in nursing homes, long-term care facilities, and even community facilities.

MRSA has become prevalent with the overuse of antibiotics. Over the years, overuse has given once-susceptible bacteria the chance to develop defenses against antibiotics. This new capability allows resistant strains to flourish when antibiotics knock out their more sensitive cousins.

Causes

MRSA enters a health care facility through an infected or colonized (symptom-free, but infected) patient or colonized health care worker. MRSA has been recovered from environmental surfaces, but it's transmitted mainly on health care workers' hands. Many colonized individuals become silent carriers. The most frequent site of colonization is the anterior nares (40% of adults and most children become transient nasal carriers). The groin, axilla, and gut are less common colonization sites. Typically, MRSA colonization is diagnosed by isolating bacteria from nasal secretions.

If a person's natural defense system breaks down, such as after an invasive procedure, trauma, or chemotherapy, the normally benign bacteria can invade tissue, proliferate, and cause infection. Today, up to 90% of *S. aureus* isolates or strains are penicillin-resistant, and about 27% of all *S. aureus* isolates are resistant to methicillin, a penicillin derivative. These strains may also resist cephalosporins, aminoglycosides, erythromycin, tetracycline, and clindamycin.

Patients most at risk for MRSA include immunosuppressed patients, burn patients, intubated patients, and those with central venous catheters, surgical wounds, or dermatitis. Others at risk include those with prosthetic devices, heart valves, and postoperative wound infections. Other risk factors include prolonged facility stays, extended therapy with multiple or broad-spectrum antibiotics, and close proximity to those colonized or infected with MRSA. Also at risk are patients with acute endocarditis, bacteremia, cervicitis, meningitis, pericarditis, and pneumonia.

Complications

This infection can lead to sepsis and death in severely affected individuals.

Assessment findings

The carrier patient is often asymptomatic. Symptomatic patients exhibit signs and symptoms related to the primary diagnosis. Depending on the source of the infection and the reason the patient is being treated, the patient may exhibit respiratory, cardiac, or other major system symptoms. Further assessment should focus on the affected system. For example, if the patient has a lung infection, assessment finding may include fever, sputum, and coarse rhonchi.

Cultures from suspicious wounds, skin, urine, or blood show a positive culture for MRSA incidentally.

Diagnostic tests

MRSA can be cultured from the suspected site with the appropriate culture method. For example, MRSA in a wound infection can be cultured, using a swab technique, as in a culturette. Blood, urine, and sputum cultures reveal sources of MRSA.

Treatment

To eradicate MRSA colonization in the nares, the doctor may order topical mupirocin applied inside the nostrils. Other protocols use a topical agent in combination with an oral antibiotic. Most facilities keep patients in isolation until cultures are negative.

To attack MRSA infection, vancomycin is the drug of choice. A serious possible adverse effect caused mostly by histamine release is itching ranging to anaphylaxis. Some clinicians also add rifampin, but whether rifampin acts synergistically or antagonistically when given with vancomycin is controversial.

Nursing diagnoses

- u Altered tissue perfusion (cardiopulmonary)
- u Fluid volume deficit
- u Hyperthermia
- u Impaired tissue integrity
- u Pain

Key outcomes

- u The patient's collateral circulation will be maintained.
- u The patient will attain hemodynamic stability.
- u The patient will maintain adequate cardiac output.
- u The patient will remain afebrile.
- u The patient's fluid volume will remain adequate.

Nursing interventions

- u Consider grouping infected patients together and having the same nursing staff care for them.
- u Wash hands before and after caring for the patient (the most effective way to prevent MRSA from spreading). Use an antiseptic soap, such as chlorhexidine; bacteria have been cultured from worker's hands after washing with milder soap. MRSA could survive on health care workers' hands for up to 3 hours.
- u Use contact isolation precautions when in contact with the patient. A private room and dedicated equipment should be used; the environment should be disinfected.
- u Change gloves when contaminated or when moving from a soiled area of the patient's body to a clean one.
- u Equipment used on the patient shouldn't be laid on the bed or bed stand and should be wiped with appropriate disinfectant before leaving the room.
- u Ensure judicious and careful use of antibiotics. Encourage physicians to limit the use of antibiotics.

Patient teaching

- u Provide teaching and emotional support to the patient and family members.
- u Instruct family and friends to wear protective garb when they visit the patient, and show them how to dispose of it.
- u Instruct the patient to take antibiotics for the full prescription period, even if he begins to feel better.

NECROTIZING FASCIITIS

Most commonly known as “flesh-eating bacteria,” necrotizing fasciitis is a progressive, rapidly spreading inflammatory infection of the deep fascia. It's also referred to as hemolytic streptococcal gangrene, acute dermal gangrene, suppurative fasciitis, and synergistic necrotizing cellulitis.

Necrotizing fasciitis destroys the fascia and fat tissues, with secondary necrosis of subcutaneous tissue. It's most commonly caused by the pathogenic bacteria, *Streptococcus pyogenes*, also known as group A streptococcus (GAS), but other aerobic and anaerobic pathogens may be present. This severe and potentially fatal infection may begin at the site of a small insignificant wound or a surgical incision and is characterized by invasive and progressive necrosis of the soft tissue and underlying blood supply.

Necrotizing fasciitis has been described in medical literature since the Civil War. It accounts for 8% of reported cases of invasive GAS infections today. Men are 3 times more likely to develop this rare condition than women. The disease rarely occurs in children except in countries with poor hygiene practices.

The mean age of the population contracting the disease is 38 to 44 years of age. The mortality rate is very high at 70% to 80%. Mortality drops significantly and prognosis improves with early intervention and treatment. Aggressive treatment with surgery, antibiotics, and hyperbaric oxygen therapy has been shown to reduce the mortality rate to as low as 9% to 20%.

Causes and pathophysiology

In necrotizing fasciitis, group A beta-hemolytic *Streptococcus* and *Staphylococcus aureus*, alone or together, are most often the primary infecting bacteria. There are more than 80 types of the causative bacteria, *S. pyogenes*, making the epidemiology of GAS infections complex. Other aerobic and anaerobic pathogens include *Bacteroides*, *Clostridium*, *Peptostreptococcus*, Enterobacteriaceae, coliforms, *Proteus*, *Pseudomonas*, and *Klebsiella*.

Risk factors for contracting necrotizing fasciitis include advanced age, human immunodeficiency virus infection, alcohol abuse, and varicella infection. Patients with chronic illness, such as cancer, diabetes, cardiac and pulmonary disease, and kidney disease requiring hemodialysis, are also at risk for contracting necrotizing fasciitis. Those using steroids are more susceptible to GAS infection due to debilitated immune responsiveness.

The infecting bacteria in this disorder enter the host through a local tissue injury or a breach in a mucous membrane barrier. Wounds as minor as pinpricks, needle punctures, blisters, and abrasions or as serious as a traumatic injury or surgical incision can provide an opportunity for bacteria to enter the body.

The organisms proliferate in an environment of tissue hypoxia caused by trauma, recent surgery, or a medical condition that compromises the patient. The end product of the invasion is necrosis of the surrounding tissue, which accelerates the disease process by creating a favorable environment for these organisms.

Complications

High mortality rates associated with necrotizing fasciitis have been attributed to the emergence of more virulent strains of streptococci caused by changes in the bacteria's deoxyribonucleic acid. This accounts for an increase in the frequency and severity of cases reported since 1985, after 50 to 60 years of insignificant clinical disease.

Other complications include renal failure, septic shock with cardiovascular collapse, and scarring with cosmetic deformities. Without treatment, involvement of deeper muscle layers can result in myositis or myonecrosis.

Assessment findings

Pain, out of proportion to the size of the wound or injury it is associated with, is usually the first symptom of necrotizing fasciitis and generally presents before all other physical findings.

The infective process usually begins with a mild area of erythema at the site of insult, which quickly progresses within the first 24 hours. During the first 24- to 48-hour period, the erythema changes from red to purple in color and then blue, with the formation of fluid-filled blisters and bullae appearing, indicating the rapid progression of the necrotizing process. By days 4 and 5, multiple patches of this erythema form, producing large areas of gangrenous skin. By days 7 to 10, dead skin begins to separate at the margins of the erythema, revealing extensive necrosis of the subcutaneous tissue. At this stage, fascial necrosis is typically more advanced than appearance would suggest.

Other clinical symptoms include fever and hypovolemia and, in later stages, hypotension, respiratory insufficiency, and signs of overwhelming sepsis requiring supportive care. In the most severe cases, necrosis advances rapidly until several large areas are involved, causing the patient to become mentally cloudy, delirious, or even unresponsive.

Diagnostic tests

Tissue biopsy is the best method of diagnosing necrotizing fasciitis. Cultures of microorganisms can be obtained locally from the periphery of the spreading infection or from deeper tissues during surgical debridement. Gram's staining and culturing of biopsied tissue are useful in establishing the type of invasive organisms and the most effective treatment against them.

Radiographic studies can pinpoint the presence of subcutaneous gases. Computed tomography scans can locate the anatomic site of involvement by locating necrosis. In combination with clinical assessment, magnetic resonance imaging is used to determine areas of necrosis and the need for surgical debridement.

Other supportive studies include laboratory values, such as complete blood count with differential, electrolytes, glucose, blood urea nitrogen and creatinine, urinalysis, and arterial blood gases.

Treatment

Prompt and aggressive exploration and debridement of suspected necrotizing fasciitis is mandatory to provide an early and definitive diagnosis and enhance the patient's prognosis. Ninety percent of patients that present with clinical signs and symptoms need immediate surgical debridement, fasciectomy, or amputation.

Penicillin, clindamycin (Cleocin), metronidazole (Flagyl), ceftriaxone (Rocephin), gentamicin (Garamycin), chloramphenicol (Chloromycetin), and ampicillin (Omnipen) are some of the medications used orally, I.V., or intramuscularly to combat the organisms involved with necrotizing fasciitis. The particular drugs used are determined by the sensitivity of the organisms in culture. Medications in combination must be used when the infection is polymicrobial. Drug recommendations continue to change as new antibiotics are developed and new resistance emerges.

Hyperbaric oxygen therapy (HBO) may decrease the mortality rate and significantly improve tissues' defense against infection. HBO prevents necrosis from spreading by increasing the normal oxygen saturations of infected wounds by a thousand-fold, causing a bactericidal effect. Typical treatment involves HBO started aggressively after the first surgical debridement and continuing for 10 to 15 sessions.

Nursing diagnoses

⌞ Altered tissue perfusion (cardiopulmonary) ⌞ Fluid volume deficit ⌞ Hyperthermia ⌞ Impaired tissue integrity ⌞ Pain

Key outcomes

- ⌞ The patient's collateral circulation will be maintained.
- ⌞ The patient will attain hemodynamic stability.
- ⌞ The patient will maintain adequate cardiac output.
- ⌞ The patient will remain afebrile.
- ⌞ The patient's fluid volume will remain adequate.

Nursing interventions

- ⌞ Administer antibiotic therapy immediately.
- ⌞ Monitor vital signs, and report changes in trends immediately.
- ⌞ Conduct accurate and frequent assessments of the patient's level of pain, mental status, wound status, and vital signs to determine the progression of wounds or the development of new signs and symptoms. Report and document changes immediately.
- ⌞ Provide supportive care, such as endotracheal intubation, cardiac monitoring, fluid replacement, and supplemental oxygen as appropriate.
- ⌞ Be alert for signs and symptoms of toxic shock syndrome, which can occur with any streptococcal soft tissue infection, and the development of shock, acute respiratory distress syndrome, renal impairment, and bacteremia, any of which can lead to sudden death.

Patient teaching

- ⌞ Explain to the patient and family members that caring for postoperative patients and those with trauma wounds requires strict aseptic technique, good hand washing, and barriers between health care providers and patients to prevent contamination.
- ⌞ Urge health care workers with sore throats to see their doctors to determine if they have streptococcal infection. If they are diagnosed positive, they should stay home from work for at least 24 hours after initiation of antibiotic therapy.

SCARLET FEVER

Although scarlet fever (scarlatina) usually follows streptococcal pharyngitis, this disorder also may follow other streptococcal infections, such as wound infections, urosepsis, and puerperal sepsis. It's most common in children ages 3 to 15. The incubation period commonly lasts from 2 to 4 days but may be only 1 day or extend to 7 days.

Causes

Group A beta-hemolytic streptococci cause scarlet fever. The infecting strain produces one of three erythrogenic toxins, which triggers a sensitivity reaction in the patient.

Complications

This disorder can lead to severe disseminated toxic illness, septicemia, rheumatic heart disease, and liver damage.

Assessment findings

The patient may report a sore throat, headache, chills, anorexia, abdominal pain, and malaise. He's likely to have a temperature of 100° to 103° F (37.8° to 39.4° C). In addition, he commonly has had contact with a person with a sore throat.

Inspection of the patient's mouth initially shows an inflamed and heavily coated tongue. As the disease progresses, you'll note a strawberry-like tongue. As it progresses further, the tongue begins to peel and becomes beefy red. It returns to normal by the end of the second week. The uvula, tonsils, and posterior oropharynx appear red and edematous, with mucopurulent exudate.

Inspection of the skin may reveal a fine, erythematous rash that appears first on the upper chest and back. It later spreads to the neck, abdomen, legs, and arms but doesn't appear on the soles and palms. The rash resembles sunburn with goose bumps and blanches when you apply pressure. The patient's face appears flushed, except around the mouth, which remains pale. During convalescence, the skin sheds.

The cervical lymph nodes feel enlarged and tender on palpation. The liver also may feel slightly enlarged and tender, and you may note tachycardia.

Diagnostic tests

A pharyngeal culture is positive for group A beta-hemolytic streptococci. A complete blood count reveals granulocytosis and, possibly, a reduced red blood cell count.

Treatment

Antibiotic therapy with penicillin or erythromycin is administered for 10 days, along with antipyretics.

Nursing diagnoses

- Activity intolerance
- Altered oral mucous membrane
- Hyperthermia
- Impaired skin integrity
- Pain
- Risk for infection

Key outcomes

- The patient's mucous membranes will remain moist, pink, and free from lesions.
- The patient will chew and swallow without discomfort.
- The patient will remain free from all signs and symptoms of infection.
- The patient will express feeling of comfort or absence of pain at rest.
- The patient's temperature will remain normothermic.

Nursing interventions

- Implement respiratory secretion precautions for 24 hours after starting antibiotic therapy.
- Keep the patient on complete bed rest while he's febrile to prevent complications, promote recovery, and help conserve his energy.
- Offer frequent oral fluids and oral hygiene, and administer antipyretics as ordered.
- Apply topical anesthetics on the patient's tongue and throat to relieve pain.
- Provide skin care to relieve discomfort from the rash.

Patient teaching

- Instruct the patient (or his parents) to make sure he takes his oral antibiotics for the prescribed length of time.

TOXIC SHOCK SYNDROME

Toxic shock syndrome, or TSS, is an acute, life-threatening condition that affects 1 in 100,000. TSS primarily affects young individuals. In the early convalescent period, it's characterized by fever, hypotension, rash, multiorgan dysfunction, and desquamation.

Causes and pathophysiology

Toxic shock syndrome is caused by penicillin-resistant *Staphylococcus aureus*, which produce exoproteins that are toxic in nature. TSST-1 is the toxin most often detected, and staphylococcal enterotoxin B is second most frequent.

For illness to develop, the patient must be infected with a toxigenic strain of *S. aureus* and lack antibodies to that strain. More than 90% develop antibodies by adulthood.

Menstruation is the most common setting for TSS occurrence, but half of all cases occur in settings other than menstruation and individuals of both sexes and all ages can be affected. Although tampons are clearly implicated in this infection, their exact role is uncertain. They may contribute to the infection by:

- introducing *S. aureus* into the vagina during insertion
- absorbing toxin from the vagina
- traumatizing the vaginal mucosa during insertion, thus leading to infection
- providing a favorable environment for growth of *S. aureus*.

Complications

TSS can complicate the patient's use of contraceptives, the puerperium, septic abortion, and gynecologic surgery. Postoperative infections can develop hours to weeks after a surgical procedure. It has also been associated with musculoskeletal and respiratory infections caused by *S. aureus* and with staphylococcal bacteremia.

Complications of organ hypoperfusion from TSS include renal and myocardial dysfunction, massive edema, adult respiratory distress syndrome, and desquamation of the skin. Late signs include peripheral gangrene, reversible nail and hair loss, muscle weakness, and neuropsychiatric dysfunction.

Assessment findings

The illness begins with a high fever (104° F [38.9° C] or higher), intense myalgia, nausea, vomiting, diarrhea, sore throat, and headache. Hypotension that develops can cause dizziness. The patient's mental status is often abnormal.

Macular erythroderma occurs over the first 2 days of the illness. The rash is usually generalized but is sometimes only locally confined and may or may not be

persistent.

Strawberry tongue develops in half of the cases, and many develop conjunctival suppression, pharyngeal infection, and peripheral edema. Inspection may reveal vaginal hyperemia and purulent vaginal discharge.

Diagnostic tests

Isolation of *S. aureus* from vaginal discharge or the infection site helps support the diagnosis, but a confirmed diagnosis must follow the criteria set by the Centers for Disease Control and Prevention. (See [Guidelines for diagnosing toxic shock syndrome.](#))

Negative results on blood tests for Rocky Mountain spotted fever, leptospirosis, and measles help rule out these disorders. Common laboratory abnormalities include azotemia, hypoalbuminemia, hypocalcemia, hypophosphatemia, elevated creatinine kinase level, leukocytosis or leukopenia, thrombocytopenia, and pyuria.

Treatment

Appropriate treatment may consist of I.V. antistaphylococcal antibiotics, such as clindamycin oxacillin, nafcillin, and methicillin. To reverse shock, the patient needs fluid replacement with saline solution and colloids.

Sustained hypotension that is unresponsive to fluids should be treated with vasopressors, and electrolyte imbalances should be corrected. I.V. immunoglobulin may be considered for severe cases.

Other measures may include supportive treatment for diarrhea, nausea, and vomiting.

Guidelines for diagnosing toxic shock syndrome

Toxic shock syndrome is typically diagnosed when the following criteria have occurred:

- fever 102° F (38.9° C) or higher
- diffuse macular erythrodermal rash (sunburn rash)
- hypotension (systolic blood pressure 90 mm Hg or less in adults or under the fifth percentile for age)
- involvement of at least three organ systems:
 - GI (vomiting, diarrhea)
 - muscular (myalgias or serum creatinine kinase level of at least two times greater than normal upper limit)
 - mucous membrane hyperemia (conjunctiva, vagina, oropharyngeal)
 - renal (BUN or creatinine level at least two times upper limit of normal or pyuria)
 - hepatic (total serum bilirubin or amine transferase level two times normal level)
 - hematologic (thrombocytopenia)
 - central nervous system (disorientation or change in level of consciousness)
 - desquamation 1 to 2 weeks after onset of illness, especially of palms and soles
 - other conditions ruled out.

Nursing diagnoses

▫ Altered tissue perfusion (renal, cerebral, cardiopulmonary, GI, or peripheral) ▫ Fluid volume deficit ▫ Hyperthermia ▫ Impaired tissue integrity ▫ Pain

Key outcomes

▫ The patient's collateral circulation will be maintained.
▫ The patient will attain hemodynamic stability (as evidenced by systolic blood pressure 90 mm Hg or higher in adults or higher than fifth percentile for age).
▫ The patient will maintain adequate cardiac output.
▫ The patient will remain afebrile.
▫ The patient's fluid volume will remain adequate.

Nursing interventions

▫ Frequently monitor the patient's vital signs.
▫ Administer I.V. antibiotics over a 15-minute period to ensure peak levels that destroy microorganisms. Watch for signs of penicillin allergy.
▫ Check the patient's fluid and electrolyte balance. Replace fluids by I.V. as ordered.
▫ Monitor intake, output, and weight daily to assess fluid balance and to prevent dehydration and renal failure.
▫ Obtain specimens of vaginal and cervical secretions for culture of *S. aureus*.
▫ Check neurologic vital signs every 4 to 8 hours. Reorient the patient as needed.
▫ Use appropriate safety measures to prevent injury.
▫ Use standard precautions for any vaginal discharge and lesion drainage.
▫ Administer analgesics cautiously because of the risk of hypotension and liver failure.

Patient teaching

▫ Advise the patient to avoid using tampons, particularly the superabsorbent type, because of the risk of recurrence.

VANCOMYCIN INTERMITTENT-RESISTANT STAPHYLOCOCCUS AUREUS

Vancomycin intermittent-resistant *Staphylococcus aureus* (VISA) is a mutation of a bacterium that is spread easily by direct person-to-person contact. It was first discovered in mid-1996 when clinicians discovered the microbe in a Japanese infant's surgical wound. Similar isolates were later reported in Michigan and New Jersey. Both patients had received multiple courses of vancomycin for methicillin-resistant *S. aureus* infections.

Another mutation, vancomycin-resistant *S. aureus* (VRSA), is fully resistant to vancomycin.

Causes

VISA or VRSA enters a health care facility through an infected or colonized (symptom-free but infected) patient or colonized health care worker. It's spread during direct contact between the patient and caregiver or patient-to-patient. It may also be spread through patient contact with contaminated surfaces, such as an over-bed table. It's able to live for weeks on surfaces. It has been detected on patient gowns, bed linens, and handrails.

A colonized patient is more than 10 times as likely to become infected with the organism, such as through a breach in the immune system. Patients most at risk for resistant organisms include immunosuppressed patients or those with severe underlying disease; patients with a history of taking vancomycin, third-generation cephalosporins, or antibiotics targeted at anaerobic bacteria (such as *Clostridium difficile*); patients with indwelling urinary or central venous catheters; elderly patients, especially those with prolonged or repeated hospital admissions; patients with malignancies or chronic renal failure; patients undergoing cardiothoracic or

intra-abdominal surgery or organ transplants; patients with wounds with an opening to the pelvic or intra-abdominal area, such as surgical wounds, burns, and pressure ulcers; patients with enterococcal bacteremia, often associated with endocarditis; and patients exposed to contaminated equipment or to a patient with the infecting microbe.

Complications

VISA can cause sepsis, multisystem organ involvement, and death in an immunocompromised patient.

Assessment findings

The carrier patient is commonly asymptomatic but may exhibit signs and symptoms related to the primary diagnosis. Depending on the source of the infection and the reason for treatment, the patient may exhibit cardiac, respiratory, or other major symptoms. Assessment should focus on the affected body system.

Diagnostic tests

The causative agent may be found incidentally when culture results show the organism. A person with no signs or symptoms of infection is considered colonized if VISA or VRSA can be isolated from stool or a rectal swab.

Treatment

There is virtually no antibiotic to combat VISA or VRSA. Because no single antibiotic is currently available, the doctor may opt not to treat an infection at all. Instead, he may stop all antibiotics and simply wait for normal bacteria to repopulate and replace the strain. Combinations of various drugs may also be used, depending on the source of the infection.

To prevent the spread of VISA and VRSA, some hospitals perform weekly surveillance cultures on at-risk patients in intensive care units or oncology units and those transferred from a long-term care facility. Any colonized patient is then placed in contact isolation until his culture is negative or he's discharged. Colonization can last indefinitely, and no protocol is established for the length of time a patient should remain in isolation.

Recently, the Centers for Disease Control and Prevention and the Hospital Infection Control Practices Advisory Committee proposed a two-level system of precautions to simplify isolation for resistant organisms. The first level calls for standard precautions, which incorporate features of universal blood and body fluid precautions and body substance isolation precautions. The second level calls for transmission-based precautions, implemented when a particular infection is suspected.

Nursing diagnoses

u Altered tissue perfusion (cardiopulmonary) u Fluid volume deficit u Hyperthermia u Impaired tissue integrity u Pain

Key outcomes

- u The patient's collateral circulation will be maintained.
- u The patient will attain hemodynamic stability.
- u The patient will maintain adequate cardiac output.
- u The patient will remain afebrile.
- u The patient's fluid volume will remain adequate.

Nursing interventions

- u Wash hands before and after care of the patient. Good hand washing is the most effective way to prevent VISA and VRSA from spreading. Use an antiseptic soap such as chlorhexidine; bacteria have been cultured from workers' hands after washing with milder soap.
- u Consider grouping infected patients together and having the same nursing staff care for them.
- u Contact isolation precautions should be used when in contact with the patient. A private room should be used. Use dedicated equipment and disinfect the environment.
- u Change gloves when contaminated or when moving from a soiled area of the body to a clean one.
- u Don't touch potentially contaminated surfaces, such as a bed or bed stand, after removing gown and gloves.
- u Be particularly cautious in caring for a patient with an ileostomy, colostomy, or draining wound that isn't contained by a dressing.
- u Equipment used on the patient shouldn't be laid on the bed or bed stand and should be wiped with appropriate disinfectant before leaving the room.
- u Ensure judicious and careful use of antibiotics. Encourage physicians to limit the use of antibiotics.

Patient teaching

- u Instruct family and friends to wear protective garb when they visit the patient. Demonstrate how to dispose of it.
- u Provide teaching and emotional support to the patient and family members.
- u Instruct the patient to take antibiotics for the full prescription period, even if he begins to feel better.

Gram-negative cocci

Most gram-negative organisms cause organ-specific disorders. *Neisseria gonorrhoeae*, however, causes gonorrhea—a disorder that can become systemic.

GONORRHEA

Gonorrhea is a common venereal disease that usually starts as an infection of the genitourinary tract, especially the urethra and cervix. It also can begin in the rectum, pharynx, or eyes. Left untreated, gonorrhea spreads through the blood to the joints, tendons, meninges, and endocardium; in women, it also can lead to chronic pelvic inflammatory disease (PID) and sterility.

Among sexually active individuals, incidence rates are highest in teenagers, nonwhites, the poor, poorly educated, city dwellers, and unmarried people who live alone. It's also prevalent in people with multiple partners. With adequate treatment, the prognosis is excellent, although reinfection is common.

Causes and pathophysiology

Transmission of *N. gonorrhoeae*, the organism that causes gonorrhea, occurs almost exclusively through sexual contact with an infected person. A child born to an infected mother can contract gonococcal ophthalmia neonatorum during passage through the birth canal. A person with gonorrhea can contract gonococcal conjunctivitis by touching his eyes with a contaminated hand.

On exposure, the gonococci infect mucus-secreting epithelial surfaces. They attach to the columnar or transitional epithelium and penetrate through or between the cells to the connective tissue. This causes inflammation and spread of the infection.

Complications

Gonorrhea can lead to PID, acute epididymitis, proctitis, salpingitis, septic arthritis, dermatitis, and perihepatitis. Severe gonococcal conjunctivitis can lead to corneal ulceration and, possibly, blindness. Rare complications include meningitis, osteomyelitis, pneumonia, and adult respiratory distress syndrome.

Assessment findings

The patient may report unprotected sexual contact (vaginal, oral, or anal) with an infected person, an unknown partner, or multiple sex partners. He also may have a history of sexually transmitted disease.

After a 3- to 6-day incubation period, a male patient may complain of dysuria, although both sexes can remain asymptomatic. A patient with a rectal infection may complain of anal itching, burning, and tenesmus and pain with defecation, or he may be asymptomatic. A patient with a pharyngeal infection may be asymptomatic or may complain of a sore throat.

Assessment of a patient with gonorrhea reveals a low-grade fever. If the disease has become systemic, or if the patient has developed PID or acute epididymitis, the fever is higher. Other assessment findings vary with the infection site.

Inspection of the male patient's urethral meatus reveals a purulent discharge; such discharge may be expressed from a female patient's urethra, and her meatus may appear red and edematous. Inspection of the cervix with a speculum discloses a friable cervix and a greenish-yellow discharge, the most common sign in females. Vaginal inspection reveals engorgement, redness, swelling, and a profuse purulent discharge. (The vagina is the most common infection site in female children over age 1.)

If the patient has a rectal infection, inspection may reveal a purulent discharge or rectal bleeding. In an ocular infection, inspection may reveal a purulent discharge from the conjunctiva; in a pharyngeal infection, inspection may reveal redness and a purulent discharge.

If the infection has become systemic, papillary skin lesions—possibly pustular, hemorrhagic, or necrotic—may appear on the hands and feet.

Palpation of the patient with PID reveals tenderness over the lower quadrant, abdominal rigidity and distention, and adnexal tenderness (usually bilateral). In a patient with perihepatitis, palpation discloses right upper quadrant tenderness.

Your assessment of a patient with a systemic infection may reveal pain and a cracking noise when moving an involved joint. Asymmetrical involvement of only a few joints—typically the knees, ankles, and elbows—may differentiate gonococcal arthritis from other forms of arthritis.

Diagnostic tests

A culture from the infection site (the urethra, cervix, rectum, or pharynx), grown on a Thayer-Martin medium, usually establishes the diagnosis. A culture of conjunctival scrapings confirms gonococcal conjunctivitis. In a male patient, a Gram stain that shows gram-negative diplococci may confirm gonorrhea.

Diagnosis of gonococcal arthritis requires identification of gram-negative diplococci on smear from joint fluid and skin lesions. Complement fixation and immunofluorescent assays of serum reveal antibody titers four times the normal rate.

Treatment

For uncomplicated gonorrhea in adults, the recommended treatment is ceftriaxone given I.M. in a single dose plus 100 mg of doxycycline hyalite given orally twice a day for 7 days. Alternatively, the patient can receive azithromycin 2 g orally in a single dose. For patients who can't take doxycycline or azithromycin, such as pregnant women, treatment consists of 500 mg of oral erythromycin for 7 days.

Disseminated gonococcal infection requires 1 g of ceftriaxone given I.M. or I.V. every 24 hours until asymptomatic, followed by 400 mg of cefepime b.i.d. or 500 mg of ciprofloxacin b.i.d. for 7 days. Adult gonococcal ophthalmia requires 1 g of ceftriaxone given I.M. in a single dose.

Because many strains of antibiotic-resistant gonococci exist, follow-up cultures are necessary 4 to 7 days after treatment and again in 6 months. (For a pregnant patient, final follow-up must occur before delivery.)

Routine instillation of 1% silver nitrate drops or erythromycin ointment into the eyes of neonates has greatly reduced the incidence of gonococcal ophthalmia neonatorum.

Nursing diagnoses

- u Altered sexuality patterns
- u Pain
- u Risk for infection
- u Self-esteem disturbance

Key outcomes

- u The patient will voice feelings about potential or actual changes in sexual activity.
- u The patient will express concern about self-concept, esteem, and body image.
- u The patient will state infection risk factors.
- u The patient will identify signs and symptoms of infection.
- u The patient will remain free from all signs and symptoms of infection.

PREVENTION

Preventing gonorrhea

To prevent gonorrhea, provide the following patient teaching:

- u Tell the patient to avoid sexual contact until cultures prove negative and infection is eradicated.
- u Advise the partner of an infected person to receive treatment even if the partner doesn't have a positive culture. Recommend that the partner avoid sexual contact with anyone until treatment is complete because reinfection is extremely common.
- u Counsel the patient and all sexual partners to be tested for human immunodeficiency virus and hepatitis B infection.
- u Instruct the patient to be careful when coming into contact with any bodily discharges to avoid contaminating the eyes.
- u Tell the patient to take anti-infective drugs for the length of time prescribed.
- u To prevent reinfection, tell the patient to avoid sexual contact with anyone suspected of being infected, to use condoms during intercourse, to wash genitalia with soap and water before and after intercourse, to avoid sharing washcloths and using douches.
- u Advise returning for follow-up testing.

Nursing interventions

- Before treatment, determine if the patient has any drug sensitivities. During treatment, watch closely for signs of a drug reaction.
- Use standard precautions when obtaining specimens for laboratory examination and when caring for the patient. Carefully place all soiled articles in containers, and dispose of them according to facility policy.
- Monitor the patient for complications.
- Isolate the patient with an eye infection.
- If the patient has gonococcal arthritis, apply moist heat to ease pain in affected joints. Administer analgesics as ordered.
- If the doctor or laboratory hasn't already done so, report all cases of gonorrhea to the local public health authorities so that they can follow up with the patient's sexual partners. Examine and test all people exposed to gonorrhea.
- Report all cases of gonorrhea in children to child abuse authorities.
- Routinely instill prophylactic medications, according to hospital protocol, in the eyes of all neonates on admission to the nursery. Check the neonate of an infected mother for any signs of infection. Take specimens for culture from his eyes, pharynx, and rectum.

Patient teaching

- Urge the patient to inform all sexual partners of the infection so that they can seek treatment. (See [Preventing gonorrhea.](#))

Gram-positive bacilli

These bacilli produce a violet color, using a Gram stain. Examples of infections caused by gram-positive bacilli include actinomycosis, botulism, *Clostridium difficile* infections, diphtheria, gas gangrene, listeriosis, nocardiosis, and tetanus.

ACTINOMYCOSIS

This infection is primarily caused by the gram-positive, anaerobic bacillus *Actinomyces israelii*, which produces granulomatous, suppurative lesions with abscesses. Common infection sites are the head, neck, thorax, and abdomen, but actinomycosis can spread to contiguous tissues, causing multiple draining sinuses. Rare sites of actinomycotic infection are the bones, brain, liver, kidneys, and female reproductive organs.

Actinomycosis can occur at any time of life. It affects three times as many males—with peak incidence in middle decades—as females. It's most likely to affect a person with poor dental hygiene or a person who doesn't have access to health care. There is also a higher incidence in those who use intrauterine contraceptive devices or have lower GI tract or female genitourinary tract problems.

Causes

A. israelii occurs as part of the normal flora of the mouth. Infection results from its traumatic introduction into body tissues.

Complications

Diffuse involvement of the maxillofacial subcutaneous tissue and sinuses is the typical complication of actinomycosis. Abscesses and fistulae may involve the brain or be aspirated and cause pneumonia and empyema.

Assessment findings

The patient's signs and symptoms reflect the organ involved. In cervicofacial actinomycosis, a traumatic injury or dental extraction that occurs days to months before the onset of symptoms may be part of the patient history. In GI actinomycosis, abdominal involvement usually is associated with previous surgery, an inflammatory bowel condition, or perforated ulcers or diverticula.

The patient may complain of pain at the infection site and fever. Inspection may reveal edema of the mouth or neck in cervicofacial actinomycosis, a productive cough with occasional hemoptysis in pulmonary actinomycosis, and draining sinuses with any form of the disorder. The exudate characteristically contains sulfur granules (yellowish-gray masses, which actually are colonies of *A. israelii*).

Palpation may reveal tender, indurated swellings in the mouth or neck if that site is infected or possibly a tender mass in the right lower quadrant if ileocecal lesions are present.

Actinomycosis nodules are often mistaken for neoplasms because they mimic their appearance and assessment. Differentiation is necessary, especially in disseminated disease.

Diagnostic tests

Isolation of *A. israelii* in exudate or tissue confirms actinomycosis. Other tests that help identify it are:

- microscopic examination of sulfur granules
- immunofluorescence testing through the Centers for Disease Control and Prevention
- chest X-ray to show lesions in unusual locations, such as the shaft of a rib.

Treatment

Treatment involves high-dose I.V. penicillin or tetracycline therapy for 2 to 6 weeks followed by oral therapy for 6 to 12 months. Surgical excision and drainage of abscesses in all forms of the disease may also be performed, but medical therapy alone is sufficient if the patient isn't critically ill.

Nursing diagnoses

- Anxiety
- Pain
- Risk for infection

Key outcomes

- The patient will express a feeling of comfort and relief from pain.
- The patient's temperature will remain within normal limits.
- The patient will remain free from all signs and symptoms of infection.
- The patient will maintain good personal and oral hygiene.
- The patient will cope with current medical situation without demonstrating severe signs of anxiety.

Nursing interventions

- Follow standard precautions when handling secretions.
- After surgery, provide proper aseptic wound management.
- Administer antibiotics as ordered. Before giving the first dose, obtain an accurate patient history of allergies. Watch for hypersensitivity reactions, such as rash, fever, itching, and signs of anaphylaxis. If the patient has a history of any allergies, keep epinephrine 1:1,000 (for subcutaneous injection) and resuscitative equipment available.

- Administer analgesics as ordered.

Patient teaching

- Stress the importance of good oral hygiene and proper dental care.
- Stress the importance of continuing antibiotic therapy for the extended time to minimize relapse of the disease.

BOTULISM

This life-threatening paralytic illness results from an exotoxin produced by the gram-positive, anaerobic bacillus *Clostridium botulinum*. It occurs as botulism food poisoning, wound botulism, and infant botulism.

Botulism occurs worldwide and affects adults more often than children. The incidence of botulism in the United States had been declining, but the current trend toward home canning has resulted in an upswing in recent years.

The mortality rate is about 25%, with death most often caused by respiratory failure during the first week of illness. Onset within 24 hours of ingestion signals critical and potentially fatal illness.

Causes

Botulism usually results from eating improperly preserved foods, such as home-canned fruits and vegetables, sausages, and smoked or preserved fish or meat. Rarely, it results from wound infection with *C. botulinum*.

Honey contaminated with *C. botulinum* spores is a common source of infection in infants. Findings have shown that an infant's GI tract can become colonized with *C. botulinum* and then the exotoxin is produced within the infant's intestine. (See [Infant botulism](#).)

Complications

Botulism can result in respiratory failure and paralytic ileus.

Assessment findings

The patient may report eating home-canned food 12 to 36 hours before the onset of symptoms.

The patient may complain of vertigo, dry mouth, sore throat, weakness, nausea, vomiting, constipation, and diarrhea. Concurrently or up to 3 days later, he may report diplopia, blurred vision, dysarthria, and dysphagia from cranial nerve impairment. Later, he may experience dyspnea from muscle weakness or paralysis. His body temperature remains normal.

The patient may appear alert and oriented on inspection. Ocular signs may include ptosis and dilated, nonreactive pupils. Oral mucous membranes commonly appear dry, red, and crusted.

Palpation may reveal abdominal distention with absent bowel sounds.

Further assessment may disclose descending weakness or paralysis of muscles in the extremities or trunk, the major physical finding in botulism. The patient's deep tendon reflexes may be intact, diminished, or absent. Pathologic reflexes and sensory impairment are absent.

Diagnostic tests

Identification of the exotoxin in the patient's serum, stool, or gastric contents, or in the suspected food, confirms the diagnosis. An electromyogram showing diminished muscle action potential after a single supramaximal nerve stimulus also is diagnostic.

Infant botulism

Infant botulism usually afflicts children between 3 and 20 weeks old, and is often associated with a history of honey ingestion. This disorder can produce floppy infant syndrome, which is characterized by constipation, a feeble cry, a depressed gag reflex, and an inability to suck. The infant also exhibits a flaccid facial expression, ptosis, and ophthalmoplegia—the result of cranial nerve deficits.

As the disease progresses, the infant develops generalized weakness, hypotonia, areflexia, and a sometimes blatant loss of head control. Respiratory arrest occurs in almost half of affected infants.

Intensive supportive care allows most infants to recover completely. Antitoxin therapy isn't recommended because of the risk of anaphylaxis.

Diagnosis must rule out conditions often confused with botulism, such as Guillain-Barré syndrome, myasthenia gravis, cerebrovascular accident, staphylococcal food poisoning, tick paralysis, chemical intoxication, carbon monoxide poisoning, fish poisoning, trichinosis, and diphtheria.

Treatment

For adults, treatment consists of I.V. or I.M. administration of botulinum antitoxin (available through the Centers for Disease Control and Prevention).

Early elective tracheotomy and ventilatory assistance can be lifesaving in respiratory failure. The patient needs nasogastric suctioning and total parenteral nutrition (TPN) if he develops significant paralytic ileus.

ALERT Antibiotics and aminoglycosides shouldn't be administered because of the risk of neuromuscular blockade. They should be used only to treat secondary infections.

Nursing diagnoses

- Altered nutrition: Less than body requirements
- Fear
- Impaired physical mobility
- Impaired swallowing
- Impaired verbal communication
- Ineffective airway clearance
- Ineffective breathing pattern
- Pain

Key outcomes

- The patient will experience no further weight loss.
- The patient will communicate feelings of comfort or satisfaction.
- The patient will maintain tissue perfusion and cellular oxygenation.
- The patient's ventilation will remain adequate.

- u The patient will show no sign of neurologic promise.

Nursing interventions

- u If you suspect the patient ate contaminated food, obtain a careful history of his food intake for the past several days. Determine if other family members exhibit similar symptoms and have eaten the same food.
- u Observe the patient carefully for abnormal neurologic signs.
- u If the patient ate the food within several hours, induce vomiting, begin gastric lavage, and give a high enema to purge any unabsorbed toxin from the bowel. Family members or friends who have eaten the same food should also receive this treatment.

Treatment

- u If clinical signs of botulism appear, have the patient admitted to the intensive care unit (isolation isn't required).
- u Monitor cardiac and respiratory function carefully. Assess vital capacity frequently; report reduced vital capacity, reduced inspiratory effort, or respiratory distress.
- u Before giving the antitoxin, obtain an accurate patient history of allergies, especially to horses, and perform a skin test. Then administer botulinum antitoxin, as ordered, to neutralize any circulating toxin. Afterward, watch for anaphylaxis or other hypersensitivity reactions as well as serum sickness. Keep epinephrine 1:1,000 (for subcutaneous administration) and emergency airway equipment available.
- u Closely assess and record the patient's neurologic function, including bilateral motor status (reflexes and ability to move arms and legs). Check the patient's cough and gag reflexes, and suction as needed.
- u If the patient has difficulty swallowing, initiate nasogastric tube feeding or TPN as ordered.
- u Administer I.V. fluids as ordered. Monitor input and output.
- u Encourage deep-breathing exercises, and turn the patient often. Position him in proper alignment, and assist with range-of-motion exercises.
- u If the patient is on mechanical ventilation, monitor his arterial blood gas levels to detect signs of hyperventilation or hypoventilation.
- u If the patient has difficulty speaking, try to anticipate his needs. Assure him that this symptom will pass, and establish an alternative method of communication.
- u Because botulism sometimes is fatal, keep the patient and family members informed about the course of the disease.
- u Immediately report all cases of botulism to local public health authorities.

Patient teaching

- u If ingestion of contaminated food is suspected but the patient returns home before neurologic symptoms occur, advise him and his family to watch for such signs as weakness, blurred vision, and slurred speech. Tell them to return the patient to the facility immediately if such signs appear.
- u To help prevent botulism in the future, encourage the patient and his family to use proper techniques in processing and preserving foods. Warn them to never taste food from a bulging can or one with a peculiar odor and to sterilize, by boiling, any utensil that comes in contact with suspected food. In addition, tell parents not to feed honey to their infants. Explain that eating even a small amount of food contaminated with botulism toxin can be fatal.

CLOSTRIDIUM DIFFICILE INFECTION

Clostridium difficile is a gram-positive anaerobic bacterium. It most often results in antibiotic-associated diarrhea. Symptoms may range from asymptomatic carrier states to severe pseudomembranous colitis and are caused by the exotoxins produced by the organism: Toxin A is an enterotoxin and toxin B is a cytotoxin.

Causes

C. difficile colitis can be caused by almost any antibiotic that disrupts the bowel flora, but it's classically associated with clindamycin use. High-risk groups include individuals on greater numbers of antibiotics, those having abdominal surgery, patients receiving antineoplastic agents that have an antibiotic activity, immunocompromised individuals, pediatric patients (commonly in day-care centers), and nursing home patients.

Other factors that alter normal intestinal flora include enemas and intestinal stimulants. *C. difficile* is most often transmitted directly from patient to patient by contaminated hands of facility personnel; it also may be indirectly spread by contaminated equipment such as bedpans, urinals, call bells, rectal thermometers, nasogastric tubes, and contaminated surfaces such as bed rails, floors, and toilet seats.

Complications

Complications of *C. difficile* include electrolyte abnormalities, hypovolemic shock, anasarca (caused by hypoalbuminemia), toxic megacolon, colonic perforation, peritonitis, sepsis, and hemorrhage. In rare cases, death may result.

Assessment findings

Risk of *C. difficile* begins 1 to 2 days after antibiotic therapy is started and extends for as long as 2 to 3 months after the last dose. The patient may be asymptomatic or may exhibit any of the following symptoms: soft, unformed, or watery diarrhea that may be foul smelling (more than 3 stools in a 24-hour period) or grossly bloody; abdominal pain, cramping, or tenderness; and fever. The patient's white blood cell count may be elevated to 20,000. In severe cases, toxic megacolon, colonic perforation, and peritonitis may develop.

Diagnostic tests

- Diagnosis is by identification of the toxin through one of the following acceptable methods:
- u *cell cytotoxin test*—tests for both toxin A and B; this takes 2 days to perform. It's highly sensitive and specific for *C. difficile*.
 - u *enzyme immunoassays*—slightly less sensitive than the cell cytotoxin test but has a turnaround time of only a few hours. Specificity is excellent.
 - u *stool culture*—the most sensitive test; has a turnaround time of 2 days to obtain results. Non-toxin-producing strains of *C. difficile* can be easily identified and must be further tested for presence of the toxin.
 - u *endoscopy (flexible sigmoidoscopy)*—may be used in a patient who presents with an acute abdomen but no diarrhea, making it difficult to obtain a stool specimen. If pseudomembranes are visualized, treatment for *C. difficile* is usually initiated.

Treatment

After withdrawing the causative antibiotic (if possible), symptoms resolve in patients who are mildly symptomatic. This is usually the only treatment needed. In more severe cases, metronidazole 250 mg should be given orally, four times a day or 500 mg orally three times a day, or vancomycin 125 mg orally, four times a day for 10 days; metronidazole is the preferred treatment. Retesting for *C. difficile* is unnecessary if symptoms resolve.

Ten to 20 percent of patients may have a recurrence with the same organism within 14 to 30 days of treatment. Beyond 30 days, a recurrence may be a relapse or reinfection of *C. difficile*. If the previous treatment was metronidazole, low-dose vancomycin 125 mg four times daily for 21 days may be an effective choice. An alternative treatment combines vancomycin 125 mg four times daily and rifampin 600 mg orally twice a day for 10 days.

There is no evidence to support the effectiveness of eating yogurt or taking lactobacillus. Other experimental treatments involve the administration of yeast *Saccharomyces boulardii* with metronidazole or vancomycin and biologic vaccines to restore the normal GI flora.

Nursing diagnoses

- u Activity intolerance
- u Altered nutrition: Less than body requirements
- u Fatigue
- u Hyperthermia
- u Impaired skin integrity
- u Pain
- u Risk for fluid volume deficit

Key outcomes

- u The patient will remain afebrile.
- u The patient's vital signs will remain stable.
- u The patient's electrolyte levels will stay within normal range.
- u The patient's fluid volume will remain adequate.
- u The patient will exhibit improved or healed lesions or wounds.
- u The patient will verbally report having an increased energy level.

Nursing interventions

- u Patients with known or suspected *C. difficile* diarrhea who are unable to practice good hygiene should be placed in a single room or cohorted with other patients with similar status.
- u Use standard precautions for contact with blood and body fluids for all direct contact with the patient and the immediate environment of the patient.
- u Wash hands with an antiseptic soap after direct contact with the patient or the immediate environment.
- u A patient who is asymptomatic, without diarrhea or fecal incontinence for 72 hours, and who is able to practice good hygiene may be transferred out of the single room.
- u The spores of *C. difficile* are resistant to most common facility disinfectants, thus contamination will remain in the room even though the patient may be discharged. The immediate environment can be thoroughly cleaned and disinfected with 0.5% sodium hypochlorite.
- u Make sure reusable equipment is disinfected before it's used on another patient.

Patient teaching

- u Teach good hand washing technique to prevent the spread of the infection.
- u Review proper disinfection of contaminated clothing or household items.
- u Tell the patient to inform health care workers of his condition before admission.

DIPHTHERIA

Diphtheria is an acute, highly contagious, toxin-mediated infection. It usually infects the respiratory tract, primarily involving the tonsils, nasopharynx, and larynx. Cutaneous, stool, and wound diphtheria are the most common types in the United States, often resulting from nontoxigenic strains. The GI and urinary tracts, conjunctivae, and ears seldom are involved.

Because of effective immunization, diphtheria has become rare in many parts of the world, including the United States. A massive and expanding epidemic of diphtheria in the former Soviet Union has been ongoing since 1990, especially in individuals age 15 and older. In the tropics, cutaneous diphtheria is more common than respiratory diphtheria. It's most likely to strike in areas where crowding and poor hygienic conditions prevail.

Causes

Diphtheria is caused by *Corynebacterium diphtheriae*, a gram-positive rod. Transmission usually occurs through intimate contact or by airborne respiratory droplets from apparently healthy carriers or convalescing patients. Many more people carry this disease than contract active infection.

Diphtheria is more prevalent during the colder months because of closer person-to-person contact indoors, but it can be contracted at any time of the year.

Complications

The extensive pseudomembrane formation and swelling that occur during the first few days of the disease can cause respiratory obstruction. Other complications include myocarditis, polyneuritis (primarily affecting motor fibers but possibly also sensory neurons), encephalitis, cerebral infarction, bacteremia, renal failure, pulmonary emboli, and bronchopneumonia caused by *C. diphtheriae* or other superinfecting organisms. Serum sickness may result from antitoxin therapy.

Assessment findings

The patient's history may show inadequate immunization and an exposure period of less than 1 week. The patient may complain of a sore throat (the most common complaint in adults) and dysphagia; a child is more likely to complain of nausea and vomiting. The patient also may complain of chills, a rasping cough, and hoarseness and may have a temperature of 100° to 102° F (37.8° to 38.9° C).

Inspection may reveal a characteristic thick, patchy grayish-green membrane over the mucous membranes of the pharynx, larynx, tonsils, soft palate, and nose.

If the patient develops respiratory obstruction, inspection reveals stridor; suprasternal and substernal retraction and, possibly, cyanosis; restlessness; and tachypnea. In cutaneous diphtheria, you'll note skin lesions that resemble impetigo.

During palpation, you may note enlarged cervical lymph nodes. If the patient has an obstructed airway, auscultation may disclose diminished breath sounds. (See [Distinguishing diphtheria from similar disorders.](#))

Your assessment may reveal palatal and pharyngeal paralysis, ocular or ciliary paralysis, progressive muscle weakness, and paresthesia in neurologic involvement. You may observe signs of peripheral neuritis 2 to 3 months after the onset of illness.

Diagnostic tests

Culture of throat swabs or of specimens taken from suspicious lesions that show *C. diphtheriae* confirms the diagnosis. Electrocardiogram abnormalities may indicate myocardium involvement.

Treatment

Initial therapy is based on clinical findings and doesn't wait for a confirmed diagnosis based on culture. Standard treatment includes diphtheria antitoxin administered by I.M. or I.V. infusion. Antibiotics, such as penicillin and erythromycin, eliminate organisms from the upper respiratory tract and elsewhere so that the patient doesn't remain a carrier.

ADVANCED PRACTICE

Distinguishing diphtheria from similar disorders

When assessing a patient for diphtheria, you can rule out similar disorders by keeping in mind the distinguishing characteristics of each disorder:

- To distinguish diphtheria from mononucleosis, remember that in diphtheria, a pseudomembrane forms over oral and nasal mucous membranes. Attempts to remove this membrane usually cause bleeding—a characteristic that distinguishes diphtheria from mononucleosis. The membrane produced by mononucleosis doesn't cause bleeding when removed.
- To distinguish diphtheria from streptococcal pharyngitis, note the intensity and onset of symptoms. Streptococcal pharyngitis usually produces a more intense local reaction, a higher fever, and more severe dysphagia.
- To differentiate diphtheria from bacterial epiglottitis, remember that the latter disorder typically develops more acutely. Also, indirect laryngoscopy shows an extremely reddened epiglottis without the membrane typical of diphtheria.

Nursing diagnoses

- Altered nutrition: Less than body requirements
- Impaired skin integrity
- Ineffective airway clearance
- Ineffective breathing pattern
- Risk for fluid volume imbalance
- Risk for infection
- Risk for injury

Key outcomes

- The patient's airway will remain patent.
- The patient's ventilation will be adequate.
- The patient will show no signs of pulmonary compromise.
- The patient will remain free from all signs and symptoms of infection.
- The patient's vital signs will remain stable.
- The patient's skin color and temperature will remain normal.

Nursing interventions

- Obtain cultures as ordered.
- Assess respiratory effort and status. Report stridor, alterations in level of consciousness or oxygen saturation, and cyanosis.
- Administer humidified oxygen as ordered, and elevate the head of the bed to prevent pressure on the diaphragm and compromised breathing.

WARNING

Diphtheria hazards

When caring for a patient with diphtheria, be alert for these potentially life-threatening hazards:

- After giving antitoxin, penicillin, or both, monitor for signs of anaphylaxis, and keep epinephrine 1:1,000 and resuscitative equipment handy.
- In a patient who receives erythromycin, watch for thrombophlebitis.
- Assess for symptoms of airway obstruction. Have a tracheostomy tray available.
- Watch for signs of shock, which can develop suddenly as a result of systemic vascular collapse, airway obstruction, or anaphylaxis.
- Be alert for signs of myocarditis, such as a sudden decrease in pulse rate, an irregular heartbeat, and pallor. Also be alert for heart murmurs and electrocardiogram changes. Ventricular fibrillation is a common cause of sudden death in diphtheria patients. Be prepared to intervene immediately.

- Keep an emergency cricothyrotomy set available in case airway obstruction occurs.
- Offer frequent, small feedings of liquids and soft foods to a patient with mild to moderate dysphagia. Administer parenteral fluids, as ordered, for a patient who can't swallow.
- Administer drugs as ordered. Before giving diphtheria antitoxin, which is made from horse serum, obtain eye and skin tests to determine sensitivity. Although time-consuming and hazardous, desensitization should be attempted if tests are positive because diphtheria antitoxin is the only specific treatment available. If sensitivity tests are negative, the antitoxin is given before laboratory confirmation of the diagnosis because mortality increases when antitoxin administration is delayed.
- After giving antitoxin or penicillin, be alert for anaphylaxis. (See [Diphtheria hazards.](#)) In patients who receive erythromycin, watch for thrombophlebitis.
- Maintain infection and strict isolation precautions until two consecutive negative nasopharyngeal cultures are obtained—at least 1 week after drug therapy stops.
- Report all cases of diphtheria to local public health authorities; follow up on others who have been exposed to the patient, if appropriate.
- If paralysis occurs, assist the patient in a rehabilitation program to restore optimal functioning.

Patient teaching

- Teach the patient proper disposal of nasopharyngeal secretions.
- Explain the need for follow-up testing. Advise the patient to expect a prolonged convalescent period.
- Treatment of exposed individuals with antitoxin remains controversial. Suggest that the patient's family members later receive diphtheria toxoid (usually given as combined diphtheria and tetanus toxoids or as a combination including pertussis vaccine for children under age 6) if they haven't been immunized.
- Stress the need for childhood immunizations to all parents.

GAS GANGRENE

This rare condition is caused by local infection with the anaerobic, spore-forming, gram-positive, rod-shaped bacillus *Clostridium perfringens* or another clostridial species. It occurs in devitalized tissues and results from compromised arterial circulation after trauma or surgery. The usual incubation period is 1 to 4 days but can vary from 3 hours to 6 weeks or longer.

Gas gangrene carries a high mortality unless therapy begins immediately. With prompt treatment, 80% of patients with gas gangrene of the extremities survive; the prognosis is poorer for gas gangrene in other sites, such as the abdominal wall or the bowel.

Causes

The organism most often responsible, *C. perfringens*, is a normal inhabitant of the GI and female genitourinary tracts; it's also prevalent in soil. Transmission occurs when the organism enters the body during trauma or surgery.

Because *C. perfringens* is anaerobic, gas gangrene occurs most frequently in deep wounds, especially those in which tissue necrosis further reduces the oxygen supply. When *C. perfringens* invades soft tissues, it produces thrombosis of regional blood vessels, tissue necrosis, and localized edema. Such necrosis releases both carbon dioxide and hydrogen subcutaneously, producing interstitial gas bubbles.

Gas gangrene occurs most commonly in the extremities and in abdominal wounds and less often in the uterus. (See [Effects of Clostridium perfringens.](#))

Complications

Possible complications include renal failure, hypotension, shock, hemolytic anemia, and tissue death, requiring amputation of the affected body part.

Assessment findings

The patient's medical history may reveal recent surgery (within 72 hours), traumatic injury, septic abortion, or delivery. The patient typically complains of sudden, severe pain at the wound site.

Your assessment in the early stage may show a normal body temperature, followed by a moderate increase, usually not above 101° F (38.3° C). Other assessment findings may include hypotension, tachycardia, and tachypnea, all signs of toxemia.

Inspection may reveal localized swelling and discoloration (often dusky brown or reddish), with formation of bullae and necrosis within 36 hours of the onset of symptoms. Soon the skin over the wound may rupture, revealing dark red or black necrotic muscle, accompanied by a foul-smelling, watery or frothy discharge. The patient may appear pale, prostrate, and motionless because of systemic toxicity but usually remains alert and oriented and is extremely apprehensive.

Palpation may reveal subcutaneous emphysema (the presence of gas in the soft tissues), the hallmark of gas gangrene.

In later stages, the patient's level of consciousness may deteriorate to delirium and coma.

Diagnostic tests

Several tests confirm the diagnosis. Anaerobic cultures of wound drainage show *C. perfringens*; a Gram stain of wound drainage discloses large, gram-positive, rod-shaped bacteria; X-rays reveal gas in tissues; and blood studies show leukocytosis and, later, hemolysis.

Diagnostic tests must rule out synergistic gangrene and necrotizing fasciitis. Unlike gas gangrene, both of these disorders anesthetize the skin around the wound.

Treatment

Appropriate treatment includes careful observation for signs of myositis and cellulitis. The patient needs *immediate treatment* if these signs appear and *immediate* wide surgical excision of all affected tissues and necrotic muscle in myositis. Delayed or inadequate surgical excision is fatal.

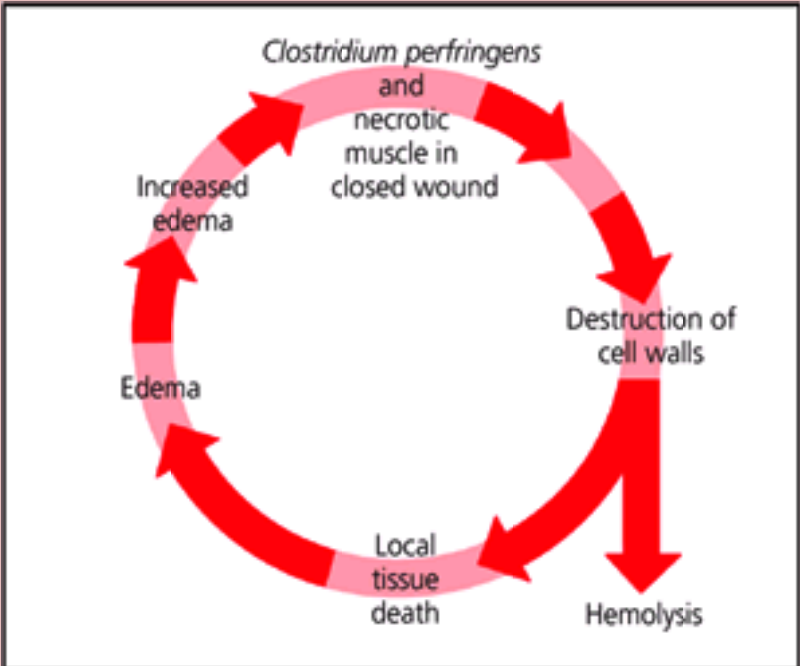

The patient also needs I.V. administration of antibiotics and, after adequate debridement, hyperbaric oxygenation, if available. For 1 to 3 hours every 6 to 8 hours, the patient is placed in a hyperbaric chamber and exposed to pressures designed to increase oxygen tension and prevent multiplication of the anaerobic Clostridia. Surgery may take place within the hyperbaric chamber if the chamber is large enough.

PATHOPHYSIOLOGY

Effects of *Clostridium perfringens*

As *Clostridium perfringens* grows in a closed wound, it destroys cell walls and causes hemolysis, local tissue death, and increasing edema.

CULTURAL TIP If the patient requires amputation of the affected part, ask family members about their wishes for disposal. Members of some cultures may wish to bury the part with a formal ceremony.

Nursing diagnoses

- u Altered tissue perfusion (cardiopulmonary, peripheral)
- u Anxiety
- u Fear
- u Impaired skin integrity
- u Impaired tissue integrity
- u Pain
- u Risk for infection

Key outcomes

- u Hemodynamic stability will be maintained.
- u The patient's skin will remain warm, dry, and intact.
- u The patient will maintain adequate cardiac output.
- u The patient will maintain collateral circulation.
- u The patient will express a feeling of comfort and relief from pain.

Nursing interventions

- u Throughout the patient's illness, provide adequate fluid replacement. Monitor intake and output and central venous pressure.
- u Assess pulmonary and cardiac function often. Maintain the airway and ventilation.
- u To prevent skin breakdown and further infection, provide good skin care. Place the patient on an air mattress or an air-fluidized bed.
- u After surgery, provide meticulous wound care.
- u Before penicillin administration, obtain a patient history of allergies. Afterward, watch closely for signs of a hypersensitivity reaction.
- u Deodorize the room to control foul odor from the wound. Prepare the patient emotionally for a large wound after surgical excision and for possible daily debridement. The wound usually is left open and requires frequent dressing changes and soaks.
- u Dispose of drainage material properly (double-bag dressings in plastic bags for incineration), and wear sterile gloves when changing dressings. No special cleaning measures are required after the patient is discharged.

- u After recovery, refer the patient for physical rehabilitation, as necessary.
- u For the patient who won't survive, psychological support is critical. The patient may remain alert until death, knowing that death is imminent and unavoidable.

Patient teaching

- u Tell any patient who reports sudden, severe, and persistent pain at a wound site to consult a doctor at once.
- u To prevent gas gangrene, routinely take precautions to render all wound sites unsuitable for growth of clostridia by attempting to keep granulation tissue viable. Adequate debridement is imperative to reduce anaerobic growth conditions. Be alert for devitalized tissues, and promptly tell the surgeon if you notice any. Position the patient to facilitate drainage, and eliminate all dead spaces in closed wounds.
- u Teach the patient with a cast or covered wound to report any foul odor or drainage.

LISTERIOSIS

Listeriosis is caused by the weakly hemolytic, gram-positive bacillus *Listeria monocytogenes*. It most often occurs in fetuses, in neonates during the first 3 weeks of life, and in older or immunosuppressed adults. The infected fetus usually is stillborn or born prematurely, almost always with lethal listeriosis. This infection produces a milder illness in pregnant women and varying degrees of illness in older or immunosuppressed patients. The prognosis depends on the severity of the underlying disease.

Causes

The primary method of transmission in neonatal infection is through the placenta in utero or during passage through an infected birth canal. Other modes of transmission include inhaling contaminated dust; drinking contaminated, unpasteurized milk; coming in contact with infected animals, contaminated sewage or mud, or soil contaminated with stool containing *L. monocytogenes*; and, possibly, person-to-person transmission.

Complications

Listeriosis can cause sepsis, diffuse clotting dyscrasias, respiratory insufficiency, circulatory insufficiency, meningitis, cerebritis, granulomatous skin infections, and nonpurulent conjunctivitis.

Assessment findings

The patient's history may be unremarkable, although the patient may report eye or skin exposure to laboratory animals or to animals seen in veterinary practice. An infected pregnant woman—especially if she's in her third trimester—may complain of back pain and malaise. She also may have a fever. The parents of an infected infant may report that he seems acutely ill or simply weak.

Your assessment of an infected pregnant woman may reveal hypotension, although the rest of the assessment may be normal.

You may note that an infant appears acutely ill on inspection. He also may exhibit skin lesions on his trunk or extremities. These may appear as papules and may ulcerate. If he has developed meningitis, you may note irritability, lethargy, seizures, or coma. You'll seldom see fulminant manifestations with coma in an adult unless he develops *Listeria* sepsis. In an infant, abscesses may make organ masses palpable; palpation also discloses tense fontanels if the infant has meningitis.

Other assessment findings may include hypotension and vasodilation if the patient has developed sepsis, although these are less profound than in gram-negative sepsis. You may note diffuse mottling, signs of coagulation abnormalities with septic emboli, and disseminated intravascular coagulation with *Listeria* sepsis.

Diagnostic tests

L. monocytogenes is identified by its tumbling motility on a wet mound of the culture. Other supportive diagnostic test results include positive culture of blood, spinal fluid, drainage from cervical or vaginal lesions, or lochia from a mother with an infected infant; however, isolation of the organism from these specimens often is difficult. The proportion of monocytes in the blood also increases.

Treatment

The patient usually receives I.V. ampicillin or penicillin for 3 to 6 weeks, possibly with gentamicin to increase its effectiveness. Alternative treatments include erythromycin, chloramphenicol, tetracycline, and co-trimoxazole.

Ampicillin and penicillin G, with or without gentamicin, are best for treating meningitis caused by *L. monocytogenes* because they more easily cross the blood-brain barrier. Pregnant women require prompt, vigorous treatment to combat fetal infection.

Nursing diagnoses

- u Altered tissue perfusion (specify type: renal, cerebral, cardiopulmonary, GI, peripheral) u Impaired skin integrity u Ineffective family coping: Disabling u Pain u Risk for infection u Risk for injury

Key outcomes

- u The patient will maintain skin integrity.
- u The patient will maintain fluid balance; input equals output.
- u The patient will express a feeling of comfort or absence of pain at rest.
- u The patient will maintain tissue perfusion and cellular oxygenation.
- u The patient will contact appropriate sources of support outside of the family.
- u The patient will identify recent loss.

Nursing interventions

- u Promptly deliver specimens to the laboratory.
- u Use secretion precautions until a series of cultures are negative. Take special care when handling lochia from an infected mother and secretions from her infant's eyes, nose, mouth, and rectum, including meconium.
- u Use standard precautions when appropriate.
- u Infuse I.V. penicillin (not aminoglycosides) over 15 minutes to ensure adequate blood levels.
- u Monitor for signs of septic shock and disseminated intravascular coagulation.
- u Evaluate neurologic status at least every 2 hours. In an infant, check fontanels for bulging. Maintain adequate I.V. fluid intake; accurately measure intake and output.
- u Institute seizure precautions as needed.
- u Provide psychological support for the parents of a critically ill neonate or a stillborn infant.

Patient teaching

- u Teach the adult patient proper disposal of infectious material.

NOCARDIOSIS

Nocardiosis is an acute, subacute, or chronic bacterial infection. It's caused by a weakly gram-positive species of the genus *Nocardia*—usually *Nocardia asteroides*. There are approximately 1,000 cases annually in the United States. The disease is more common among adults, especially males. Eighty-five percent of these cases are pulmonary or systemic, with the risk greater in individuals with different cell-mediated immunity, particularly those with lymphoma, transplantation, or acquired immunodeficiency syndrome.

Causes

Nocardia is a genus of aerobic, gram-positive bacteria with branching filaments similar in appearance to fungi. Normally found in soil, these organisms occasionally cause disease in humans and animals throughout the world. Their incubation period is unknown, but it is probably several weeks. The usual mode of contact is through soil or vegetable matter. Less often, transmission occurs by direct inoculation through puncture wounds or abrasions.

Complications

Meningitis, seizures, and cardiac arrhythmias are possible complications.

Assessment findings

The patient history may reveal the coexistence of a debilitating disease, such as human immunodeficiency virus infection. The patient may complain of anorexia, weight loss, pleural pain, or dyspnea. With central nervous system (CNS) infection, the patient may report dizziness, headache, and nausea. His body temperature may be as high as 105° F (40.6° C).

You'll note a cough that produces thick, tenacious, mucopurulent and, possibly, blood-tinged sputum. Chills and night sweats also may develop. With CNS infection, the patient may have seizures and become disoriented and confused.

Palpation may reveal subcutaneous abscesses that feel more firm than fluctuant and that lack the induration associated with actinomycosis.

Auscultation of the lungs may reveal crackles. Other assessment findings are variable but may include manifestations of tracheitis, bronchitis, pericarditis, endocarditis, peritonitis, mediastinitis, septic arthritis, keratoconjunctivitis, and purulent meningitis.

Diagnostic tests

Identification of *Nocardia* is by culture of sputum or discharge for crooked, branching, beaded, gram-positive filaments with acid-fast smears. Because *Nocardia* can take up to 4 weeks to grow and culture, the laboratory should be alerted when *Nocardia* infection is suspected. Diagnosis occasionally requires biopsy of lung or other tissue. Chest X-rays vary and may show fluffy or interstitial infiltrates, nodules, or abscesses.

Computed tomography or magnetic resonance imaging of the head, with and without contrast, should be done if brain involvement is suspected. Cerebrospinal fluid (CSF) or urine should be concentrated and cultured. Several presumptive diagnostic tests are under study (antibody testing and metabolites for *Nocardia* in serum or CSF) but aren't yet used clinically.

Treatment

Nocardiosis is treated with sulfonamides as the treatment of choice; minocycline is an alternative to sulfonamides. If the patient fails to respond to sulfonamide treatment, other drugs, such as ampicillin or amikacin can be substituted. Immunosuppressive agents can also be considered if the underlying disease involves organ transplantation. Treatment also includes surgical drainage of abscesses and excision of necrotic tissue. The acute phase requires complete bed rest; as the patient improves, activity can increase.

Nursing diagnoses

⌞ Altered nutrition: Less than body requirements ⌞ Altered tissue perfusion (cerebral, cardiopulmonary) ⌞ Hyperthermia ⌞ Impaired gas exchange ⌞ Impaired physical mobility ⌞ Ineffective airway clearance ⌞ Pain ⌞ Risk for injury

Key outcomes

- ⌞ The patient will cough effectively.
- ⌞ The patient will expectorate sputum.
- ⌞ The patient will have normal breath sounds.
- ⌞ The patient will remain normothermic.
- ⌞ The patient will report pain relief with analgesia on other measures.
- ⌞ The patient will experience no further weight loss.

Nursing interventions

- ⌞ Nocardiosis requires no isolation because it isn't transmitted from person to person.
- ⌞ Provide adequate nourishment through total parenteral nutrition, nasogastric tube feeding, or a balanced diet.
- ⌞ Give tepid sponge baths and antipyretics as ordered to reduce fever and analgesics for headache as needed.
- ⌞ Monitor for allergic reactions to antibiotics.
- ⌞ High-dose sulfonamide therapy (especially sulfadiazine) predisposes the patient to crystalluria and oliguria. So assess frequently, force fluids, and alkalinize the urine with sodium bicarbonate as ordered to prevent these complications.
- ⌞ In a patient with pulmonary infection, perform chest physiotherapy. Auscultate the lungs daily, checking for increased crackles or consolidation. Note and record the amount, color, and thickness of sputum.
- ⌞ In brain infection, regularly assess neurologic function. Watch for signs of increased intracranial pressure, such as decreased level of consciousness and respiratory abnormalities. Use appropriate safety measures to protect the patient from injury.
- ⌞ In long-term hospitalization, turn the patient often, and assist with range-of-motion exercises.
- ⌞ Provide support and encouragement to help the patient and his family cope with this long-term illness.

Patient teaching

- ⌞ Before the patient is discharged, stress the need for a regular medication schedule to maintain therapeutic blood levels, even after symptoms subside. Explain the importance of frequent follow-up examinations.
- ⌞ Teach the patient how to identify symptoms of recurrent disease by assessing sputum and degree of respiratory difficulty.

TETANUS

Also referred to as lockjaw, tetanus is an acute exotoxin-mediated infection caused by the anaerobic, spore-forming, gram-positive bacillus *Clostridium tetani*. The infection usually is systemic, but it may be localized.

Tetanus is entirely preventable by immunization but continues to be common in areas where soil is cultivated, in rural areas, in warm climates, during summer months, and among males. Neonates and the elderly are prominently involved. Because reporting is incomplete, the burden of illness is greater than statistics indicate. In the

United States most cases follow injury, such as a puncture wound, laceration, or abrasion, and are often acquired outdoors.

Tetanus occurs worldwide, but it's more prevalent in agricultural regions and developing countries that lack mass immunization programs. It's one of the most common causes of neonatal deaths in developing countries.

When *C. tetani* enters the body, it causes local infection and tissue necrosis. It also produces toxins that enter the bloodstream and lymphatics and eventually spread to central nervous system tissue.

Causes

Transmission occurs through a puncture wound that is contaminated by soil, dust, or animal excreta containing *C. tetani* or by way of burns or minor wounds.

Complications

Atelectasis, pneumonia, pulmonary emboli, airway obstruction, acute gastric ulcers, seizures, flexion contractures, and cardiac arrhythmias can result from tetanus.

Assessment findings

The patient's history may reveal inadequate immunization, and the patient may report a recent skin wound or burn. He may complain of pain or paresthesia at the site of injury and recall early complaints of difficulty chewing or swallowing food. He usually has a normal body temperature or a slight fever in the early stages, although his fever may increase as the disease progresses.

If the tetanus remains localized, your assessment may disclose signs of spasm and increased muscle tone near the wound. If the tetanus becomes systemic, your assessment may reveal an irregular heartbeat, marked muscle hypertonicity, hyperactive deep tendon reflexes, tachycardia, profuse sweating, low-grade fever, and painful, involuntary muscle contractions. Specific findings may include:

- rigid neck and facial muscles (especially cheek muscles), resulting in lockjaw (trismus) and a grotesque, grinning expression called risus sardonicus
- rigid somatic muscles, causing arched-back rigidity (opisthotonos); palpation reveals boardlike abdominal rigidity
- intermittent tonic seizures that last for several minutes and may result in cyanosis and sudden death by asphyxiation.

Despite pronounced neuromuscular symptoms, assessment shows normal cerebral and sensory function.

The diagnosis must be differentiated from meningitis, rabies, phenothiazine, strychnine toxicity, and other conditions that can mimic tetanus.

Diagnostic tests

Blood cultures and tetanus antibody tests commonly are negative; only one-third of patients have a positive wound culture. Cerebrospinal fluid pressure may increase above normal.

Treatment

Within 72 hours after a puncture wound, a patient with no previous history of tetanus immunization first requires tetanus immune globulin or tetanus antitoxin to confer temporary protection. Next, he needs active immunization with tetanus toxoid. A patient who hasn't received tetanus immunization within 5 years needs a booster injection of tetanus toxoid.

If tetanus develops despite immediate postinjury treatment, the patient requires airway maintenance and a muscle relaxant, such as diazepam, to decrease muscle rigidity and spasm. If muscle contractions aren't relieved by muscle relaxants, a neuromuscular blocker may be needed.

The patient with tetanus also requires high-dose antibiotics—preferably penicillin administered I.V. if he isn't allergic to it. If he is allergic to penicillin, tetracycline can be substituted.

Nursing diagnoses

- Altered nutrition: Less than body requirements
- Altered tissue perfusion (specify type: renal, cerebral, cardiopulmonary, GI, peripheral)
- Impaired physical mobility
- Ineffective airway clearance
- Ineffective breathing pattern
- Pain
- Risk for injury

Key outcomes

- The patient will maintain fluid balance; intake will equal output.
- The patient will express a feeling of comfort or absence of pain at rest.
- The patient will maintain tissue perfusion and cellular oxygenation.
- The patient's airway will remain patent.
- The patient's ventilation will remain adequate.
- The patient will show no signs of neurologic compromise.

Nursing interventions

- Before tetanus develops, thoroughly debride and clean the injury site with 3% hydrogen peroxide, and check the patient's immunization history. Record the cause of the injury. If it was caused by an animal bite, report the case to local public health authorities.
- Before giving penicillin and tetanus immune globulin, antitoxin, or toxoid, obtain an accurate history of the patient's allergies to immunizations or penicillin. If the patient has a history of any allergies, keep epinephrine 1:1,000 (for subcutaneous injection) and emergency airway equipment available.
- After tetanus develops, maintain an adequate airway and ventilation to prevent pneumonia and atelectasis. Suction as needed and watch for signs of respiratory distress.
- Keep emergency airway equipment on hand because the patient may require artificial ventilation or oxygen administration. Have endotracheal and tracheotomy equipment on hand. In an emergency, the doctor may perform a tracheotomy if the patient becomes extremely rigid.
- Administer I.V. therapy as prescribed. Monitor intake and output.
- Monitor the patient's electrocardiogram for arrhythmias frequently. Also check vital signs. Be prepared to resuscitate the patient and initiate life support.
- Because even minimal external stimulation provokes muscle spasms, keep the patient's room dark and quiet. Warn visitors not to upset or overstimulate the patient.
- Turn the patient frequently to prevent contractures, pressure ulcers, and pulmonary stasis. Perform range-of-motion exercises to maintain flexibility.
- Perform all activities of daily living for the sedated patient.
- Give muscle relaxants and sedatives, as ordered, and schedule patient care to coincide with heaviest sedation.
- Check the patient's skin for signs of pressure ulcers. Place the patient on an air mattress, and use other skin protective measures, as warranted.
- If urine retention develops, insert an indwelling urinary catheter.
- Insert an artificial airway, if necessary, to prevent tongue injury, and maintain the airway during spasms.
- Provide adequate nutrition to meet the patient's increased metabolic needs. He may need nasogastric feeding or total parenteral nutrition.

Patient teaching

- During the patient's convalescence, encourage gradual active exercises.
- Institute a bladder retraining program if the patient was catheterized.

- u Stress the importance of maintaining active immunization with a booster dose of tetanus toxoid every 10 years.
- u Inform the patient with a skin injury or burn that he should receive tetanus prophylaxis.

Gram-negative bacilli

Infections caused by gram-negative bacilli may be mild to life-threatening and have local to systemic effects. Such infections include salmonella infection, shigellosis, *Escherichia coli* and other Enterobacteriaceae infections, *Pseudomonas* infections, and many others.

BRUCELLOSIS

Brucellosis is an acute febrile illness that is transmitted to humans from animals. It's also called undulant fever, Malta fever, Gibraltar fever, Cyprus fever, and Mediterranean fever.

Brucellosis occurs throughout the world, but such measures as pasteurization of dairy products and immunization of cattle have reduced the incidence of brucellosis in the United States.

Sources of infection occur through travel abroad, consuming imported cheese, and occupation-related exposure. Brucellosis most frequently occurs among farmers, stock handlers, butchers, and veterinarians.

The incubation period usually ranges from 5 to 35 days but sometimes lasts for months. The prognosis is good. With treatment, brucellosis seldom is fatal, although complications can cause permanent disability.

Causes

Brucellosis is caused by the nonmotile, non-spore-forming, gram-negative coccobacillus *Brucella*, notably *B. suis* (found in swine), *B. melitensis* (in goats), *B. abortus* (in cattle), and *B. canis* (in dogs).

The disease is transmitted through the consumption of unpasteurized dairy products or uncooked or undercooked, contaminated meat. It's also passed on through contact with infected animals or their secretions or excretions.

Complications

Brucellosis can result in endocarditis, orchitis, persistent hepatosplenomegaly, and osteoarticular problems, such as arthritis and osteomyelitis. Skin manifestations, such as eczematous rashes, petechiae, and purpura, are possible, as is pulmonary involvement, including pleural effusions and pneumothorax.

Brucellosis can cause abscesses in the testes, ovaries, kidneys, spleen, liver, bone, and brain (meningitis and encephalitis). About 15% of patients with such brain abscesses develop hearing and visual disorders, hemiplegia, and ataxia.

Assessment findings

The patient's history may reveal direct exposure to animals, especially cattle or swine, possibly related to the patient's occupation. Or the patient may report ingestion of unpasteurized dairy products, most notably goat's milk cheese, or recent travel to an endemic area.

Because the disease has an insidious onset, the patient usually doesn't report symptoms until he reaches the acute phase. Then he may complain of fatigue, headache, backache, weight loss, anorexia, myalgia, and arthralgia. When he reaches the chronic phase, he may report recurrent depression, anxiety, sleep disturbances, fatigue, headache, and malaise.

Despite this disease's common name of undulant fever, assessment seldom shows a truly intermittent (undulant) fever. The patient is more likely to have a normal temperature or low-grade fever in the morning and an increase in temperature in the afternoon.

On inspection, you may note drenching sweats, chills, and weakness in the acute phase and persistent fatigue in the chronic phase. Palpation may reveal lymphadenopathy and hepatosplenomegaly with tenderness in the left upper quadrant. It also may show abscesses and granuloma formation in subcutaneous tissue.

Diagnostic tests

Multiple agglutination tests help to confirm the diagnosis. About 90% of patients with brucellosis have agglutinin titers of 1:160 or more within 3 weeks of developing this disease. However, elevated agglutination titers also follow a relapse, skin tests, and vaccination against tularemia, *Yersinia* infection, or cholera. Agglutination tests also allow monitoring of treatment effectiveness.

Multiple (three to six) cultures of blood and bone marrow and biopsies of infected tissue (such as the spleen) provide a definitive diagnosis. Culturing is best done during the acute phase.

Blood studies indicate an increased erythrocyte sedimentation rate and a normal or reduced white blood cell count.

Treatment

The most effective therapy is a combination of doxycycline and aminoglycoside, such as streptomycin, gentamicin, or netilmicin for 4 weeks, followed by a combination of doxycycline and rifampin for 4 to 8 weeks. In pregnancy, trimethoprim-sulfamethoxazole can be given in combination with rifampin for 8 to 12 weeks. Alternative treatments include chloramphenicol, with or without streptomycin, and co-trimoxazole.

Cardiac surgery may be necessary in some cases.

Nursing diagnoses

- u Altered nutrition: Less than body requirements
- u Anxiety
- u Fatigue
- u Impaired tissue integrity
- u Pain
- u Risk for infection
- u Sleep pattern disturbance

Key outcomes

- u The patient will maintain weight without further loss.
- u No pathogens will appear in cultures.
- u The patient will remain free from all signs and symptoms of infection.
- u The patient will experience feelings of comfort or absence of pain at rest.
- u The patient will discuss activities that tend to decrease anxiety behavior.
- u The patient will attain relief from immediate symptoms.

Nursing interventions

- u Keep suppurative granulomas and abscesses dry. Properly dispose of all secretions, soiled dressings, and wet linens.

- u Monitor and record the patient's temperature every 4 hours. Use the same route (oral or rectal) every time. Assess for enlarged lymph nodes and liver after treatment.
- u Provide frequent hygiene, especially after sweating.
- u Use soothing mentholated or diphenhydramine lotion to relieve itching. Avoid deodorant soaps, powders, and lotions.
- u Ask the dietary department to provide between-meal milk shakes and other supplemental foods to counter weight loss. Determine the patient's food preferences and attempt to obtain these foods. Provide a pleasant environment at mealtime.
- u Give antibiotics and analgesics, as ordered.
- u Assess the patient for murmurs, weakness, vision loss, and joint inflammation, all of which may indicate complications.
- u During the chronic phase, watch the patient for signs of depression and disturbed sleep patterns. Administer sedatives as ordered, and plan activities to allow adequate rest. Try to create a quiet environment conducive to sleep.

Patient teaching

- u Stress the importance of continuing medication for the prescribed duration. To prevent recurrence, advise the patient to cook meat thoroughly and avoid using unpasteurized dairy products.
- u Warn meat packers and other people at risk for occupational exposure to wear rubber gloves and goggles.
- u Teach the patient about the risk of fertility problems resulting from brucellosis.

CHANCROID

Chancroid (or soft chancre) is a sexually transmitted disease characterized by painful genital ulcers and inguinal adenitis.

Chancroid is a common cause of genital ulcers in developing countries. The infection is on the rise in the United States and is associated with increased risk for human immunodeficiency virus (HIV) infection. It affects males more often than females.

The incubation period varies but typically ranges from 5 to 7 days. Chancroidal lesions may heal spontaneously and usually respond well to treatment when no secondary infections are present.

Causes

Chancroid results from *Haemophilus ducreyi*, a short, nonmotile, gram-negative bacillus. Poor personal hygiene may predispose men—especially those who are uncircumcised—to this disease.

Complications

Phimosis and urethral fistulas may occur in men. Secondary infections can cause extensive inflammation.

Assessment findings

The patient may report unprotected sexual contact with an infected person or with unknown or multiple partners. He may complain of pain associated with ulcers and lymphadenopathy. He also may experience headaches and malaise (in 50% of patients).

An inspection of the genital area initially reveals single or multiple papules surrounded by redness. These rapidly become pustular and then ulcerate. The ulcers are nonindurated with ragged edges, have a base of granulation tissue, and bleed easily. They range from 1 to 2 mm in diameter.

You may observe the ulcers on the prepuce, frenulum, coronal sulcus, shaft, or glans penis in a male patient. In a female patient, you may note ulcers on the labia, fourchette, vestibule, clitoris, cervix, or anus, although many women are asymptomatic. Rarely, you'll observe lesions on the tongue, lip, or breast.

When you inspect the inguinal area within 2 to 3 weeks of onset, you're likely to observe unilateral lymphadenopathy with overlying erythema. If the patient hasn't received treatment, you may observe suppuration with bubo formation. Rupture of the abscess may follow.

On palpation, you may note tender, fluctuant inguinal nodes.

Diagnostic tests

Cultures from the lesion are necessary to confirm diagnosis.

Dark-field examination and serologic testing rule out other sexually transmitted diseases (genital herpes, syphilis, lymphogranuloma venereum) that cause similar ulcers.

Treatment

Ceftriaxone can be given 250 mg as a single intramuscular dose. Oral dosing with erythromycin, trimethoprim-sulfamethoxazole, or ciprofloxacin is also effective.

Aspiration of fluid-filled nodes and careful personal hygiene help prevent the infection from spreading.

Nursing diagnoses

- u Altered sexuality patterns
- u Body image disturbance
- u Impaired skin integrity
- u Pain
- u Risk for infection

Key outcomes

- u The patient will communicate feelings about changes in body image.
- u The patient will regain skin integrity with decrease in size of chancroids.
- u The patient will state infection risk factors.
- u The patient will remain free from all signs and symptoms of infection.
- u The patient will voice feelings about potential or actual changes in sexual activity.
- u The patient will exhibit healed or improved lesions or wounds.

Nursing interventions

- u Use standard precautions whenever you may come into contact with genital secretions (for instance, when collecting specimens and performing a physical examination).
- u Administer anti-infectives and, possibly, analgesics, as ordered. Make sure the patient isn't allergic to the medication before giving the first dose, and ask him to rate the pain both before and after intervention.
- u Provide topical care by washing the affected area with soap and water, followed by a bactericidal agent. Don't allow the area to remain moist; this can enhance the growth of the organism.
- u Report all cases of chancroid to the local board of health, if required in your state.

- u Examine the patient's sexual contacts, and refer them for treatment, even if they're asymptomatic.

Patient teaching

- u Instruct the patient to take his anti-infective medication for the period prescribed.
- u Teach the patient not to apply creams, lotions, or oils on or near his genitalia or on other lesion sites. Doing so may enhance the spread of the disease.
- u Advise the patient to abstain from sexual contact until follow-up shows that healing is complete (usually about 2 weeks after treatment begins).
- u Instruct the patient to wash his genitalia three times daily with soap and water. If he's uncircumcised, tell him to retract the foreskin to thoroughly clean the glans penis.
- u Counsel the patient about human immunodeficiency virus (HIV) infection. Also, recommend HIV testing because of the heightened risk chancroid causes.
- u Inform the patient that condoms may provide protection from future infection.

CHOLERA

Cholera is also called Asiatic cholera and epidemic cholera. It's an acute, enterotoxin-mediated GI infection caused by the gram-negative rod *Vibrio cholerae*. Cholera produces profuse diarrhea, vomiting, and fluid and electrolyte losses. A similar bacterium, *Vibrio parahaemolyticus*, causes food poisoning. (See [Vibrio parahaemolyticus food poisoning](#).)

Cholera is native to the Ganges delta in the Indian subcontinent. Pandemics have affected the United States Gulf Coast of Louisiana and Texas and Latin and Central America. Southeast Asia has also had outbreaks. It usually occurs during the warmer months and is most prevalent in coastal areas among lower socioeconomic groups. In India, cholera is especially common among children ages 1 to 5, but in other endemic areas, it's equally distributed among all age groups.

Even with prompt diagnosis and treatment, cholera can be rapidly fatal because of difficulty with fluid replacement. Cholera infection confers only transient immunity. About 3% of patients who recover continue to carry *V. cholerae* in the gall bladder; however, most patients are free from the infection after about 2 weeks.

Causes

Humans are the only documented hosts and victims of *V. cholerae*, a motile, aerobic rod bacterium. The disease is transmitted directly through food and water contaminated with fecal material from carriers or people with active infections. Cholera is a toxin-mediated disease affecting the small intestine that results in watery diarrhea.

Complications

Cholera can lead to hypoglycemia, severe electrolyte depletion, hypovolemic shock, metabolic acidosis, renal failure, liver failure, bowel ischemia, and bowel infarction.

***Vibrio parahaemolyticus* food poisoning**

A common cause of gastroenteritis in Japan, *Vibrio parahaemolyticus* also has caused outbreaks on American cruise ships and in the eastern and southeastern coastal areas of the United States, especially during the summer.

This organism, which thrives in a salty environment, is transmitted by ingesting uncooked or undercooked contaminated shellfish, particularly crabs and shrimp. After an incubation period of 2 to 48 hours, the organism causes watery diarrhea, moderately severe cramps, nausea, vomiting, headache, weakness, chills, and fever. Food poisoning usually is self-limiting and subsides spontaneously within 2 days. Occasionally it's more severe and may even be fatal in debilitated or elderly people.

Diagnosis requires bacteriologic examination of vomitus, blood, stool smears, or fecal specimens collected by rectal swab. Diagnosis must rule out other causes of food poisoning and other acute GI disorders.

Supportive treatment consists primarily of bed rest, oral fluid replacement and, sometimes, oral tetracycline. I.V. fluid replacement seldom is necessary.

Thorough cooking of seafood prevents this infection.

Assessment findings

After 24 to 48 hours of incubation, profuse watery diarrhea begins and is followed shortly by vomiting. Stool volume can exceed 250 ml/kg in the first 24 hours. Fever is absent. The patient may complain of abdominal gurgling and fullness, the result of increased peristalsis.

As the number of stools increases, the patient may report white flecks of mucus in his stools (“rice water stools”). He also may complain of intense thirst, weakness, muscle cramps (especially in the extremities), and oliguria—all from the massive fluid and electrolyte losses that result from diarrhea and vomiting. Fluid loss in adults may reach 1 L/hour.

If fluid loss is severe, your assessment reveals fever, tachycardia, and thready or absent peripheral pulses. (Fever isn't noted if cholera isn't complicated by severe dehydration.) You may note hypotension within an hour of the onset of symptoms.

During inspection, you may observe dry skin and mucous membranes (with loss of skin turgor), cyanosis, a pinched facial expression, sunken eyeballs, and profound weakness. The patient usually has an altered level of consciousness; he's likely to appear apathetic or detached, although oriented to person, place, and time.

Auscultation may reveal inaudible bowel sounds with profuse fluid and electrolyte depletion. Palpation of the abdomen may reveal a distended abdomen but no generalized or focal tenderness.

In children, you may observe unconsciousness or seizures, possibly caused by hypoglycemia.

Diagnostic tests

A culture of *V. cholerae* from stool or vomitus indicates cholera, but definitive diagnosis requires agglutination and other clear reactions to group- and type-specific antisera.

A dark-field microscopic examination of fresh stool showing rapidly moving bacilli (like shooting stars) allows for a quick, tentative diagnosis. Immunofluorescence also allows rapid diagnosis. Diagnosis must rule out *Escherichia coli* infection, salmonella infection, and shigellosis.

Treatment

Travelers to endemic areas can receive the cholera vaccine. Vaccination is impractical for residents of endemic areas due to cost at this time. Only an improvement in sanitation can control the disease.

When the patient has cholera, he requires rehydration by oral fluids containing sodium at 90 mmol/L to replace losses in the stool. For severe dehydration, often accompanied by acidosis, I.V. fluid is preferred, particularly Ringer's lactate, to replace losses. Total fluid deficit in severely dehydrated patients can be replaced in the first 4 hours of therapy; half within the first hour. Oral rehydration of electrolytes, particularly potassium, is safer than by the I.V. route. Thirst and urine output guide fluid replacement. The patient also may receive calcium and magnesium replacements in the I.V. solution.

After the I.V. infusions have corrected hypovolemia, the patient only needs fluid infusions sufficient to maintain normal pulse rate and skin turgor or to replace fluid lost through diarrhea. An oral glucose-electrolyte solution can be substituted for I.V. infusions.

In mild cholera, the patient only needs early oral fluid replacement. A patient who is suspected of having cholera can receive a single dose of doxycycline or tetracycline. However, with the emergence of bacterial strains that resist traditional antibiotic therapy, he's likely to receive ciprofloxacin or erythromycin instead. Antibiotic therapy shortens the duration of diarrhea, diminishing fluid and electrolyte losses.

ALERT Tetracycline-type antibiotics aren't recommended for children under age 8 because of possible deposition in the bones and developing teeth, resulting in permanent changes.

Nursing diagnoses

- u Altered tissue perfusion (cardiopulmonary, renal)
- u Diarrhea
- u Fatigue
- u Fluid volume deficit
- u Risk for infection

Key outcomes

- u The patient will regain and maintain normal fluid and electrolyte balance.
- u The patient's elimination patterns will return to normal.
- u The patient will report increased comfort.
- u The patient's vital signs will remain stable.
- u The patient will produce adequate urine volume.
- u The patient will have normal skin turgor and moist mucous membranes.

Nursing interventions

- u During the acute phase of the disease, provide enteric precautions and supportive care, and closely observe the patient.
- u Accurately measure intake and output (making sure to include stool volume), and assess the patient for other signs of fluid loss.
- u Monitor results of serum electrolyte and glucose tests. Administer replacement fluids and electrolytes as ordered.
- u During therapy, continue to evaluate peripheral and central pulses, central venous pressure, and orthostatic blood pressure. The results help in adjusting infusion rates, particularly when the patient has renal failure. Carefully observe neck veins and auscultate the lungs for indications of fluid overload from cardiac failure.
- u Administer tetracycline or other antibiotics to the patient as ordered.

Patient teaching

- u Instruct the patient and family members on proper hand-washing technique and the need to wash their hands before eating or preparing food and after bowel movements, changing diapers, or any contact with stool.
- u Teach the patient's family how to take the oral antibiotic, if ordered.
- u If the family cares for the patient at home, make sure they know how to replace his fluids, salt, and glucose orally.
- u Advise any patient traveling to an endemic area to boil all drinking water.
- u If the doctor orders a cholera vaccine, tell the patient that he'll need a booster 3 to 6 months later for continuing protection.

ESCHERICHIA COLI AND OTHER ENTEROBACTERIACEAE INFECTIONS

Enterobacteriaceae—a family of mostly aerobic, gram-negative bacilli —cause local and systemic infections, including an invasive diarrhea that resembles shigellosis and, more often, a noninvasive, toxin-mediated diarrhea that resembles cholera. With other bacilli of this family, *Escherichia col*. causes most nosocomial infections. Noninvasive, enterotoxin-producing *E. coli* infections may be a major cause of diarrheal illness in children in the United States.

The prognosis in mild to moderate infection is good. Severe infection requires immediate fluid and electrolyte replacement to avoid fatal dehydration, especially among children in whom the risk of death may be quite high.

The incidence of *E. coli* infection is highest among travelers returning from other countries, particularly Mexico (noninvasive), Southeast Asia (noninvasive), and South America (invasive). *E. coli* infection also causes other diseases, especially in people whose resistance is low. (See [Enterobacterial infections.](#))

Causes

Although some strains of *E. coli* exist as part of the normal GI flora, infection usually comes from nonindigenous strains. For example, noninvasive diarrhea results from two toxins produced by enterotoxigenic or enteropathogenic strains of *E. coli*. These toxins interact with intestinal juices and promote excessive loss of chloride and water. In the invasive form, *E. coli* directly invades the intestinal mucosa without producing enterotoxins, thereby causing local irritation, inflammation, and diarrhea. Normal strains can cause infection in immunocompromised patients.

Transmission can occur directly from an infected person or indirectly by ingestion of contaminated food or water or by contact with contaminated utensils. Incubation takes 12 to 72 hours.

Enterobacterial infections
Bacteria of the family Enterobacteriaceae cause enterobacterial infections. These gram-negative bacilli include <i>Escherichia coli</i> , <i>Arizona</i> , <i>Citrobacter</i> , <i>Enterobacter</i> , <i>Erwinia</i> , <i>Hafnia</i> , <i>Klebsiella</i> , <i>Morganella</i> , <i>Proteus</i> , <i>Providencia</i> , <i>Salmonella</i> , <i>Serratia</i> , <i>Shigella</i> , and <i>Yersinia</i> .
Enterobacterial infections can be exogenous (from other people or the environment), endogenous (from one part of the body to another), or a combination of both. They may cause many bacterial diseases: bacterial (gram-negative) pneumonia, empyema, endocarditis, osteomyelitis, septic arthritis, urethritis, cystitis, bacterial prostatitis, urinary tract infection, pyelonephritis, perinephric abscess, abdominal abscess, cellulitis, skin ulcers, appendicitis, gastroenterocolitis, diverticulitis, corneal conjunctivitis, meningitis, bacteremia, and intracranial abscess.
Appropriate antibiotic therapy depends on the results of culture and sensitivity tests. The aminoglycosides, quinolones, cephalosporins, and penicillins—such as ampicillin, meziocillin, and piperacillin—are most effective.

Complications

Bacteremia, severe dehydration, life-threatening electrolyte disturbances, acidosis, and shock can result.

Assessment findings

Recent travel to another country, ingestion of contaminated food or water, or recent close contact with a person who has diarrhea may be part of the patient history.

The cardinal symptom is diarrhea. In the noninvasive form, watery diarrhea begins abruptly, along with cramping abdominal pain; in infants, the infection begins with loose, watery stools that change from yellow to green and contain little mucus or blood. In the invasive form, abdominal cramps are accompanied by diarrheal stools that may contain blood and pus. The patient may report that vomiting and anorexia precede diarrhea. He also may typically report a low-grade fever that occurs on the first and second days of infection.

In infants, inspection may reveal listlessness and irritability before the onset of diarrhea. With dehydration, especially in children, you'll note dry skin and mucous membranes (with decreased skin turgor), sunken fontanel, and sunken eyes. Expect to see signs and symptoms of hyponatremia, hypokalemia, hypomagnesemia, and hypocalcemia from electrolyte losses caused by vomiting and diarrhea.

In dehydration, auscultation may reveal hyperactive bowel sounds and orthostatic hypotension; palpation may reveal a rapid, thready pulse.

Diagnostic tests

Because certain strains showing *E. coli* normally reside in the GI tract, culturing is of little value. However, blood cultures of *E. coli* point to systemic infection.

A firm diagnosis requires sophisticated identification procedures, such as bioassays, which are expensive, time-consuming and, consequently, not widely available. Diagnosis must rule out salmonella infection and shigellosis, other common infections that produce similar signs and symptoms.

Treatment

Appropriate treatment consists of enteric precautions, correction of fluid and electrolyte imbalances and, in an infant or immunocompromised patient, I.V. antibiotics based on the organism's drug sensitivity. For severe diarrhea that poses a risk of dehydration, bismuth subsalicylate or tincture of opium may be ordered.

Nursing diagnoses

- u Altered nutrition: Less than body requirements
- u Altered tissue perfusion (cardiopulmonary, GI)
- u Diarrhea
- u Fluid volume deficit
- u Pain
- u Risk for infection

Key outcomes

- u The patient will regain and maintain normal fluid and electrolyte balance.
- u The patient's elimination pattern will return to normal.
- u The patient will show no further evidence of weight loss.
- u The patient will maintain normal cardiac output.
- u The patient won't exhibit arrhythmias.

Nursing interventions

- u Institute contact precautions for all patients to prevent transmission of the organism to healthy people.
- u Use proper hand-washing technique.
- u Keep accurate intake and output records. Measure stool volume and note the presence of blood and pus.
- u Replace fluids and electrolytes as needed, monitoring for decreased serum sodium and chloride levels and signs of gram-negative septic shock.
- u Watch for signs of dehydration. Monitor vital signs to detect early indications of circulatory collapse.
- u Clean the perianal area and lubricate it after each episode of diarrhea. Provide a room deodorizer.
- u Give nothing by mouth; administer antibiotics as ordered; and maintain body warmth.
- u During epidemics, screen all facility personnel and visitors for diarrhea, and prevent people with the disorder from having direct patient contact.
- u Resistant strains of *E. coli* develop in patients on antibiotic therapy. Obtain routine surveillance cultures, and evaluate culture and sensitivity results, as indicated.

Patient teaching

- u Explain proper hand-washing technique to facility personnel, patients, and their families. Stress the importance of washing hands before eating or preparing food and after defecating, changing diapers, or having any contact with stool.
- u Advise travelers to other countries to avoid unbottled water, ice, unpeeled fruit, and uncooked vegetables.
- u If the patient will be cared for at home, teach him the signs of dehydration, and tell him to seek prompt medical attention if these occur.

HAEMOPHILUS INFLUENZAE INFECTION

Although *Haemophilus influenzae* can affect many organ systems, it most frequently attacks the respiratory system. It's a common cause of epiglottitis, laryngotracheobronchitis, pneumonia, bronchiolitis, otitis media, and meningitis. Less often, it causes bacterial endocarditis, conjunctivitis, facial cellulitis, septic arthritis, and osteomyelitis.

H. influenzae type B (Hib) infection predominantly affects children, at a rate of 3% to 5%. This incidence was higher before vaccinations were used in day-care centers. The vaccine is administered at ages 2, 4, 6, and 15 months. The incidence of meningitis in black children is higher due to Hib. In Native Americans, the incidence of the disease is 10 times higher, possibly due to exposure, socioeconomic conditions, and genetic differences in immune response.

Causes

A small, gram-negative, pleomorphic aerobic bacillus, *H. influenzae* appears predominantly in coccobacillary exudates. It's usually found in the pharynx and less often in the conjunctiva and genitourinary tract. Transmission occurs by direct contact with secretions or by airborne droplets.

Complications

The microorganism can cause subdural effusions and permanent neurologic sequelae from meningitis, complete upper airway obstruction from epiglottitis, cellulitis, and pericarditis, pleural effusion, and respiratory failure from pneumonia.

Assessment findings

The patient may report a recent viral infection. He commonly complains of a generalized malaise and is likely to have a high fever. Other symptoms vary. For example, with acute epiglottitis, the patient may complain of a sore throat, severe dysphagia, and dyspnea. With pneumonia, he may report a productive cough, dyspnea, and pleuritic chest pain. With meningitis, he may experience headache, vomiting, photophobia, and diplopia.

Expect your inspection findings to vary with the site of infection. For example, a child with acute epiglottitis appears restless and irritable and may exhibit use of accessory muscles to breathe. Typically, he attempts to relieve severe respiratory distress by hyperextending his neck, sitting up, and leaning forward with his mouth open, tongue protruding, and nostrils flaring.

You also may observe stridor and inspiratory retractions. The trachea appears normal. The pharyngeal mucosa may look reddened (rarely with soft yellow exudate) but usually appears normal or shows only slight, diffuse redness. The epiglottis appears red with considerable edema. Severe pain makes swallowing difficult or impossible.

ALERT Take steps to avoid obstruction in acute epiglottitis. If a child develops symptoms of acute epiglottitis, don't attempt to examine his throat or obtain a throat culture—either could lead to a fatal respiratory obstruction. Only an experienced professional, such as an anesthetist or anesthesiologist, should perform such a procedure and only with emergency airway equipment nearby.

Your inspection of a patient with pneumonia may reveal shaking chills, tachypnea, a productive cough, and impaired or asymmetrical chest movement caused by pleuritic pain.

With meningitis, you may note an altered level of consciousness (LOC) progressing to seizures and coma as the disease progresses. You also may observe positive Brudzinski's and Kernig's signs and exaggerated and symmetrical deep tendon reflexes. If the patient is a young child, he's less likely to exhibit the nuchal rigidity you may see in other patients. With severe meningeal irritation, you may observe opisthotonus.

If the patient has advanced pneumonia, chest percussion may reveal dullness over areas of lung consolidation.

In epiglottitis or pneumonia, auscultation may detect gurgles; in lung consolidation and upper airway obstruction, decreased breath sounds.

Diagnostic tests

Isolation of the organism, usually with a blood culture, confirms *H. influenzae* infection. Hib meningitis is detectable in cerebrospinal fluid cultures. A positive nasopharyngeal culture isn't diagnostic because this may be a normal finding in healthy people.

Treatment

H. influenzae type B infections may be rapidly fatal without prompt, effective treatment. Patients with meningitis due to Hib are treated with cefotaxime or ceftriaxone. As an alternative, doctors may prescribe a combination of chloramphenicol and ampicillin. Glucocorticoids can reduce neurologic sequelae. Airway maintenance is critical in epiglottitis.

Nursing diagnoses

⌞ Altered nutrition: Less than body requirements ⌞ Anxiety ⌞ Fluid volume deficit ⌞ Impaired gas exchange ⌞ Ineffective airway clearance ⌞ Ineffective breathing pattern ⌞ Pain ⌞ Risk for aspiration ⌞ Risk for infection

Key outcomes

- ⌞ Adventitious breath sounds will be absent.
- ⌞ The patient's airway will remain patent.
- ⌞ The patient's arterial blood gas (ABG) levels will return to normal.
- ⌞ No pathogens will appear in cultures.
- ⌞ The patient will remain free from all signs and symptoms of infection.
- ⌞ The patient will attain and maintain normal fluid and electrolyte balance.

Nursing interventions

- ⌞ Maintain respiratory isolation. Use proper handwashing technique, properly dispose of respiratory secretions, and place soiled tissues in a biohazard container.
- ⌞ Maintain adequate respiratory function. Provide cool humidification and oxygenation therapy for respiratory infection as needed; use croup tents for children and face tents for adults. Frequently monitor respiratory status. Watch for increasing restlessness and for tachycardia, cyanosis, dyspnea, and retractions, which may indicate the need for an emergency tracheotomy.
- ⌞ Keep emergency equipment readily available, especially for the patient with meningitis or epiglottitis. This includes an oral airway, a tracheotomy tray, endotracheal tubes, a handheld resuscitation bag, suction and oxygen equipment, and a laryngoscope with blades of various sizes. The patient may need a smaller endotracheal tube because of laryngeal edema.
- ⌞ Monitor pulse oximetry and ABG levels. Remember to assess the patient's LOC or degree of lethargy to estimate the severity of hypoxemia.
- ⌞ Suction the patient as needed, using sterile technique.
- ⌞ Check the patient's history for drug allergies before administering antibiotics. Monitor his complete blood count for signs of bone marrow depression when therapy includes ampicillin or chloramphenicol.
- ⌞ Administer racemic epinephrine to the oropharynx.
- ⌞ Monitor intake (including I.V. infusions) and output. Watch for signs of dehydration, such as decreased skin turgor, parched lips, concentrated urine, decreased urine output, and increased pulse rate. Provide sufficient oral or I.V. fluids, or both, as ordered.
- ⌞ Provide a quiet, calm environment. Organize your physical care measures, and perform them quickly to avoid disrupting the patient's rest.
- ⌞ Avoid fluid overload in a patient with meningitis because of the danger of cerebral edema.
- ⌞ For the patient with meningitis, assess neurologic function often, watching for deterioration. Be alert for a temperature increase up to 102° F (38.9° C), deteriorating LOC, nuchal rigidity, onset of seizures, and altered respirations, all of which may signal an impending crisis.
- ⌞ Frequently reorient the patient with an altered LOC.
- ⌞ Maintain adequate nutrition and elimination.
- ⌞ Position the patient carefully. Elevate the head of the bed, turn him often, and assist with range-of-motion exercises.

Patient teaching

- ⌞ Inform the parents of a child infected with *H. influenzae* about the high risk of acquiring this infection at day-care centers.
- ⌞ Encourage parents to have their young children receive the *H. influenzae* vaccine to prevent these infections.
- ⌞ Ensure that the patient or his parents understand the importance of continuing the prescribed antibiotic until the entire prescription is finished. The patient shouldn't stop taking the drug because he begins feeling better.
- ⌞ Provide support and a careful explanation of procedures (especially intubation, tracheotomy, and suctioning) to the patient and his family or to the patient's parents.
- ⌞ If the patient undergoes a tracheotomy, explain to him and his family that this measure typically will be used for 4 to 7 days.
- ⌞ Teach the patient with pneumonia how to cough and perform deep-breathing exercises to clear secretions.
- ⌞ To control the spread of infection, teach the patient to dispose of secretions properly and to use proper hand-washing technique.
- ⌞ For home treatment of a respiratory infection, suggest using a room humidifier or breathing moist air from a shower or bath, as necessary.

LEGIONNAIRES' DISEASE

Legionnaires' disease is an acute bronchopneumonia produced by a gram-negative bacillus. This disease was named for 221 persons (34 of whom died) who became ill during an American Legion convention in Philadelphia in July 1976. Outbreaks, usually in late summer and early fall, may be epidemic or confined to a few cases. The disease may range from a mild illness (with or without pneumonitis) to serious multilobed pneumonia with mortality as high as 15%.

Pontiac fever is a less severe, self-limiting form of the illness that subsides within a few days but leaves the patient fatigued for several weeks. This disorder is caused by the same organism as Legionnaires' disease but produces few or no respiratory symptoms, no pneumonia, and no fatalities.

Legionnaires' disease is more common in men than in women and is most likely to affect:

- u elderly people
- u immunocompromised patients (particularly those receiving corticosteroids after transplantation) or those with lymphoma or other disorders associated with impaired humoral immunity
- u patients with chronic underlying disease, such as diabetes, chronic renal failure, or chronic obstructive pulmonary disease
- u alcoholics
- u cigarette smokers (who are three to four times more likely to contract Legionnaires' disease than nonsmokers).

Causes and pathophysiology

Legionnaires' disease results from infection with *Legionella pneumophila*, an aerobic, gram-negative bacillus that is probably transmitted by air. The organism's natural habitat seems to be water, either hot or cold. In the past, air-conditioning systems were thought to be the main source of transmission. Recently, public health officials have identified water distribution systems as the primary reservoir for the organism.

The *Legionella* enter the lungs after aspiration or inhalation and enter the pili. Alveolar macrophages phagocytize the legionella; however, the organisms aren't killed and proliferate intracellularly. The cells rupture, releasing the legionella, and the cycle starts again. Lesions develop a nodular appearance and alveoli become filled with fibrin, neutrophils, and alveolar macrophages. Conditions impairing mucociliary clearance (smoking, lung disease, or alcoholism) predispose the patient to infection.

Complications

Patients in whom pneumonia develops also may experience hypoxia and acute respiratory failure. Other complications include hypotension, delirium, seizures, congestive heart failure, arrhythmias, renal failure, and shock, which usually is fatal.

Assessment findings

The patient history may include presence at a suspected source of infection. Onset of Legionnaires' disease may be gradual or sudden. After a 2- to 10-day incubation period (or a 1- to 2-day incubation period in Pontiac fever), the patient may report nonspecific prodromal symptoms, including diarrhea, anorexia, malaise, diffuse myalgia and generalized weakness, headache, and recurrent chills.

With Legionnaires' disease, the patient typically reports a cough that is initially nonproductive but is eventually productive. He also may complain of dyspnea and chest pain or sometimes nausea, vomiting, and abdominal pain.

With Pontiac fever, the patient may complain of myalgia, malaise, chills, headache, a nonproductive cough, and nausea. Fever is present. Complete recovery occurs in a few days without antibiotic therapy, and a few patients may develop lassitude for a few weeks after.

Inspection may reveal grayish or rust-colored, nonpurulent and, occasionally, blood-streaked sputum. You also may note tachypnea, bradycardia (in about 50% of patients), and neurologic signs, especially an altered level of consciousness.

Chest percussion may disclose dullness over areas of secretions and consolidation or pleural effusions. Auscultation may reveal fine crackles, developing into coarse crackles as the disease progresses.

Diagnostic tests

Chest X-ray typically shows patchy, localized infiltration, which progresses to multilobed consolidation (usually involving the lower lobes) and pleural effusion. In fulminant disease, chest X-ray reveals opacification of the entire lung.

Laboratory tests include various blood studies and cultures. Blood test findings may include leukocytosis; increased erythrocyte sedimentation rate; a moderate increase in liver enzyme (alkaline phosphatase, alanine aminotransferase, and aspartate aminotransferase) levels; and decreased partial pressure of oxygen and, initially, decreased partial pressure of carbon dioxide. Hyponatremia (serum sodium level less than 131 mg/L) is evident on chemistry.

Bronchial washings, blood and pleural fluid cultures, and transtracheal aspirate studies rule out other pulmonary infections. Gram staining reveals numerous neutrophils but no organism. Isolation of the organisms from respiratory secretions or bronchial washings or through thoracentesis is a definitive method of diagnosis.

Definitive tests include direct immunofluorescence of *L. pneumophila* and indirect fluorescent serum antibody testing. These tests compare findings from initial blood studies with findings from those done at least 3 weeks later. A convalescent serum sample showing a fourfold or greater increase in antibody titer for *L. pneumophila* confirms the diagnosis.

Treatment

Antibiotic treatment begins as soon as Legionnaires' disease is suspected and diagnostic material is collected. Treatment need not await test results. Erythromycin and tetracycline are most effective. Azithromycin or other nerve macrolides are preferred for immunocompromised patients. For severely ill patients, a combination of rifampin and a macrolide or quinoline may be used.

Supportive therapy includes administration of antipyretics, fluid replacement, circulatory support with pressor drugs if necessary, and oxygen administration by mask or cannula or by mechanical ventilation with positive end-expiratory pressure.

Nursing diagnoses

u Altered tissue perfusion (cardiopulmonary) u Fluid volume deficit u Hyperthermia u Impaired gas exchange u Ineffective airway clearance u Ineffective breathing pattern u Pain

Key outcomes

- u The patient will cough effectively.
- u The patient will expectorate sputum effectively.
- u The patient will express feelings of comfort in maintaining air exchange.
- u The patient will regain and maintain normal fluid and electrolyte balance.
- u The patient will have normal breath sounds.
- u The patient will remain normothermic.

Nursing interventions

- u Monitor the patient's respiratory status. Evaluate chest wall expansion, depth and pattern of respirations, cough, and chest pain. Watch the patient for restlessness, which may indicate hypoxemia. He may need suctioning, repositioning, postural drainage, chest physiotherapy, or aggressive oxygen therapy.
- u Provide mechanical ventilation or other respiratory therapy if ordered.
- u Continually evaluate vital signs, arterial blood gas levels, hydration, and color of lips and mucous membranes. Be alert for signs of shock (decreased blood pressure; tachycardia; weak, thready pulse; diaphoresis; and clammy skin).

- u Keep the patient comfortable and protected from drafts. Give tepid sponge baths or use cooling blankets to lower his fever.
- u Provide mouth care frequently. If necessary, apply soothing cream to irritated nostrils.
- u Replace fluids and electrolytes as needed. Nausea and vomiting may require administration of antiemetics as ordered. If renal failure develops, prepare the patient for dialysis.
- u Monitor the patient's level of consciousness for signs of neurologic deterioration. As needed, institute seizure precautions.
- u Administer antipyretics and antibiotic therapy as ordered.
- u Administer antianxiety agents as ordered to decrease oxygen requirements and improve tolerance.

Patient teaching

- u Provide pulmonary hygiene instructions. Explain the purpose of postural drainage, and tell the patient how to perform coughing and deep-breathing exercises.
- u Teach the patient how to dispose of soiled tissues to prevent disease transmission.

PERTUSSIS

Also called whooping cough, pertussis is a highly contagious infection caused by *Bordetella pertussis*. It characteristically produces an irritating cough that becomes paroxysmal and often ends in a high-pitched, inspiratory whoop.

About half the time it strikes under-immunized children under age 1. It also occurs in persons age 20 years or older and in outbreaks in schools, nursing homes, facilities, and residential facilities.

Since the 1940s, immunization and aggressive diagnosis and treatment have significantly reduced mortality from whooping cough in the United States. Pertussis mortality in children under age 1 usually is a result of insufficient immunization. Pertussis also is dangerous in elderly people but tends to be less severe in older children and adults.

Causes

Pertussis usually results from the nonmotile, gram-negative coccobacillus *B. pertussis*; occasionally, it's caused by the related similar bacteria *B. parapertussis* or *B. bronchiseptica*. (See [Bordetella pertussis](#).)

Pertussis usually is transmitted by direct inhalation of contaminated droplets from a patient in the acute stage. It also may be spread indirectly through soiled linen and other articles contaminated by respiratory secretions.

Complications

The paroxysmal coughing that pertussis causes may induce complications, such as increased venous pressure, epistaxis, periorbital edema, conjunctival hemorrhage, hemorrhage of the anterior chamber of the eye, detached retina and blindness, rectal prolapse, inguinal or umbilical hernia, seizures, atelectasis, and pneumonitis.

In infants, choking spells may cause apnea, anoxia, and disturbed acid-base balance. Pneumonia due to superinfection is common, and neurologic complications can occur, such as encephalopathy and seizures.

Bordetella pertussis

This microscopic enlargement shows *Bordetella pertussis*, the nonmotile, gram-negative coccobacillus that commonly causes whooping cough. After entering the tracheobronchial tree, pertussis causes mucus to become increasingly tenacious. The classic 6-week course of whooping cough then follows.

Assessment findings

The patient's history may reveal a lack of immunization coupled with exposure to pertussis during the previous 3 weeks. Pertussis follows a 6- to 8-week course that includes three 2-week stages with varying symptoms.

- u During the first (catarrhal) stage, the patient experiences a hacking, nocturnal cough, anorexia, sneezing, lacrimation, and rhinorrhea.
- u During the second (paroxysmal) stage, he experiences spasmodic and recurrent coughing that may expel tenacious mucus. Each cough characteristically ends in a loud, crowing, inspiratory whoop, and choking on mucus causes vomiting. (If the patient is a very young infant, he may not develop the typical whoop.)
- u In the third (convalescent) stage, paroxysmal coughing and vomiting gradually subside. However, for months afterward, even a mild upper respiratory tract infection may trigger paroxysmal coughing.

During your assessment, you may find the patient's temperature normal or low. Inspection in the first stage may reveal mild conjunctivitis and listlessness; in later stages, you may note engorgement of neck veins or epistaxis during paroxysmal coughing and exhaustion and cyanosis afterward.

During auscultation, you may hear diminished breath sounds in the lung periphery because of hypoventilation. You'll also detect wheezes, particularly after coughing, in the upper airways.

Diagnostic tests

Nasopharyngeal swabs and sputum cultures show *B. pertussis* only in the early stages of pertussis. Although fluorescent antibody screening of nasopharyngeal smears provides quicker results than cultures, it's less reliable.

Serologic assays are used to diagnose pertussis when cough persists longer than 2 to 3 weeks. Other common causes of respiratory infections include influenza virus, adenovirus, *Mycoplasma pneumonia*, *Chlamydia pneumonia*, and pyogenic bacteria.

Treatment

Infants and elderly patients usually require hospitalization and vigorous supportive therapy and fluid and electrolyte replacement. Other measures include adequate nutrition, oxygen therapy as warranted, and administration of antitussives and antibiotics, chiefly erythromycin, as ordered.

Nursing diagnoses

- u Activity intolerance u Anxiety u Fluid volume deficit u Impaired gas exchange u Ineffective airway clearance u Ineffective breathing pattern u Pain u Risk for infection u Risk for injury

Key outcomes

- u Adventitious breath sounds will be absent.
- u The patient's airway will remain patent.
- u The patient's arterial blood gas levels will return to normal.

- u No pathogens will appear in cultures.
- u The patient will attain and maintain normal fluid and electrolyte balance.

Nursing interventions

- u Pertussis calls for aggressive supportive care and respiratory isolation (masks only) for 5 to 7 days after initiation of antibiotic therapy.
- u To decrease exposure to infective organisms, change soiled linen, empty the suction bottle, and change the trash bag at least once each shift.
- u Collect nasopharyngeal specimens for laboratory testing.
- u Provide oxygen and moist air, and assist respiration, if needed.
- u Suction secretions as necessary. Elevate the head of the bed to facilitate breathing.
- u Encourage the patient to breathe deeply after receiving antitussives to enhance ventilation.
- u Create a quiet environment to decrease coughing stimulation.
- u Provide small, frequent meals to ensure adequate nutrition.
- u Monitor acid-base, fluid, and electrolyte balance. Administer parenteral fluid therapy as ordered, if vomiting is severe.
- u Assess for complications related to excessive coughing.
- u Report pertussis cases to local public health authorities.
- u Administer antibiotic therapy promptly as ordered.

Patient teaching

- u Encourage the patient or his parents to inform anyone the patient has contacted to see a doctor promptly.
- u Carefully explain all procedures to parents of young children, and offer emotional support.
- u Tell the patient or his parents to report complications to the doctor, including increasing fever, abdominal protrusion, seizures, and a return of symptoms. Tell the parents of infants (who are particularly susceptible to pertussis) that immunization—usually with the diphtheria and tetanus toxoids and pertussis vaccine—should take place at 2, 4, and 6 months of age. Boosters follow at 18 months and at ages 4 to 6. Inform them that the risk of pertussis is greater than the risk of vaccine complications, such as neurologic damage. However, the vaccination may cause seizures or unusual and persistent crying, a possible sign of a severe neurologic reaction. If this happens, the doctor may not order the other doses. Explain that the vaccine is contraindicated in children over age 6 because it can cause a high fever.
- u Direct the parents to report adverse reactions to the vaccine to the doctor.

PSEUDOMONAS INFECTIONS

Pseudomonas is a small, gram-negative bacillus that primarily produces nosocomial infections, superinfections of various parts of the body, and a rare disease called melioidosis. The most common infections associated with *Pseudomonas* include skin infections (such as burns and pressure ulcers), urinary tract infections, infant epidemic diarrhea and other diarrheal illnesses, bronchitis, pneumonia, bronchiectasis, meningitis, corneal ulcers, mastoiditis, otitis externa, and otitis media. This bacillus is especially associated with bacteremia, endocarditis, and osteomyelitis in drug addicts.

In local *Pseudomonas* infections, treatment usually is successful and complications rare. However, in patients with poor resistance to infection (for example, premature infants, elderly people, and persons with debilitating disease, burns, or wounds), septicemic *Pseudomonas* infections are considered serious. In some patients they may even cause death. (See [Melioidosis](#).)

Causes

The most common species of *Pseudomonas* is *P. aeruginosa*. Other pathogenic species include *P. maltophilia*, *P. cepacia*, *P. fluorescens*, *P. testosteroni*, *P. acidovorans*, *P. alcaligenes*, *P. stutzeri*, *P. putrefaciens*, and *P. putida*.

These organisms frequently are found in facility liquids that have been allowed to stand for a long time, such as benzalkonium chloride, hexachlorophene soap, saline solution, water in flower vases, and fluids in incubators, humidifiers, and respiratory therapy equipment. Outside the facility, *Pseudomonas* skin infections have been associated with the use of contaminated whirlpools, hot tubs, spas, and swimming pools.

In elderly patients, *Pseudomonas* infection usually enters through the genitourinary tract; in infants, *Pseudomonas* infection usually enters through the umbilical cord, skin, or GI tract.

Complications

Septic shock, the most serious complication of *Pseudomonas* infections, can cause death in people who are severely immunocompromised or resistant to antibiotics. *Pseudomonas* produces severe mucopurulent pneumonia, which may be necrotizing. The infection may invade the bloodstream, resulting in septicemic-inflammatory response syndrome (SIRS), multiple organ dysfunction, and death.

ADVANCED PRACTICE

Melioidosis

Wound penetration, inhalation, or ingestion of the gram-negative bacterium *Pseudomonas pseudomallei* causes melioidosis. Once endemic in Southeast Asia, incidence in the United States is rising because of the recent influx of Southeast Asian immigrants.

Two forms: Chronic and acute

Melioidosis occurs in two forms: chronic melioidosis, which causes osteomyelitis and lung abscesses, and acute melioidosis (rare), which causes pneumonia, bacteremia, and prostration. Acute melioidosis is commonly fatal. Most infections are chronic, however, and produce clinical symptoms only with accompanying malnutrition, major surgery, or severe burns.

Diagnostic measures consist of isolation of *P. pseudomallei* in a culture of exudate, blood, or sputum; serology tests (complement fixation, passive hemagglutination); and chest X-ray, with findings that resemble tuberculosis.

Treatment includes ceftazidime for clinical disease; alternatives are trimethoprim-sulfamethoxazole, cefotaxime, imipenem, and amoxicillin-clavulanate. Acute pulmonary infections are treated for up to 150 days for acute illness and longer for chronic conditions. In addition, surgical drainage of abscesses and aggressive treatment of septicemia may be necessary. Most cases are curable if treated appropriately, but septicemic infections continue to have a high mortality rate.

Assessment findings

The immunocompromised facility patient is the most vulnerable to *Pseudomonas*. Signs and symptoms vary with the infection site. In respiratory infection, the patient may complain of dyspnea, a cough producing purulent sputum, and chills. In urinary tract infection, he may report urinary urgency and frequency, dysuria, nocturia, low back pain, and malaise. In otitis externa, he may describe a painful or itching ear that is draining.

If the heart valves are involved, such as in I.V. drug abuse or prosthetic heart valve replacement, endocarditis results. Infection of the central nervous system includes

meningitis and brain abscess. Keratitis, corneal ulcer, or endophthalmitis results from infection of the eye.

PREVENTION

Preventing *pseudomonas* infection

To prevent *Pseudomonas* infection, maintain proper endotracheal and tracheostomy suctioning technique.

- Use strict sterile technique when caring for I.V. lines, catheters, and other tubes.
- Properly dispose of suction bottle contents.
- Label and date solution bottles and change them frequently, according to policy.
- Change water for fresh flowers daily.
- Avoid using humidifiers in the patient's room.

Although the patient's body temperature may be normal in some local infections, it's elevated in severe infection, such as bacteremia associated with *Pseudomonas*.

Inspection findings also vary. For example, in a respiratory infection, you may note cyanosis, apprehension, dyspnea and, possibly, mental confusion. In otitis externa using an otoscope, you may observe a tender, swollen external auditory canal filled with drainage. The drainage has a sickly sweet odor and consists of greenish-blue pus that forms a crust on wounds.

Abscesses may be palpable and tender on the skin surface. In *Pseudomonas* pneumonia, percussion discloses dullness over areas of mucopurulent drainage consolidation, and auscultation of the lungs may reveal crackles in areas of drainage collection.

Diagnostic tests

Diagnosis relies on isolation of the *Pseudomonas* organism in blood, cerebrospinal fluid, urine, exudate, or sputum culture.

Treatment

In the debilitated or otherwise vulnerable patient with clinical evidence of *Pseudomonas* infection, treatment should begin immediately, without waiting for laboratory test results. Most types of *P. aeruginosa* diseases are treated with one or more antibiotics to which the organism is sensitive. Antibiotic treatment includes aminoglycosides, such as gentamicin or amikacin, combined with a *Pseudomonas*-sensitive penicillin, such as ceftazidime or imipenem/cilastatin. Such combination therapy is necessary because *Pseudomonas* quickly becomes resistant to penicillin derivatives alone.

Pulmonary infections, particularly in individuals with cystic fibrosis, require aggressive pulmonary toiletry and bronchial lavage. Aerosolized antibiotics may also be used successfully in some cases. Lung transplantation may also be an option.

Surgical intervention is often required for *Pseudomonas* infections. Debridement of dentiled tissue, such as in otitis externa that is malignant, chronic osteomyelitis, or osteochondritis, is necessary. Drainage of pus areas is necessary. Affected heart valves require replacement. Necrotizing enterocolitis requires bowel resection, and urinary tract obstruction necessitates surgery.

With proper treatment, most infections with *P. aeruginosa* are curable. Extremely high mortality is associated with conditions that involve bacteremic pneumonia, septicemia, brain-wound sepsis, and meningitis. Chronic conditions, such as contiguous osteomyelitis, malignant otitis externa, and lower respiratory tract infections in patients with cystic fibrosis are difficult to eradicate and may end in death after long-term illness.

Nursing diagnoses

▫ Altered tissue perfusion (specify: cardiopulmonary, renal, cerebral, GI, peripheral) ▫ Impaired gas exchange ▫ Impaired skin integrity ▫ Ineffective airway clearance ▫ Pain ▫ Risk for infection

Key outcomes

- The patient will maintain normal cardiac output.
- Peripheral pulses will be present and strong.
- The patient will express a feeling of comfort in maintaining air exchange.
- The patient will cough effectively.
- The patient will exhibit improved or healing wounds or lesions.
- The patient will report increased comfort.
- Complications will be avoided or minimized.

Nursing interventions

- Observe and record the character of wound exudate and sputum.
- Before administering antibiotics, ask the patient about a history of allergies, especially to penicillin.
- Monitor the patient's hearing and renal function (urine output, specific gravity, urinalysis, and blood urea nitrogen and serum creatinine levels) during treatment with aminoglycosides.
- For respiratory infections, maintain a patent airway by suctioning secretions whenever necessary, and provide adequate oxygenation. Perform chest physiotherapy and postural drainage as needed.
- Administer ordered analgesics as needed.
- Protect immunocompromised patients from exposure to this infection. Attention to hand washing and aseptic techniques prevents further spread.
- Use strict sterile technique when changing dressings that involve infected wounds. Clean the wounds with a bactericidal solution and apply local antibiotic ointment, if ordered. (See [Preventing Pseudomonas infection.](#))

Patient teaching

- Reinforce the importance of completing the course of antibiotic therapy as prescribed.
- Educate the patient who wears contact lenses, especially extended-wear soft lenses, to care for them properly and to report any associated eye trauma or other symptoms.
- Teach the immunocompromised patient to avoid having sources of stagnant or contaminated water at home. Advise him to change the water for fresh flowers daily and, if a humidifier is essential, to change its water daily. Whirlpools and swimming pools must be scrupulously clean.

SALMONELLA INFECTION

Salmonella is one of the most common infections in the United States. It's caused by gram-negative bacilli of the genus *Salmonella*, a member of the Enterobacteriaceae family. It occurs as enterocolitis, bacteremia, localized infection, typhoid fever, or paratyphoid fever. Nontyphoidal forms of salmonella infection usually produce mild to moderate illness, with low mortality. Enterocolitis and bacteremia are especially common (and more virulent) among infants, elderly people,

and people already weakened by other infections, especially human immunodeficiency virus infection. Paratyphoid fever is rare in the United States.

Typhoid fever, the most severe form of salmonella infection, usually lasts from 1 to 4 weeks. The incidence of typhoid fever in the United States is increasing as a result of travel to endemic areas, especially the borders of Mexico. An attack of typhoid fever confers lifelong immunity, although the patient may become a carrier.

Causes

The most common species of *Salmonella* include *S. typhi*, which causes typhoid fever; *S. enteritidis*, which usually causes enterocolitis; and *S. choleraes*, which commonly causes bacteremia. Of an estimated 1,700 serotypes of *Salmonella*, 10 cause the diseases most common in the United States. All 10 can survive for weeks in water, ice, sewage, and food.

Nontyphoidal salmonella infection usually follows the ingestion of contaminated or inadequately processed foods, especially eggs, chicken, turkey, and duck. Proper cooking reduces the risk of contracting salmonella infection but doesn't eliminate it. Other causes include contact with infected people or animals and ingestion of contaminated dry milk, chocolate bars, or pharmaceuticals of animal origin. Salmonella infection may occur in children under age 5 from fecal-oral spread.

Typhoid fever usually results from drinking water contaminated by excretions of a carrier.

Complications

Salmonella infections may result in complications, such as intestinal perforation or hemorrhage, cerebral thrombosis, pneumonia, endocarditis, myocarditis, meningitis, pyelonephritis, osteomyelitis, cholecystitis, hepatitis, septicemia, and acute circulatory failure.

Assessment findings

Clinical manifestations of salmonella infections vary, depending on the specific clinical syndrome. (See [Assessing for salmonella infection](#).)

Assessment findings for paratyphoid fever are the same as for typhoid fever, but the clinical course usually is milder. In localized infections, assessment findings depend on the site.

Diagnostic tests

In most cases, diagnosis requires isolating the organism in a culture, particularly blood (in typhoid or paratyphoid fever and bacteremia) or stool (in typhoid or paratyphoid fever and enterocolitis). Other appropriate culture specimens include urine, bone marrow, pus, and vomitus. In endemic areas, clinical symptoms of enterocolitis allow a working diagnosis before the cultures are positive. The presence of *S. typhi* in stools 1 or more years after treatment indicates that the patient is a carrier (about 3% of patients).

Assessing for salmonella infection

Depending on the form of salmonella infection, the patient experiences various signs and symptoms. Typical findings in three forms of salmonella infection — enterocolitis, bacteremia, and typhoid fever—are discussed below.

Enterocolitis

In this form of salmonella infection, the patient may report having eaten contaminated food 6 to 48 hours before the onset of symptoms. He also may report sudden onset of nausea, vomiting (usually self-limiting), myalgia, headache, and a rise in temperature up to 102° F (38.9° C). The cardinal sign, diarrhea, usually persists for less than 7 days and may be accompanied by mild to severe abdominal cramping.

Inspection may reveal signs of dehydration — dry mucous membranes and decreased skin turgor. Auscultation may detect increased bowel sounds; palpation may detect abdominal tenderness.

Bacteremia

The patient's history commonly reveals immunocompromise, especially acquired immunodeficiency syndrome. Typically, the patient complains of anorexia, weight loss (without GI symptoms), joint pain, and chills. The disorder may follow a severe febrile course, lasting for days or weeks. The patient feels profoundly warm, and inspection may reveal dry skin with poor turgor and rapid, shallow breathing.

Auscultation may disclose normoactive or hypoactive bowel sounds and a systolic murmur if tachycardia develops. Palpation may detect a rapid, thready pulse and varying degrees of peripheral edema.

Typhoid fever

In this infection, the patient's history may reveal ingestion of contaminated food or water, typically 1 to 2 weeks before symptoms developed. Symptoms of enterocolitis occasionally arise within hours of ingesting *Salmonella typhi*.

Signs and symptoms follow a typical course. In the first week, the patient may report the insidious onset of malaise, anorexia, myalgia, and headache. In the second week, he may complain of chills, weakness, cough, increasing abdominal pain, and diarrhea or, more frequently, constipation. In the third week, he may experience worsening fatigue and weakness (which usually subside by the week's end), although relapses or complications can develop.

The patient's temperature may rise to 104° F (40° C), usually in the evening. The patient looks acutely ill, and rose-colored spots that blanch with pressure may appear on the trunk. Delirium, confusion, and coma may occur. Bowel sounds are typically hypoactive; chest auscultation may reveal crackles. Palpation may disclose abdominal distention and tenderness, the characteristic sensation of displacing air- and fluid-filled loops of bowel, an enlarged liver and spleen and, sometimes, cervical lymphadenopathy.

Widal's test, an agglutination reaction against somatic and flagellar antigens, may suggest typhoid fever with a fourfold increase in titer. Drug use or liver disease also can increase these titers and invalidate test results. Other supportive laboratory values may include transient leukocytosis during the first week of typhoidal salmonella infection, leukopenia during the third week, and leukocytosis in local infection.

Treatment

The type of antimicrobial agent chosen to treat typhoid fever, paratyphoid fever, or bacteremia depends on organism sensitivity. Choices include ampicillin, amoxicillin, chloramphenicol, ciprofloxacin, ceftriaxone, cefotaxime and, for the severely toxemic patient, co-trimoxazole. Localized abscesses may require surgical drainage. Enterocolitis requires a short course of antibiotics only if it causes septicemia or prolonged fever.

Symptomatic treatment includes bed rest and fluid and electrolyte replacement. Camphorated opium tincture, kaolin and pectin mixtures, diphenoxylate, codeine, or small doses of morphine can relieve diarrhea and control cramps for patients who remain active.

Nursing diagnoses

u Activity intolerance u Altered nutrition: Less than body requirements u Diarrhea u Fluid volume deficit u Hyperthermia u Pain u Risk for infection

Key outcomes

- u The patient will regain and maintain fluid and electrolyte balance.
- u The patient's elimination pattern will return to normal.
- u The patient will demonstrate skill in conserving energy while carrying out daily activities to tolerance level.
- u The patient will report adequate pain relief with analgesia or other measures.
- u The patient will experience no further weight loss.

Nursing interventions

- u Follow contact precautions. Wash your hands thoroughly before and after any contact with the patient.
- u Wear gloves and a gown when disposing of stool or fecally contaminated objects. Continue enteric precautions until three consecutive stool cultures are negative—the first one 48 hours after antibiotic treatment ends, followed by two more at 24-hour intervals.
- u Observe the patient closely for signs of bowel perforation: sudden pain in the lower right abdomen and rebound tenderness, one or more rectal bleeding episodes, sudden decreasing temperature or blood pressure, orthostatic hypotension, and increasing pulse rate.
- u During acute infection, promote rest, take safety precautions (because the patient may become delirious), and assign him a room close to the nurses' station so that you can check on him often. Use a room deodorizer to minimize odor from diarrhea.
- u Record intake and output. Maintain adequate I.V. fluid and electrolyte therapy as ordered. When the patient can tolerate oral feedings, encourage high-calorie fluids, such as milk shakes. Watch for constipation.
- u Provide good skin and mouth care. Turn the patient frequently, and perform mild passive exercises, as indicated. Apply mild heat to relieve abdominal cramps.
- u *Don't* administer antipyretics. They mask fever and may lead to hypothermia. Instead, promote heat loss by applying tepid, wet towels (don't use alcohol or ice) to the patient's groin and axillae or by wiping wet towels down his arms and legs.
- u Report salmonella cases to public health officials.

Patient teaching

u Advise the patient's close contacts to obtain a medical examination and treatment if cultures are positive. (See [Preventing recurrence of salmonella infection.](#))

PREVENTION

Preventing recurrence of salmonella infection

To prevent salmonella infection from recurring, follow these teaching guidelines:

- u Explain the causes of salmonella infection.
- u Show the patient how to wash his hands by wetting them under running water, lathering with soap and scrubbing, rinsing under running water with his fingers pointing down, and drying with a clean towel or paper towel.
- u Tell the patient to wash his hands after using the bathroom and before eating.
- u Tell him to cook foods thoroughly—especially eggs and chicken—and to refrigerate them at once.
- u Teach him how to avoid cross-contaminating foods by cleaning preparation surfaces with hot, soapy water and drying them thoroughly after use; cleaning surfaces between foods when preparing more than one food; and washing his hands before and after handling each food.
- u Tell the patient with a positive stool culture to avoid handling food and to use a separate bathroom or clean the bathroom after each use.
- u Tell the patient to report dehydration, bleeding, or recurrence of signs of salmonella infection.

u Urge those at high risk for contracting typhoid fever (laboratory workers and travelers) to be vaccinated.

SHIGELLOSIS

Shigellosis, which is also called bacillary dysentery, is an acute intestinal infection that causes a high fever (especially in children) and acute, self-limiting diarrhea with tenesmus; it also may cause electrolyte imbalance and dehydration. There are about 140 million cases of shigellosis worldwide, with almost 600,000 deaths, particularly in children under age 5, especially in underdeveloped countries.

Shigellosis commonly occurs in low-income, minority-group residents. Rates are especially high in children who attend day-care centers, retarded children in custodial care, and in people from poor, urban communities.

The prognosis for this infection is good. Mild infections normally subside within 10 days; severe infections may persist for 2 to 6 weeks.

Causes

Shigellosis is caused by *Shigella*, a short, nonmotile, gram-negative, rod-shaped bacterium. *Shigella* can be classified into four groups, all of which may cause shigellosis: group A, consisting of *S. dysenteriae*, which is most common in Central America and causes particularly severe infection and septicemia; group B, consisting of *S. flexneri*; group C, consisting of *S. boydii*; and group D, consisting of *S. sonnei*, which accounts for most cases reported in the United States.

Transmission is through the fecal-oral route, by direct contact with contaminated objects, or through ingestion of contaminated food or water. The housefly may be a vector.

Complications

Although not common, complications may be fatal in children and debilitated patients. Such complications include electrolyte imbalance (especially hypokalemia), metabolic acidosis, and shock. Less common complications include conjunctivitis, iritis, arthritis, rectal prolapse, secondary bacterial infection, acute blood loss from mucosal ulcers, and toxic neuritis.

Assessment findings

The patient's history commonly reveals crowded living conditions and family members or close contacts with acute diarrhea (the incubation period is 1 to 4 days between cases).

The patient initially may complain of nausea, abdominal pain, and diarrhea. In a day or two, stools usually increase in number but are smaller and contain pus, mucus, and blood (associated with tenesmus). High fever usually is present in children but not in adults unless it's associated with dehydration.

Inspection may reveal a patient in considerable discomfort, with dehydration, dry mucous membranes, loss of skin turgor, and decreased urine output. Central venous

pressure and blood pressure also may fall.

Auscultation may detect hyperactive bowel sounds. Palpation may elicit abdominal tenderness, especially over the lower abdominal quadrants, with accompanying distention. A dehydrated patient may have a rapid, thready pulse.

Diagnostic tests

During acute illness, stool cultures usually are positive. Microscopic examination of a fresh stool specimen may reveal mucus, red blood cells, and polymorphonuclear leukocytes; direct immunofluorescence with specific antisera may reveal *Shigella*. Severe infection increases hemagglutinating antibody levels. Sigmoidoscopy may reveal typical superficial ulcerations.

Diagnosis must rule out other causes of diarrhea, such as enteropathogenic *Escherichia coli* infection, malabsorption diseases, and amoebic or viral diseases.

Treatment

Shigellosis treatment involves contact precautions and includes nutritional support to reverse catabolism and, most important, replacement of fluids and electrolytes with I.V. infusions in sufficient quantities to maintain a urine output of 40 to 50 ml/hour and correct imbalances.

Antibiotics are of questionable value but may be used in an attempt to eliminate the pathogen and thereby prevent further spread. Ampicillin or trimethoprim-sulfamethoxazole is generally recommended and may be useful in severe cases, especially in children with overwhelming fluid and electrolyte losses.

Antidiarrheals that slow intestinal motility are contraindicated in shigellosis because they delay fecal excretion of *Shigella* and prolong fever and diarrhea.

Nursing diagnoses

u Altered nutrition: Less than body requirements u Diarrhea u Fluid volume deficit u Hyperthermia u Pain u Risk for infection

Key outcomes

- u The patient will regain and maintain normal fluid and electrolyte balance.
- u The patient's elimination pattern will return to normal.
- u The patient will report adequate pain relief with analgesia or other measures.
- u The patient will experience no further weight loss.
- u The patient will remain afebrile.

Nursing interventions

- u Provide supportive care to minimize complications and increase patient comfort.
- u Administer I.V. fluids and electrolytes as ordered. Measure intake and output, including stools, carefully. Weigh the patient daily. Encourage oral fluids when the patient can tolerate them.
- u Correct identification of *Shigella* requires examination and culture of fresh stool specimens. Therefore, hand carry specimens directly to the laboratory. If shigellosis is suspected, include this information on the laboratory slip.
- u Use a disposable hot water bottle to relieve abdominal discomfort, and schedule care to conserve patient strength.
- u To help prevent spreading this disease, maintain enteric precautions until three stool cultures are negative for *Shigella*. If you're at risk for exposure to the patient's stool, put on a gown and gloves before entering the room. Keep the patient's (and your own) nails short to avoid harboring organisms. Change soiled linens promptly and store them in an isolation container.
- u Keep the perianal area clean and lubricate it after each episode of diarrhea.
- u Provide a room deodorizer to minimize odor from diarrhea.
- u Report shigellosis to local health authorities.

Patient teaching

- u Instruct the patient to use proper hand-washing technique, especially after defecating and before eating or handling food.
- u Inform parents of the signs and symptoms of dehydration in infants and young children, and tell them when they should notify the doctor.
- u Children in day care should be kept at home while ill and should have a negative stool culture before returning to the day-care facility.
- u Food handlers should also have a negative stool culture before returning to the work environment.

Spirochetes and mycobacteria

Diseases caused by spirochetes and mycobacteria may advance from mild to incapacitating and life threatening. Most progress in stages and all affect skin integrity to some extent.

LEPROSY

Leprosy is a chronic, systemic infection characterized by progressive cutaneous lesions. It's sometimes called Hansen's disease. Ninety percent of leprosy cases in the United States are found in immigrants from leprosy-endemic regions (Mexico, India, and Southeast Asia). Incubation time is frequently 3 to 5 years but has been reported 6 months to several decades. It's commonly transmitted by humans, but a few cases have been transmitted from animals (armadillos and primates).

With timely and correct treatment, this seldom fatal disease has a good prognosis. Acute episodes may intensify leprosy's slowly progressing course, but whether such exacerbations are part of the disease process or a reaction to therapy remains unclear.

Untreated, leprosy can cause severe disability, blindness, and deformities. Leprosy takes three distinct forms:

- u Lepromatous leprosy, the most serious form, causes damage to the upper respiratory tract, eyes, testes, nerves, and skin.
- u Tuberculoid leprosy affects peripheral nerves and sometimes the surrounding skin, especially on the face, arms, legs, and buttocks.
- u Borderline (dimorphous) leprosy has characteristics of both lepromatous and tuberculoid leprosy. In this form of leprosy, skin lesions appear diffuse and poorly defined.

Causes

Leprosy is caused by *Mycobacterium leprae*, an acid-fast bacillus that attacks cutaneous tissue and peripheral nerves, especially the ulnar, radial, posteropopliteal, anterotibial, and facial nerves. The central nervous system appears highly resistant.

Susceptibility is highest during childhood and seems to decrease with age. Presumably, transmission occurs through airborne respiratory droplets that contain *M. leprae* or by inoculation through skin breaks (from a contaminated hypodermic or tattoo needle, for example).

Complications

Erythema nodosum leprosum, seen in lepromatous leprosy, may produce fever, malaise, lymphadenopathy, and painful, red skin nodules, usually during antimicrobial treatment, although the skin lesions may occur in untreated people.

In Mexico and other Central American countries, some patients with lepromatous disease develop *Lucio's phenomenon*: generalized reddened lesions with necrotic centers. These ulcers may extend into muscle and fascia.

Leprosy also may be complicated by secondary bacterial infection of skin ulcers, amyloidosis, deformity contractures, ocular disorders that can result in blindness and, rarely, hepatitis and exfoliative dermatitis.

Assessment findings

The patient may report living in close contact with another person who has leprosy. When the bacilli damage the skin's fine nerves, he may notice anesthesia, anhidrosis, and dryness. If the bacilli attack a large nerve trunk, he may experience motor nerve damage, weakness, and pain followed by peripheral anesthesia, muscle paralysis, or atrophy. In later stages, he may seek treatment for clawhand, footdrop, and visual disturbances, such as photophobia and blindness.

Lepromatous and tuberculoid leproses affect the skin in markedly different ways. In lepromatous disease, early multiple lesions appear symmetrical and erythematous. Sometimes they erupt as macules or papules with smooth surfaces. Later, they enlarge and form plaques or nodules called lepromas on the earlobes, nose, eyebrows, and forehead, giving the patient a characteristic leonine appearance.

In advanced stages, *M. leprae* may infiltrate the entire skin surface. Lepromatous leprosy also causes loss of eyebrows, eyelashes, and sebaceous and sweat gland function, as well as conjunctival and scleral nodules. Upper respiratory tract lesions cause epistaxis, ulcerated uvula and tonsils, septal perforation, and nasal collapse. Lepromatous leprosy can lead to orchitis and resultant testicular atrophy. Fingertips and toes deteriorate as bone resorption follows trauma and infection in these insensitive areas. Injury, ulceration, infection, and disuse of the deformed parts cause scars and contractures.

When tuberculoid leprosy affects the skin (sometimes it affects only the neurologic system), it produces large, raised, erythematous plaques or macules with clearly defined borders. As the lesions progress, they become rough, hairless, and hypopigmented. The patient usually reports numbness in the resultant scars.

In the patient with borderline leprosy, you'll see numerous skin lesions, but they're smaller and less sharply defined than tuberculoid lesions. The patient may report some feeling in the lesions. (Keep in mind that untreated borderline leprosy may deteriorate into lepromatous disease.)

Palpation may reveal hepatosplenomegaly in a patient with lepromatous leprosy. Lesions are all superficial and easily palpable.

Diagnostic tests

Identification of acid-fast bacilli in skin and nasal mucosa scrapings confirms a diagnosis of leprosy. A skin biopsy shows the typical histologic pattern of nerve changes. The skin biopsy and scrapings also are evaluated to determine the percentage of fully intact cells (morphologic index) and to measure the amount of bacteria present (bacterial index).

Treatment

Leprosy usually responds to antimicrobial therapy with sulfones, primarily oral dapsone, which may cause hypersensitivity reactions. Especially dangerous—but rare—reactions include hepatitis and exfoliative dermatitis. If these reactions occur, sulfone therapy should stop at once.

If leprosy fails to respond to sulfones or if the patient has respiratory or other complications, an alternative therapy, such as rifampin or clofazimine, may be effective.

Plantar ulcers are prevented by having the patient wear rigid-soled footwear or walking plaster casts. Contractures of the hand may be prevented by physical therapy. Reconstructive surgery is sometimes helpful. Nerve and tendon transplants and release of contractures also increase function. Plastic surgery for facial deformities may be needed. Ophthalmologic examinations should be done for all patients because 48% have evidence of sight-threatening ocular complications.

Nursing diagnoses

u Body image disturbance u Impaired physical mobility u Impaired skin integrity u Pain u Risk for infection u Risk for injury u Social isolation

Key outcomes

- u The patient will communicate feelings about changed body image.
- u The patient will express positive feelings about self.
- u The patient will state relief from pain.
- u The patient will exhibit improved or healed lesions or wounds.
- u The patient will interact with family or friends.
- u The patient will perform self-care activities independently.

Nursing interventions

- u Provide supportive patient care, taking steps to control acute infection, prevent complications, speed recovery and rehabilitation, and provide emotional encouragement.
- u Give antipyretics, analgesics, and sedatives, as needed. Watch for and report erythema nodosum leprosum, Lucio's phenomenon, and other complications.
- u Take precautions against the possible spread of infection even though leprosy isn't highly contagious. Instruct patients to cover coughs or sneezes with a paper tissue and to dispose of it properly. Take infection precautions when handling clothing or articles that touch open skin lesions.
- u Plan care to promote adequate rest and optimal nutrition.
- u Give the patient and family opportunities to express their feelings.
- u Initiate or participate in consultations with other health team members, especially for the patient with deformities. An interdisciplinary rehabilitation program, including physiotherapy and plastic surgery, may be necessary.
- u Inspect the patient's skin, and report observed changes. Assist with general hygiene and comfort measures, and provide a skin care program.

Patient teaching

- u Instruct the patient to be careful not to injure an anesthetized leg by putting too much weight on it. Advise him to carefully test bath water to avoid scalding. To prevent ulcerations, suggest wearing sturdy footwear and soaking feet in warm water after any kind of exercise, even a short walk. Advise rubbing the feet with petrolatum, oil, or lanolin.
- u Recommend that the patient use a tear substitute twice a day and protect his eyes, especially if he experiences decreased corneal sensation and lacrimation. Tell him to avoid rubbing his eyes and to wear sunglasses. Explain that these measures help prevent the corneal irritation and ulceration that lead to blindness.
- u Tell the patient to take antimicrobial medications exactly as prescribed for the entire length of time prescribed—in some cases, for life.
- u If appropriate, refer the patient to a regional treatment center or to the Gillis W. Long Hansen's Disease Center in Carville, La. This international research and education center provides diagnostic studies, treatment, and education for patients with leprosy. Patients are encouraged to return home as soon as their medical condition permits. The federal government pays the full cost of medical and nursing care.

Lyme disease, named for the small Connecticut town where it was first recognized in 1975, affects multiple body systems. Persons of all ages and both sexes are affected, with onset during the summer months. It occurs in areas where the geographic ranges of certain ixodid ticks are located. It typically begins with the classic skin lesion called erythema chronicum migrans. Weeks or months later, cardiac, neurologic, or joint abnormalities develop, possibly followed by arthritis.

Causes

Lyme disease is caused by the spirochete *Borrelia burgdorferi*. Carried by the minute tick *Ixodes dammini* (or another tick in the Ixodidae family), the disease occurs when a tick injects spirochete-laden saliva into the bloodstream or deposits fecal matter on the skin. After incubating for 3 to 32 days, the spirochetes migrate outward on the skin, causing a rash and disseminating to other skin sites or organs by the bloodstream or lymph system. The spirochete's life cycle isn't completely understood: They may survive for years in the joints, or they may die after triggering an inflammatory response in the host.

Complications

Myocarditis, pericarditis, arrhythmias, heart block, meningitis, encephalitis, cranial or peripheral neuropathies, and arthritis are among the known complications of Lyme disease.

Assessment findings

Your assessment findings may be deceptive. Patient complaints vary in frequency and severity, probably because the illness typically occurs in stages.

The patient's history may reveal recent exposure to ticks, especially if the patient lives, works, or plays in wooded areas where Lyme disease is endemic. He may report the onset of symptoms in warmer months. Typically reported symptoms include fatigue, malaise, and migratory myalgias and arthralgias.

Nearly 10% of patients report cardiac symptoms, such as palpitations and mild dyspnea, especially in the early stage. Severe headache and stiff neck, suggestive of meningeal irritation, also may occur in the early stage when the rash erupts. At a later stage, the patient may report neurologic symptoms, such as memory loss.

ADVANCED PRACTICE

Differentiating Lyme disease

Lyme disease, or chronic neuroborreliosis, needs to be differentiated from chronic fatigue syndrome or fibromyalgia. This differentiation is difficult in later stages of Lyme disease due to the chronic pain and fatigue that occur. The other diseases produce more generalized and disabling symptoms; also, patients lack evidence of joint inflammation, have normal neurologic tests, and have a greater degree of anxiety and depression than patients with Lyme disease.

Especially in children, body temperature may increase to 104° F (40° C) in the early stage and be accompanied by chills. You may see erythema chronicum migrans, which begins as a red macule or papule at the tick bite site and may grow as large as 2" (5.1 cm) in diameter. The patient may describe the lesion as hot and pruritic. Characteristic lesions (not seen in all patients) have bright red outer rims and white centers. They usually appear on the axilla, thigh, and groin. Within a few days, other lesions may erupt, as may a migratory, ringlike rash and conjunctivitis. In 3 to 4 weeks, the lesions fade to small red blotches, which persist for several more weeks.

Bell's palsy may be seen in the second stage and may occur alone. In the later stage, inspection may disclose signs and symptoms of intermittent arthritis: joint swelling, redness, and limited movement. Typically, the disease affects one or only a few joints, especially large ones, such as the knee.

Palpation of the pulse may detect tachycardia or irregular heartbeat. During the first or second stage, you may detect regional lymphadenopathy as well. The patient may complain of tenderness in the skin lesion site or the posterior cervical area. You'll note generalized lymphadenopathy less commonly.

If the patient has neurologic involvement, Kernig's and Brudzinski's signs usually aren't positive, and neck stiffness usually occurs only with extreme flexion. (See [Differentiating Lyme disease.](#))

Diagnostic tests

Blood tests, including antibody titers to identify *B. burgdorferi*, are the most practical diagnostic tests. The enzyme-linked immunosorbent assay (ELISA) may be ordered because of its greater sensitivity and specificity. However, serologic test results don't always confirm the diagnosis—especially in Lyme disease's early stages before the body produces antibodies—or seropositivity for *B. burgdorferi*. Also, the validity of test results depends on laboratory techniques and interpretation.

Mild anemia in addition to elevated erythrocyte sedimentation rate, white blood cell count, serum immunoglobulin M levels, and aspartate aminotransferase levels support the diagnosis.

A lumbar puncture may be ordered if Lyme disease involves the central nervous system. Analysis of cerebrospinal fluid may detect antibodies to *B. burgdorferi*.

Treatment

A 10- to 20-day course of antibiotics is the treatment of choice. Adults typically receive doxycycline; amoxicillin, cefuroxime axetil, and erythromycin are alternatives. Children usually receive oral amoxicillin. Administered early in the disease, these medications can minimize later complications. In later stages, high-dose ceftriaxone, cefotaxime, or penicillin G sodium administered I.V. may produce good results.

Nursing diagnoses

u Altered tissue perfusion (cerebral, cardiopulmonary, peripheral) u Fatigue u Hyperthermia u Impaired physical mobility u Knowledge deficit u Pain u Risk for infection

Key outcomes

- u The patient will maintain a normal body temperature.
- u The patient's rash will decrease in size.
- u The patient will verbalize accurate information about the disease.
- u The patient will state relief from pain.
- u The patient will attain the highest degree of mobility possible.

Nursing interventions

- u Plan care to provide adequate rest.
- u Ask the patient about possible drug allergies before administering antibiotics.
- u Administer analgesics and antipyretics as ordered.
- u If the patient has arthritis, help him with range-of-motion and strengthening exercises, but avoid overexerting him.

u Protect the patient from sensory overload, and reorient him if needed. Also, encourage him to express his feelings and concerns about memory loss, if appropriate.

Patient teaching

- u Instruct the patient to take antibiotic medications as prescribed.
- u Urge him to return for follow-up care and to report recurrent or new symptoms to the doctor.
- u Inform the patient, family members, and other caregivers about ways to prevent Lyme disease. Advise them to avoid tick-infested areas, if possible. If this isn't feasible, suggest covering the skin with clothing, using insect repellents, inspecting exposed skin for attached ticks at least every 4 hours, and removing ticks, if present, with tweezers or forceps and firm traction. A vaccine has been developed for persons at risk for contracting Lyme disease. The patient can consult a doctor or local clinic for information.

RELAPSING FEVER

Whether it's called bilious typhoid or tick, fowl-nest, cabin, or vagabond fever, relapsing fever is an acute infectious disease caused by a species of the *Borrelia* spirochetes. Relapsing fever is transmitted by lice or ticks and is characterized by relapses and remissions. This disease occurs most often in northwestern Africa, especially the highlands of Ethiopia, due to louse-borne relapsing fever. Tick-borne relapsing fever is endemic to sub-Saharan Africa and is also found in the Mediterranean and Middle Eastern regions, southern Russia, the Indian subcontinent, China, and west of the Mississippi River in the United States.

The incubation period for relapsing fever is 5 to 15 days (the average is 7 days). With treatment, the prognosis for both louse- and tick-borne relapsing fever is excellent.

Untreated louse-borne fever has a high mortality risk, especially for persons in poor health, such as famine-affected populations.

Causes

The body louse (*Pediculus humanus corporis*) carries the spirochete responsible for relapsing fever (*B. recurrentis*). This louse transmits the disease from person to person. Inoculation occurs when the victim crushes the louse, causing its infected blood or body fluid to seep into the victim's broken skin or mucous membranes. Louse-borne relapsing fever typically erupts epidemically during wars, famines, and mass migrations. Cold weather and crowded living conditions favor the spread of body lice.

Tick-borne relapsing fever is caused by several species of *Borrelia* transmitted to humans by *Ornithodoros* ticks. Outbreaks usually occur during the summer when ticks and their hosts (chipmunks, goats, prairie dogs) are most active. Cold-weather outbreaks may afflict people who sleep in tick-infested cabins, such as campers. Because tick bites are painless and *Ornithodoros* ticks frequently feed at night without imbedding themselves in the victim's skin, many people are bitten unknowingly.

Complications

Nephritis, bronchitis, pneumonia, endocarditis, seizures, cranial nerve lesions, paralysis, and coma are complications of this disease. Death may result from hyperpyrexia, massive bleeding, circulatory failure, splenic rupture, or a secondary infection.

Assessment findings

The patient's history may reveal recent travel in an epidemic or a louse-infested area. Or you may find that the patient was recently exposed to ticks or a tick-infested area.

Clinical signs and symptoms of louse- and tick-borne relapsing fever are similar. The patient may relate sudden prostration, headache, severe myalgia, arthralgia, diarrhea, vomiting, coughing, and eye or chest pains.

Palpation commonly discloses splenomegaly and, possibly, hepatomegaly and lymphadenopathy. During febrile periods, when body temperature may increase suddenly to 105° F (40.6° C), the patient's pulse rate and respiratory rate increase, and you may note a transient, petechial rash that may spread over his torso.

The first attack usually lasts from 3 to 6 days; then the patient's temperature drops quickly, accompanied by profuse sweating, About 5 to 10 days later, a second febrile, symptomatic period begins. In louse-borne infection, additional relapses are unusual, but in tick-borne disease, a second or third relapse is common. As the afebrile intervals lengthen, relapses become shorter and milder as the body accumulates antibodies to fight the infection.

Diagnostic tests

Blood smears done with Wright's or Giemsa stain may confirm the diagnosis by revealing the infecting spirochete if blood is obtained during a febrile period. *Borrelia* spirochetes may be less detectable in subsequent relapses because their number in the blood declines.

In such cases, a sample of the patient's blood or tissue may be injected into a young rat and incubated there for 1 to 10 days. If the patient has relapsing fever, subsequent testing of the rat's tail blood may disclose large numbers of spirochetes.

Urine and cerebrospinal fluid analyses may uncover spirochete-induced infection. Other abnormal findings include a white blood cell (WBC) count as high as 25,000/mm³, with increases in lymphocyte levels and erythrocyte sedimentation rate. However, the WBC count may be within normal limits. Because the *Borrelia* organism is a spirochete, test findings in relapsing fever may be similar to those in syphilis.

Treatment

Treatment with erythromycin, tetracycline, chloramphenicol, or penicillin results in clearance of the spirochetes and a remission of symptoms. In children under age 9 and pregnant women, erythromycin and penicillin are preferred. Hydrocortisone and acetaminophen given at the same time as antibiotics reduce peak body temperature. Vitamin K and other soluble vitamins may help counter deficiencies in louse-type induced fever.

An adult usually receives oral antibiotic therapy—tetracycline for 4 to 5 days—as the first choice. In children and seriously ill patients who can't take tetracycline, penicillin G, erythromycin, or ceftriaxone may be administered as an alternative.

Antibiotics given at the height of a severe febrile attack can result in a Jarisch-Herxheimer reaction, causing malaise, rigor, leukopenia, flushing, fever, tachycardia, increasing respiratory rate, and hypotension. This reaction, which is caused by toxic by-products from massive spirochete destruction, can mimic septic shock and may be fatal.

Nursing diagnoses

- u Decreased cardiac output u Diarrhea u Fluid volume deficit u Hyperthermia u Impaired skin integrity u Pain

Key outcomes

- u The patient will attain hemodynamic status.
- u The patient will maintain adequate cardiac output.
- u The patient will state relief from pain.
- u The patient's elimination pattern will return to normal.

- u The patient will exhibit healed or improved lesions or wounds.
- u The patient's vital signs will remain stable.
- u The patient's fluid volume will remain adequate.

Nursing interventions

- u Monitor the patient's vital signs, level of consciousness (LOC), and temperature every 2 to 4 hours throughout febrile periods. Watch for and immediately report any signs of neurologic complications, such as decreasing LOC and seizures. To reduce fever, give tepid sponge baths or apply a hypothermia blanket, and administer antipyretics as ordered.
- u Administer analgesics, as ordered, to alleviate discomfort during febrile periods.
- u Maintain adequate fluid intake to prevent dehydration. Provide I.V. fluids as ordered. Accurately measure intake and output, especially for the patient with vomiting and diarrhea.
- u Give antibiotics carefully. Document and report any hypersensitivity reaction (rash, fever, anaphylaxis), especially a Jarisch-Herxheimer reaction.
- u Treat flushing, hypotension, and tachycardia with vasopressors or fluids as ordered.
- u Look for symptoms of relapsing fever in family members and in others who may have been exposed to ticks or lice along with the victim.
- u Use proper hand-washing technique. Isolation is unnecessary because the disease isn't transmitted from person to person.
- u Report all cases of louse- or tick-borne relapsing fever to the local public health department, as required by law.

Patient teaching

- u Teach the patient and family members measures to reduce body temperature and prevent dehydration, if patient care is to occur at home. Also, demonstrate proper hand-washing technique.
- u Advise the patient to plan frequent rest periods.
- u Encourage the patient to take antibiotic medications exactly as prescribed.
- u Help the patient and family members recognize the signs and symptoms of neurologic toxicity: altered memory, hallucinations, and agitation.
- u To help prevent relapsing fever, advise anyone traveling to tick-infested areas to wear clothing that covers as much skin as possible. Recommend fastening sleeves and collars and tucking pant legs into boots or socks.

SYPHILIS

Syphilis is a chronic, infectious, sexually transmitted disease that begins in the mucous membranes and quickly becomes systemic, spreading to nearby lymph nodes and the bloodstream. Untreated, the disease progresses in four stages: primary, secondary, latent, and late (formerly called tertiary).

Incidence in the United States is highest among urban populations, especially in people between ages 15 and 39, drug users, and those infected with the human immunodeficiency virus (HIV).

Untreated syphilis can lead to crippling or death. With early treatment, the prognosis is excellent. The incubation period varies but typically lasts about 3 weeks.

Causes

The spirochete *Treponema pallidum* causes syphilis. Transmission occurs primarily through sexual contact during the primary, secondary, and early latent stages of infection. Prenatal transmission (from an infected mother to the fetus) also is possible. (See [Understanding congenital syphilis.](#))

Transmission by way of a fresh blood transfusion is rare. After 96 hours in stored blood, the *T. pallidum* spirochete dies.

Complications

Aortic regurgitation or aneurysm, meningitis, and widespread central nervous system damage can result from advanced syphilis.

CULTURAL TIP Members of some cultures, such as Vietnamese, believe certain illnesses, such as pustules and open wounds, are temporary and don't require treatment. Education about the importance of prompt treatment can deter the onset of complications in such patients.

Assessment findings

The typical patient history points to unprotected sexual contact with an infected person or with multiple or anonymous sexual partners.

In a patient with *primary syphilis*, you may observe one or more chancres (small, fluid-filled lesions) on the genitalia and others on the anus, fingers, lips, tongue, nipples, tonsils, or eyelids. In female patients, chancres may develop on the cervix or the vaginal wall. These usually painless lesions start as papules and then erode. They have indurated, raised edges and clear bases and typically heal after 3 to 6 weeks, even when untreated. In the primary stage, palpation may reveal enlarged unilateral or bilateral regional lymph nodes (adenopathy).

In *secondary syphilis* (beginning within a few days or up to 8 weeks after the initial chancres appear), the patient may complain of headache, nausea, vomiting, malaise, anorexia, weight loss, sore throat, and a slight fever.

On inspection, you may see symmetrical mucocutaneous lesions. The rash of secondary syphilis may appear macular, papular, pustular, or nodular. Lesions are uniform, well defined, and generalized. Macules typically erupt between rolls of fat on the trunk and proximally on the arms, palms, soles, face, and scalp. In warm, moist body areas (the perineum, scrotum, or vulva, for example), the lesions enlarge and erode, producing highly contagious, pink or grayish-white lesions (condylomata lata).

Alopecia, which usually is temporary, may occur with or without treatment. The patient also may complain of brittle, pitted nails.

Palpation may disclose generalized lymphadenopathy.

In *latent syphilis*, physical signs and symptoms are absent except for possible recurrence of mucocutaneous lesions that resemble those of secondary syphilis.

In *late syphilis*, the patient's complaints vary with the involved organ. Late syphilis has three subtypes: neurosyphilis, late benign syphilis, and cardiovascular syphilis.

If *neurosyphilis* affects meningovascular tissues, the patient may report headache, vertigo, insomnia, hemiplegia, seizures, and psychological difficulties. If neurosyphilis affects parenchymal tissue, he may report paresis, alteration in intellect, paranoia, illusions, and hallucinations. Inspection may reveal Argyll Robertson pupil (a small, irregular pupil that is nonreactive to light but accommodates for vision), ataxia, slurred speech, trophic joint changes, positive Romberg's sign, and a facial tremor.

If the patient has *late benign syphilis*, he may complain of gummas—lesions that develop between 1 and 10 years after infection. A single gumma may be a chronic, superficial nodule or a deep, granulomatous lesion that is solitary, asymmetrical, painless, indurated, and large or small. Visible on the skin and mucocutaneous tissues, gummas commonly affect bones and can develop in any organ. If they involve the nasal septum or palate, they may cause perforation and disfigurement.

Understanding congenital syphilis

A woman can transmit syphilis transplacentally to the fetus throughout pregnancy. Congenital syphilis is sometimes called prenatal syphilis because about 50% of infected fetuses die before or shortly after birth. The prognosis improves for infants who develop overt infection after age 2.

Suspicious signs and symptoms

The infant with congenital syphilis may appear healthy at birth but usually develops characteristic lesions—vesicular, bullous eruptions on the palms and soles—3 weeks later. Soon thereafter, a maculopapular rash similar to that in secondary syphilis may erupt on the face, mouth, or genitalia.

Condylomata lata typically break out around the anus. Lesions also may erupt on the mucous membranes of the mouth, pharynx, and nose. If lesions affect the larynx, the infant's cry sounds weak and forced. If nasal mucous membranes are involved, a discharge may develop and may be slight and mucopurulent or copious with blood-tinged pus. Visceral and bone lesions, liver or spleen enlargement with ascites, and nephrotic syndrome may develop.

Late congenital syphilis becomes apparent after age 2 and may be identified through blood studies or through unmistakable syphilitic manifestations: screwdriver-shaped central incisors, deformed molars or cuspids, thick clavicles, saber shins, bowed tibias, nasal septum perforation, nerve deafness, and neurosyphilis.

Test findings

In the infant with congenital syphilis, the Venereal Disease Research Laboratory titer, if reactive at birth, stays the same or increases, indicating active disease. The infant's titer decreases in 3 months if the mother received effective prenatal treatment. Absolute diagnosis requires dark-field microscopic examination of umbilical vein blood or lesion drainage.

Therapy

An infant with abnormal cerebrospinal fluid (CSF) may receive aqueous crystalline penicillin G, I.M. or I.V. (50,000 units/kg of body weight daily divided in two doses for at least 10 days) or aqueous penicillin G procaine I.M. (50,000 units/kg of body weight daily for at least 10 days). An infant with normal CSF may receive a single injection of penicillin G benzathine (50,000 units/kg of body weight).

Nursing interventions

When caring for an infant with congenital syphilis, record the extent of the rash, and watch for signs of systemic involvement, especially laryngeal swelling, jaundice, and decreased urine output.

In *cardiovascular syphilis*, decreased cardiac output may cause decreased urine output and decreased sensorium related to hypoxia. Auscultation may reveal pulmonary congestion.

Diagnostic tests

Dark-field microscopy identifies *T. pallidum* from lesion exudate provides an immediate syphilis diagnosis. This method is most effective when moist lesions are present, as in primary, secondary, and congenital syphilis. (See [Identifying syphilis by dark-field microscopy.](#))

Nontreponemal serologic tests include the Venereal Disease Research Laboratory (VDRL) slide test, the rapid plasma reagin (RPR) test, and the automated reagin test. These tests can detect nonspecific antibodies, which become reactive within 1 to 2 weeks after the primary syphilis lesion appears or 4 to 5 weeks after the infection begins. Rapid and inexpensive, the tests are used for screening patients and blood products.

Treponemal serologic studies include the fluorescent treponemal antibody absorption test, the *T. pallidum* hemagglutination assay, and the microhemagglutination assay. These tests detect the specific antitreponemal antibody and can confirm positive screening results. Once reactive, a patient's blood samples will always be reactive.

Cerebrospinal fluid examination identifies neurosyphilis when the total protein level is above 40 mg/dl, the VDRL slide test is reactive, and the white blood cell count exceeds five mononuclear cells/mm³.

Treatment

Antibiotic therapy—penicillin administered I.M.—is the treatment of choice. For early syphilis, treatment may consist of a single injection of penicillin G benzathine I.M. (2.4 million units). Syphilis of more than 1 year's duration may respond to penicillin G benzathine I.M. (2.4 million units/week for 3 weeks).

Patients who are allergic to penicillin may be successfully treated with tetracycline or erythromycin (in either case, 500 mg by mouth four times a day for 15 days for early syphilis, 30 days for late infections). Tetracycline is contraindicated during pregnancy.

Nursing diagnoses

⌘ Altered sexuality patterns ⌘ Body image disturbance ⌘ Impaired physical mobility ⌘ Impaired skin integrity ⌘ Risk for infection ⌘ Risk for injury ⌘ Sexual dysfunction

Key outcomes

- ⌘ The patient will voice feelings about potential or actual changes in sexual activity.
- ⌘ The patient will express concern about self-concept, esteem, and body image.
- ⌘ The patient will state infection risk factors.
- ⌘ The patient will remain free from all signs and symptoms of infection.
- ⌘ The patient will exhibit improved or healed lesions or wounds.
- ⌘ The patient will report feelings of comfort.
- ⌘ Complications will be avoided or minimized.

Nursing interventions

- ⌘ Follow standard precautions when assessing the patient, collecting specimens, and treating lesions.
- ⌘ Check for a history of drug sensitivity before administering the first dose of medication.
- ⌘ Promote rest and adequate nutrition.
- ⌘ In secondary syphilis, keep lesions clean and dry. If they're draining, dispose of contaminated materials properly.
- ⌘ Assess for complications of late syphilis if the patient's infection is older than 1 year. In late syphilis, provide symptomatic care during prolonged treatment.
- ⌘ As needed, obtain a physical or occupational therapy consultation. Also consult with a social worker to determine home care needs.
- ⌘ Report all syphilis cases to the appropriate health authorities.

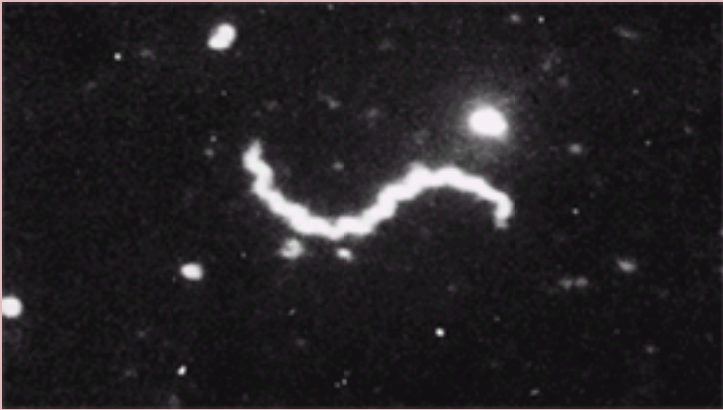

Patient teaching

- ⌘ Make sure the patient clearly understands his medication and dosage schedule and knows how to obtain the medication.
- ⌘ Stress the importance of completing the prescribed course of therapy even after symptoms subside. Evaluate the need for home nursing care.

- u Urge the patient to inform sexual partners of his infection and to encourage them to seek testing and treatment.
- u Remind the patient to schedule follow-up tests.
- u Advise the patient to refrain from sexual activity until he completes treatment and follow-up VDRL and RPR test results are normal.

Identifying syphilis by dark-field microscopy

In syphilis, the presence of spiral-shaped bacteria (*Treponema pallidum*) on dark-field examination confirms the diagnosis.

- u Counsel the patient and sexual partners about human immunodeficiency virus infection and recommend HIV testing.
- u Inform the patient that using condoms may provide protection against sexually transmitted diseases.

Mycoses

Mycotic diseases, which are caused by fungi such as yeasts and molds, may be superficial or systemic. Candidiasis, cryptococcosis, histoplasmosis, coccidioidomycosis, and sporotrichosis are among prevalent mycotic diseases.

BLASTOMYCOSIS

Also called North American blastomycosis and Gilchrist's disease, blastomycosis is a fungal infection that usually affects the lungs and produces bronchopneumonia. During the chronic stage of illness, the disease may disseminate through the blood and cause skin disorders (most commonly), osteomyelitis, genitourinary (GU) disorders, and central nervous system (CNS) disorders (rarely). In contrast to other fungal diseases, it seldom acts as an opportunistic infection.

Blastomycosis is found in North America (where *Blastomyces dermatitidis* normally inhabits the soil). Sporadic cases have been reported in Africa.

The incubation period ranges from weeks to months. Untreated blastomycosis is slowly progressive and usually fatal, although spontaneous remission may occur. The mortality rate is 15% in appropriately treated cases.

Causes

A yeastlike fungus, *B. dermatitidis*, causes blastomycosis. The fungus is probably inhaled by people whose work or recreation brings them in close contact with the soil. No occupational link has been found.

Complications

Blastomycosis can cause skin abscesses or fistulas, meningitis, cerebral abscesses, Addison's disease, pericarditis, and arthritis.

Assessment findings

The patient may report exposure to soil in a wooded area. Symptoms vary, depending on the involved site. The patient with acute pulmonary blastomycosis may complain of a dry, hacking, or productive cough (occasionally with hemoptysis); pleuritic chest pain; myalgia; and arthralgia—symptoms similar to those of a viral upper respiratory tract infection.

If the disease reaches the chronic stage, the patient may complain of a productive cough accompanied by hemoptysis, anorexia, malaise, weight loss, and pleuritic chest pain.

A patient with bone involvement usually doesn't report pain. But a patient with a GU infection may complain of deep perineal pain; patients with epididymitis, orchitis, or prostatitis also report pain.

Your assessment is likely to reveal fever and chills in the acute stage, although you may detect only a low-grade fever or no fever in the chronic stage.

With CNS involvement, inspection may reveal an altered level of consciousness (LOC), lethargy, and a change in mood or affect.

With pneumonia, inspection may show tachypnea and shortness of breath.

With cutaneous involvement, you may see two types of skin lesions on exposed body parts: small, pustular, gray or white papules that spread and become encrusted and, less frequently, ulcerative lesions.

If the disease disseminates to the bone, you may see soft-tissue swelling and redness over bony lesions. These findings usually occur in the thoracic, lumbar, and sacral regions; the long bones of the legs; and the skull (in children).

As you inspect the patient with GU involvement, you may note swelling in the groin and scrotum. His urine may appear cloudy or show hematuria.

Palpation may reveal warmth and tenderness over involved bones or genital sites.

Auscultation may disclose decreased breath sounds if consolidation occurs. In acute pulmonary infection, the lower lobes are affected most often.

Diagnostic tests

Accurate diagnosis of blastomycosis requires the following:

- u A culture of *B. dermatitidis* from skin lesions, pus, sputum, or pulmonary secretions.
- u Microscopic examination of tissue biopsy from the skin or the lungs or of bronchial washings, sputum, or pus.
- u Complement fixation testing (a high titer in extrapulmonary disease suggests a poor prognosis but isn't conclusive).
- u Immunodiffusion testing to detect antibodies for the A and B antigen of blastomycosis.

⌞ Suspected pulmonary blastomycosis also requires a chest X-ray, which may show pulmonary infiltrates.

Other abnormal laboratory findings include an increased white blood cell count, an elevated erythrocyte sedimentation rate, slightly increased serum globulin levels, mild normochromic anemia and, with bone lesions, increased alkaline phosphatase levels.

Treatment

Amphotericin B is used to treat all patients with rapidly progressive infections, severe illness, or meningitis. Itraconazole is used to treat patients with mild to moderately severe indolent non-meningeal blastomycosis, and ketoconazole is the alternative treatment.

Nursing diagnoses

⌞ Impaired gas exchange ⌞ Impaired physical mobility ⌞ Impaired skin integrity ⌞ Ineffective airway clearance ⌞ Ineffective breathing pattern ⌞ Pain ⌞ Risk for injury

Key outcomes

- ⌞ The patient will be free from pain.
- ⌞ Patient's arterial blood gas (ABG) levels will return to baseline.
- ⌞ The patient will express a feeling of comfort in maintaining air exchange.
- ⌞ The patient will cope effectively.
- ⌞ The patient's airway will remain patent.
- ⌞ The patient will maintain functional mobility.

Nursing interventions

- ⌞ Administer analgesics, as ordered, for pain.
- ⌞ If the patient is receiving ketoconazole, monitor for elevated liver enzyme levels and nausea that doesn't subside. Also watch for unusual fatigue, jaundice, dark urine, and pale stools.
- ⌞ If ordered, slowly infuse I.V. amphotericin B. During the infusion, closely monitor the patient's vital signs. His temperature may increase, but it should subside within 1 to 2 hours.
- ⌞ Watch for adverse effects of amphotericin B, such as decreased urine output, and monitor laboratory results for increased blood urea nitrogen and serum creatinine levels as well as hypokalemia. These may indicate renal toxicity. Report hearing loss, tinnitus, or dizziness immediately.
- ⌞ To relieve adverse effects of amphotericin B, give antiemetics, antihistamines, and antipyretics as ordered.
- ⌞ If the patient has a pulmonary infection, assess his respiratory status frequently, and monitor ABG levels. Also, administer oxygen and suction the patient's airway as needed, encourage coughing and deep breathing, and observe secretions for changes in character and amount. Watch especially for hemoptysis.
- ⌞ If the patient experiences joint pain or swelling, elevate the joint and apply heat.
- ⌞ If CNS infection occurs, watch the patient carefully for decreasing LOC and unequal pupillary response.
- ⌞ Watch for hematuria in men with disseminated disease.
- ⌞ If cutaneous involvement occurs, frequently inspect the patient's skin. Also, provide supportive measures, such as assisting with hygiene, using protective skin care devices, and keeping the patient's linens clean, dry, and wrinkle-free.

Patient teaching

- ⌞ Explain that the disease is infectious but not contagious.
- ⌞ Teach the patient about drug therapy, including adverse effects. Stress the importance of completing the prescribed course of treatment, which may take up to 6 months.
- ⌞ Show the patient how to clean skin lesions with a bactericidal agent to prevent superinfection. Tell him he also can use soothing non-deodorant lotions.
- ⌞ Inform the patient that he needs regular follow-up treatment.

CANDIDIASIS

Also known as candidosis and moniliasis, this usually mild, superficial fungal infection can lead to severe disseminated infections and fungemia in an immunocompromised patient. In most cases, the causative fungi infect the nails (paronychia), skin (diaper rash), or mucous membranes, especially the oropharynx (thrush), vagina (vaginitis), esophagus, and GI tract.

These fungi may enter the bloodstream and invade the kidneys, lungs, endocardium, brain, or other structures, causing serious systemic infection. Such systemic infection predominates among drug abusers and facility patients (particularly diabetic and immunosuppressed patients).

The prognosis varies, depending on the patient's resistance. The incidence of candidiasis continues to increase because of increasing use of I.V. antibiotic therapy and increasing numbers of immunocompromised patients in the acute care setting.

Causes

Most cases of candidiasis result from infection with *Candida albicans* or *C. tropicalis*, although eight other potentially disease-causing strains exist among the more than 150 species of *Candida*. One of the normal flora of the GI tract, mouth, vagina, and skin, *C. albicans* causes infection when some change in the body permits their sudden proliferation. The changes may be triggered by increasing glucose levels from diabetes mellitus, lowered resistance from such diseases as cancer, immunosuppressant drug therapy, radiation, aging, or irritation from dentures.

The infecting organism may enter the body through I.V. or urinary catheterization, drug abuse, total parenteral nutrition, or surgery. The most common precipitator is the use of broad-spectrum antibiotics such as tetracycline. These agents decrease the number of normal bacterial flora, which permits the number of fungi, including candidal organisms, to increase.

Identifying thrush

Candidiasis of the oropharyngeal mucosa (thrush) causes cream-colored or bluish-white pseudomembranous patches on the tongue, mouth, or pharynx (as shown). Fungal invasion may extend to circumoral tissues.

A mother with vaginitis can transmit the organism (as oral thrush) to the neonate during vaginal delivery.

Complications

The most common complications include *Candida* dissemination with organ failure of the kidneys, brain, GI tract, eyes, lungs, and heart.

Assessment findings

The patient's history may reveal an underlying illness, such as cancer, diabetes, or human immunodeficiency virus infection; a recent course of antibiotic or antineoplastic therapy; or drug abuse.

Depending on the infection site, superficial infection may cause the following signs and symptoms:

- u Skin—scaly, erythematous, papular rash, possibly covered with exudate and erupting in breast folds, between fingers, and at the axillae, groin, and umbilicus (in diaper rash, papules appear at the edges of the rash)
- u Nails—red, swollen, darkened nailbeds; occasionally, purulent discharge; sometimes the nail separates from the nail bed
- u Esophageal mucosa—occasionally, scales in the mouth and throat
- u Vaginal mucosa—white or yellow discharge, with local excoriation; white or gray raised patches on vaginal walls, with local inflammation
- u Oropharyngeal mucosa—cream-colored or bluish white lacelike patches of exudate on the tongue, mouth, or pharynx that reveal bloody engorgement when scraped. Pain and a burning sensation in the mouth and throat may occur. These lesions may swell, causing respiratory distress in infants. (See [Identifying thrush.](#))

If the patient has systemic disease, he also may report myalgia, arthralgia, chills with a high and spiking fever, prostration, and rash. Other specific complaints vary, depending on the infection site:

- u Lungs—hemoptysis, cough; coarse breath sounds in the lung fields infected by *Candida*
- u Kidneys—flank pain, dysuria, hematuria, cloudy urine with casts
- u Brain—headache, nuchal rigidity, seizures, focal neurologic deficits
- u Eyes—blurred vision, orbital or periorbital pain, exudate, floating scotomata, and lesions with a white, cotton-ball appearance seen during ophthalmoscopy
- u Endocardium—chest pain and arrhythmias. Auscultation may reveal a systolic or diastolic murmur with endocarditis.

Diagnostic tests

Detection of candidal organisms by a Gram stain of skin, vaginal scrapings, pus, or sputum or on skin scrapings prepared in potassium hydroxide solution confirms the diagnosis.

Tests for systemic infection include blood and tissue cultures.

Treatment

Initial treatment aims to improve the underlying condition that predisposes the patient to candidiasis. For example, measures may be taken to control diabetes or to discontinue antibiotic therapy or catheterization, if possible.

For superficial candidiasis, the doctor may prescribe an antifungal medication such as nystatin. Clotrimazole, fluconazole, and miconazole are effective in mucous membrane and vaginal candidiasis. Ketoconazole or fluconazole is the primary choice for chronic candidiasis of the mucous membranes.

Treatment for systemic infection consists mainly of I.V. amphotericin B, but flucytosine or miconazole may be added.

Removing infected prostheses (including, for example, cardiac valves or prosthetic joints) or catheters is essential. Draining abscesses surgically or percutaneously is also recommended.

Nursing diagnoses

- u Altered oral mucous membrane
- u Altered urinary elimination
- u Hyperthermia
- u Impaired skin integrity
- u Pain
- u Risk for aspiration
- u Sexual dysfunction

Key outcomes

- u The patient will show no signs of aspiration.
- u The patient's temperature and white cell count will remain normal.
- u The patient will maintain fluid balance; input should equal output.
- u The patient will report increased comfort.
- u Complications will be avoided or minimized.
- u The patient will maintain skin integrity.

Nursing interventions

- u Observe standard precautions.
- u Swab nystatin on the oral mucosa of an infant with thrush. Have older children and adults swish nystatin in the mouth. Some clinicians believe that oral thrush leads to esophagitis. They suggest swallowing the nystatin after swishing.
- u Provide a nonirritating mouthwash to loosen tenacious secretions and a soft toothbrush to avoid irritation.
- u Relieve mouth discomfort with a topical anesthetic, such as lidocaine or benzocaine, at least 1 hour before meals. Be cautious, however: Using excessive anesthetic

may suppress the gag reflex and lead to aspiration.

- u Suggest a soft diet for the patient with severe dysphagia. Advise the patient with mild dysphagia to chew food thoroughly.
- u Apply cornstarch, nystatin powder, or dry padding in intertriginous areas of obese patients to prevent irritation and candidal growth.
- u Record dates of I.M. catheter insertion, and replace the catheter according to your hospital's policy, to prevent phlebitis.
- u Frequently check vital signs of patients with systemic infection. Provide appropriate supportive care. In patients with renal involvement, carefully monitor intake and output. Also monitor blood urea nitrogen, serum creatinine, and urine blood and protein levels.
- u Check high-risk patients daily, especially those receiving antibiotics. Watch for patchy areas, irritation, sore throat, oral and gingival bleeding, and other signs of superinfection. If you note a vaginal discharge, document the color and amount.
- u Assess the patient with candidiasis for underlying systemic causes such as diabetes mellitus. If the patient is receiving amphotericin B for systemic candidiasis, he may have severe chills, fever, anorexia, nausea, vomiting, hypokalemia, and renal impairment. Premedicate him with aspirin, antihistamines, or antiemetics, as ordered, to help reduce adverse reactions.
- u Carefully monitor intake and output and potassium levels while the patient is receiving medication.
- u Prepare to give a blood transfusion if ordered and if the patient has a low platelet count (for example, from underlying disease or from treatment with amphotericin B).

Patient teaching

- u Demonstrate comprehensive oral hygiene practices, and have the patient perform a return demonstration. Recommend that the patient use alkaline mouth care products because increased acidity promotes candidal growth.
- u Tell a patient using nystatin solution to swish it around his mouth for several minutes before swallowing. Be sure he knows not to scrape the lesions but to coat them with the medication.
- u Encourage a woman in her third trimester of pregnancy to be examined for vaginitis to protect her infant from thrush infection at birth.
- u Direct the patient with dyspareunia to take intravaginal medication as prescribed. Listen to her concerns and reassure her that sexual impairment should resolve when her infection subsides. Tell her that her sexual partner usually won't need concomitant treatment.

COCCIDIOIDOMYCOSIS

Also called valley fever and San Joaquin Valley fever, coccidioidomycosis is a fungal infection. It occurs primarily as a respiratory infection, although generalized dissemination may occur. The primary pulmonary form usually is self-limiting and seldom fatal. The rare secondary (progressive, disseminated) form produces abscesses throughout the body and carries a mortality of up to 60%, even with treatment.

Such dissemination is more common in dark-skinned men and pregnant women. Immunosuppressive conditions, especially human immunodeficiency virus infection, Hodgkin's disease, and malignant lymphoma, also are risk factors for disseminated disease.

Coccidioidomycosis is endemic to the southwestern United States, especially between the San Joaquin Valley in California and southwestern Texas. It's also found in Mexico and central and South America.

Because of population distribution and an occupational link (it's common in migrant farm laborers), coccidioidomycosis strikes many Philippine Americans, Mexican Americans, Native Americans, and Blacks. In primary infection, the incubation period ranges from 1 to 4 weeks.

Causes

Coccidioidomycosis is caused by the fungus *Coccidioides immitis*. It may result from inhalation of *C. immitis* spores found in the soil in endemic areas or from inhalation of spores from dressings or plaster casts of infected people. It's most prevalent during warm, dry months.

Complications

This disease can cause bronchiectasis, osteomyelitis, meningitis, hepatosplenomegaly, and liver failure.

Assessment findings

The patient may report living in or travel to an endemic area. If he has primary coccidioidomycosis, he'll usually complain of acute or subacute respiratory symptoms, such as dry cough, pleuritic chest pain, sore throat, chills, malaise, headache, anorexia, and arthralgias.

In rare cases, coccidioidomycosis disseminates to other organs several weeks or months after the primary infection. If this happens, the patient may complain of bone pain if the disease causes skeletal abscesses. He may complain of headache and a stiff neck from meningitis if central nervous system (CNS) abscesses occur. Less frequently, splenic, hepatic, renal, and subcutaneous abscesses develop.

The patient may report hemoptysis, with or without chest pain, in chronic pulmonary cavitation. This can occur in both the primary and the disseminated form.

During your assessment, you'll probably note fever. A fever that persists for weeks may be the sole sign of the disease.

In some patients, particularly white women, you may note tender red nodules (erythema nodosum) on the legs, especially the shins, on inspection. These may develop from 3 days to several weeks after onset. With musculoskeletal involvement, you may see local swelling and redness in involved sites. If the patient develops meningitis, you may note an altered level of consciousness (LOC), sluggishness, and seizures.

On palpation, you may note warmth and tenderness over involved musculoskeletal sites. You also may note nuchal rigidity if the patient has meningitis.

Diagnostic tests

Sputum, urine, and pus should be examined for *C. immitis* by wet smear and culture. The mold form must be handled with care as it can infect laboratory personnel. Serologic tests are also helpful in the diagnosis.

The primary form—and sometimes the disseminated form—produces a positive coccidioidin skin test. In the first week of illness, complement fixation for immunoglobulin G antibodies, or in the first month, positive serum precipitins (immunoglobulins) also establish the diagnosis. Examination or immunodiffusion testing of sputum, pus from lesions, and a tissue biopsy may show *C. immitis* spores. Antibodies in pleural and joint fluid and an increasing serum or body fluid antibody titer indicate dissemination.

Treatment

Mild primary coccidioidomycosis usually requires only rest and relief of symptoms. Severe primary disease and dissemination require I.V. amphotericin B. Patients with more indolent disseminated infection are given ketoconazole, itraconazole, or fluconazole.

CNS dissemination is usually treated with fluconazole but may require intrathecal administration of amphotericin B. Severe pulmonary lesions may require lobectomy in addition to chemotherapy if the infection is confined to one lung.

Nursing diagnoses

u Altered tissue perfusion (cerebral and cardiopulmonary) u Impaired gas exchange u Impaired skin integrity u Ineffective breathing pattern u Pain u Risk for injury

Key outcomes

- u The patient will be free from pain.
- u Patient's arterial blood gas (ABG) levels will return to baseline.
- u The patient will express a feeling of comfort in maintaining air exchange.
- u The patient will cough effectively.
- u Patient's airway will remain patent.

Nursing interventions

- u Don't wash off the circle marked on the skin for serial skin tests because this aids in reading test results.
- u In mild primary disease, encourage bed rest and adequate fluid intake. Record the amount and color of sputum. Watch for shortness of breath, which may point to pleural effusion. Provide analgesics, as ordered, for a patient with arthralgia or headache.
- u In the patient with pneumonia, frequently assess respiratory status, including ABG results. Administer oxygen, if needed, and encourage coughing and deep breathing.
- u Coccidioidomycosis requires strict secretion precautions if the patient has draining lesions. Sterile dressing technique and careful hand washing are essential. If the patient has CNS dissemination, carefully monitor him for a decreased LOC, a change in mood or affect, or muscle twitching.
- u Before intrathecal administration of amphotericin B, explain the procedure to the patient, and reassure him that he'll receive analgesics before a lumbar puncture. If he needs an I.V. infusion of amphotericin B, administer it slowly as ordered. Rapid infusion may cause circulatory collapse.
- u During infusion, monitor the patient's vital signs. His temperature may increase but should return to normal within 1 to 2 hours. Watch for decreased urine output, and monitor laboratory test results for elevated blood urea nitrogen and creatinine levels and for hypokalemia. Tell the patient to immediately report hearing loss, tinnitus, dizziness, and all symptoms of toxicity.
- u To ease the adverse effects of amphotericin B, give antiemetics, antihistamines, and antipyretics as ordered.

Patient teaching

- u Teach the patient that the illness is infectious but not contagious.
- u Instruct the patient about drug therapy, including adverse effects.
- u Inform the patient about the need for continued follow-up care and long-term medication management.

CRYPTOCOCCOSIS

Cryptococcosis (also known as torulosis and European blastomycosis) usually begins as a pulmonary infection that produces no signs or symptoms. It then disseminates to extrapulmonary sites, including the central nervous system (CNS), skin, bones, prostate gland, liver, and kidneys.

With treatment, the prognosis in pulmonary cryptococcosis is good. Without treatment (particularly in immunocompromised patients), the disease can lead to CNS infection and death (invariably within 3 years). Treatment dramatically reduces mortality but not necessarily neurologic deficits, such as paralysis and hydrocephalus.

Cryptococcosis is especially likely to attack immunocompromised patients, particularly those with Hodgkin's disease, sarcoidosis, leukemia, or lymphomas and those taking immunosuppressant drugs. The incidence is increasing, especially in patients with acquired immunodeficiency syndrome (AIDS).

Causes

The airborne fungus *Cryptococcus neoformans* causes cryptococcosis. It's found in dust particles contaminated by pigeon stool.

Complications

Optic atrophy, ataxia, hydrocephalus, deafness, paralysis, organic mental syndrome, and personality changes are possible complications of cryptococcosis.

Assessment findings

The patient's history may be unremarkable, or you may learn that the patient has human immunodeficiency virus infection or another immunosuppressive disorder. The patient with pulmonary cryptococcosis usually is asymptomatic but may complain of dull chest pain and a cough producing a slight amount of white, blood-streaked sputum. He may or may not be febrile.

The onset of CNS involvement (cryptococcal meningitis) is gradual. It causes progressively severe frontal and temporal headache, diplopia, blurred vision, dizziness, ataxia, aphasia, vomiting, tinnitus, memory changes, inappropriate behavior, irritability, and psychosis. Untreated symptoms may progress to coma and death, usually as a result of cerebral edema or hydrocephalus.

Other signs and symptoms include facial weakness, seizures (only in the late stage), and papilledema. Nuchal rigidity is typically absent, but you may elicit hyperactive reflexes.

The patient with bone involvement may complain of pain in the long bones, skull, spine, and joints.

With skin involvement, you'll observe red facial papules and other skin abscesses, with or without ulceration.

Rarely, auscultation reveals pleural friction rub or crackles.

Diagnostic tests

Although imaging tests (a routine chest X-ray or computed tomography scan of the chest) showing a pulmonary lesion may point to pulmonary cryptococcosis, this infection commonly escapes diagnosis until it disseminates. A definitive diagnosis requires identification of *C. neoformans* by analysis or culture of the sputum, urine, prostatic secretions, or bone marrow aspirate. Other test procedures include tissue or neural biopsy.

In CNS infection, *C. neoformans* detected in an India ink preparation of cerebrospinal fluid (CSF) is diagnostic. Blood cultures are positive only in severe infection.

Test results that support the diagnosis include elevated antigen titer in serum and CSF in disseminated infection; increased CSF pressure, protein levels, and white blood cell count in CNS infection; and moderately decreased CSF glucose levels in about 50% of patients. Patients with AIDS typically have slight or no CSF abnormalities, although *C. neoformans* usually can be cultured.

Treatment

Cryptococcosis is best treated with a combination of amphotericin B and flucytosine, typically for 6 weeks. Because flucytosine may produce adverse reactions, amphotericin B alone may be used in selected cases. This therapy is continued indefinitely in the patient with AIDS. In the non-AIDS patient, weekly lumbar punctures should be performed until cultural conversion occurs.

Nursing diagnoses

u Altered tissue perfusion (cerebral and cardiopulmonary) u Impaired gas exchange u Impaired physical mobility u Ineffective breathing pattern u Pain u Risk for injury

Key outcomes

- u The patient will maintain or improve current level of consciousness.
- u The patient will be free from pain.
- u The patient will maintain a clear airway.
- u Patient's arterial blood gas levels will return to baseline.
- u The patient will express a feeling of comfort in maintaining air exchange.

Nursing interventions

- u Check the patient's vital signs, and note changes in mental status, orientation, pupillary response, and motor function. Watch for headache and vomiting.
- u Assess the patient for phlebitis before giving I.V. amphotericin B. Infuse the drug slowly, and dilute as ordered—rapid infusion may cause circulatory collapse.
- u Before therapy, draw serum for testing to determine electrolyte levels and baseline renal status. During drug therapy, watch for decreased urine output, elevated blood urea nitrogen and serum creatinine levels, and hypokalemia. Monitor complete blood count and urinalysis results. Monitor magnesium and potassium levels and hepatic function as well.
- u Tell the patient to report hearing loss, tinnitus, or dizziness.
- u Monitor blood levels of flucytosine, observing for adverse effects such as diarrhea. Also be alert for decreased white blood cell and platelet counts.
- u Give analgesics, antihistamines, and antiemetics, as ordered, for fever, chills, nausea, and vomiting. Manage shaking chills with small doses of meperidine or morphine sulfate as ordered. Give these drugs in the early morning or late evening so that they don't sedate the patient for the entire day.
- u Evaluate the need for long-term venous access for administering amphotericin B.
- u Provide psychological support to help the patient cope with long-term treatment.
- u If the patient exhibits altered mental status, reorient him throughout the day, follow a consistent routine, speak slowly and clearly, use safety measures as needed to protect him from injury, and refer him and his family to appropriate resources to plan postdischarge care.
- u If the patient has vision loss, provide a safe environment. Modify the environment to maximize retained vision. Provide nonvisual sensory stimulation as possible. Encourage the patient to express his feelings, and refer him and his family to appropriate community services for information and support.

Patient teaching

- u Explain medication therapy. Discuss dosage, desired drug actions, adverse effects, and need for long-term treatment.
- u Urge the patient to return for follow-up care and evaluation. Typically, the patient needs an examination every few months for 1 year, even if he feels well and has no symptoms.

HISTOPLASMOSIS

This fungal infection has several other names, including Ohio Valley disease, Central Mississippi Valley disease, Appalachian Mountain disease, and Darling's disease. In the United States, histoplasmosis occurs in three forms: primary acute histoplasmosis, progressive disseminated histoplasmosis (acute disseminated or chronic disseminated disease), and chronic pulmonary (cavitary) histoplasmosis. The last form produces cavitations in the lung similar to those seen in pulmonary tuberculosis.

A fourth form, African histoplasmosis, occurs only in Africa and is caused by the fungus *Histoplasma capsulatum* var. *duboisii*.

Histoplasmosis occurs worldwide, especially in the temperate areas of Asia, Africa, Europe, and North and South America. In the United States, it's most prevalent in the southeastern, mid-Atlantic, and central states.

The incubation period ranges from 5 to 18 days, although chronic pulmonary histoplasmosis may progress slowly for many years. The prognosis varies with each form. In a small number of patients, histoplasmosis becomes progressive and potentially fatal. Chronic pulmonary infections occur more often in males over age 40, particularly those with a history of cigarette smoking. An acute and rapidly fatal course is more likely to occur in young children and immunosuppressed patients, such as persons with acquired immunodeficiency syndrome.

Causes

Histoplasmosis is caused by *H. capsulatum*, which is found in the stool of birds and bats and in soil contaminated by their stool, such as that near roosts, chicken coops, barns, caves, and underneath bridges.

Transmission occurs through inhalation of *H. capsulatum* or *H. capsulatum* var. *duboisii* spores or through the invasion of spores after minor skin trauma.

Complications

Possible complications include vascular or bronchial obstruction, acute pericarditis, pleural effusion, mediastinal fibrosis or granuloma, intestinal ulceration, Addison's disease, endocarditis, and meningitis.

Assessment findings

The patient may have a history of an immunocompromised condition or exposure to contaminated soil in an endemic area.

The severity of symptoms depends on the size of the inhaled inoculum and the immune condition of the host. Also, symptoms vary with the form of the disease. For example, a patient with *primary acute histoplasmosis* may be asymptomatic, or he may complain of a mild respiratory illness similar to a severe cold or influenza. He also may report malaise, headache, myalgia, anorexia, cough, and chest pain. A patient with *progressive disseminated histoplasmosis* may complain of anorexia, weight loss and, possibly, pain, hoarseness, and dysphagia. A patient with *chronic pulmonary histoplasmosis* may have symptoms that mimic pulmonary tuberculosis. He may complain of a productive cough, dyspnea, and occasional hemoptysis. He'll eventually experience weight loss and breathlessness.

During your assessment, you usually note fever, which may rise as high as 105° F (40.6° C), although its severity and duration can vary.

Inspection findings vary with the kind of histoplasmosis. A patient with primary acute histoplasmosis usually won't reveal any characteristic signs. If the patient has disseminated histoplasmosis, however, you may observe ulceration of the oropharynx, tachypnea in later stages, and pallor from anemia. You also may observe jaundice and ascites. In the patient with late-stage chronic pulmonary histoplasmosis, inspection may reveal shortness of breath, extreme weakness, and cyanosis.

Palpation may reveal hepatosplenomegaly and lymphadenopathy, characteristic findings in the progressive disseminated form of the disease.

Diagnostic tests

Culture is the preferred method of diagnosis but is difficult. Blood cultures should be done by lysis-centrifugation technique. In disseminated forms, culture of bone marrow, mucosal lesions, liver, and bronchiolar lavage are helpful. Sputum cultures are preferred in chronic pulmonary histoplasmosis but may take 2 to 4 weeks to

culture. A radioactive assay for histoplasma antigen in blood or urine is commercially available and useful in diagnosis.

Treatment

Treatment includes antifungal therapy, surgery, and supportive care.

Antifungal therapy plays the most important role. Except for asymptomatic primary acute histoplasmosis (which resolves spontaneously) and the African form, histoplasmosis requires high-dose or long-term (10-week) therapy with amphotericin B or ketoconazole.

Surgery includes lung resection to remove pulmonary nodules, a shunt for increased intracranial pressure, and cardiac repair for constrictive pericarditis.

Supportive care includes oxygen for respiratory distress, glucocorticoids for adrenal insufficiency, and parenteral fluids for dysphagia caused by oral or laryngeal ulcerations. Histoplasmosis doesn't necessitate isolation.

Nursing diagnoses

⌞ Activity intolerance ⌞ Altered nutrition: Less than body requirements ⌞ Decreased cardiac output ⌞ Ineffective breathing pattern ⌞ Pain ⌞ Risk for injury

Key outcomes

- ⌞ The patient will be free from pain.
- ⌞ The patient will maintain a clear airway.
- ⌞ Patient's arterial blood gas levels will return to baseline.
- ⌞ The patient will express a feeling of comfort in maintaining air exchange.
- ⌞ The patient will experience no further weight loss.
- ⌞ The patient will maintain hemodynamic stability.
- ⌞ The patient will maintain adequate cardiac output.

Nursing interventions

- ⌞ Provide supportive nursing care for the patient with histoplasmosis.
- ⌞ Administer drugs as ordered. Because amphotericin B may cause pain, chills, fever, nausea, and vomiting, give appropriate antipyretics, antihistamines, analgesics, and antiemetics, as ordered. Small doses of meperidine or morphine sulfate may help reduce shaking chills. Give these drugs in the early morning or late evening so that they don't sedate the patient for the entire day.
- ⌞ Perform a respiratory assessment every shift. Note diminished breath sounds or pleural friction rub, and evaluate for effusion.
- ⌞ Refer to the chest X-ray results to determine if the patient has pulmonary or pleural effusion.
- ⌞ Provide oxygen therapy if needed. Plan rest periods.
- ⌞ Assess the patient's cardiovascular status every shift. If you note muffled heart sounds, jugular vein distention, pulsus paradoxus, or other signs of cardiac tamponade, report these signs to the doctor immediately. Assess neurologic status every shift and report any changes in level of consciousness or nuchal rigidity.
- ⌞ Consult with the dietitian and patient concerning food preferences. Provide an appetizing, nutritious diet. The patient may benefit from small, frequent feeding. If he has oropharyngeal ulceration, he may need soft, bland foods. If the ulcerations are severe, he may need I.V. therapy.
- ⌞ Monitor for signs and symptoms of hypoglycemia and hyperglycemia, which indicate adrenal dysfunction.
- ⌞ Test all stools for blood and report its presence.
- ⌞ Make sure a patient with chronic pulmonary or disseminated histoplasmosis receives psychological support to help him cope with long-term treatment. As needed, refer him to a social worker or an occupational therapist. Help the parents of a child with this disease arrange for a visiting teacher.

Patient teaching

- ⌞ Teach the patient about drug therapy, including adverse effects.
- ⌞ Inform the patient about the need for follow-up care on a regular basis for at least a year.
- ⌞ Tell the patient to report to the doctor cardiac and pulmonary signs that could indicate effusions.
- ⌞ To help prevent histoplasmosis, teach people in endemic areas to watch for early signs of this infection and to seek treatment promptly. Instruct people who risk occupational exposure to contaminated soil to wear face masks.

SPOROTRICHOSIS

Sporotrichosis is a chronic fungal disease that results from inoculation into the subcutaneous tissue through minor trauma. Plant nursery workers, florists, and gardeners can acquire it from roses, sphagnum moss, and other plants. Plague sporotrichosis is limited to the site of the infection, and lymphangitis sporotrichosis occurs when the infection spreads along proximal lymph channels. Spread beyond the extremity is rare. Osteoarticular, pulmonary, and other extracutaneous forms are likely to evolve from the lung.

Causes

Sporotrichosis is caused by the fungus, *Sporothrix schenckii*, which is found in soil, wood, sphagnum moss, and decaying vegetation throughout the world. The fungus usually enters through broken skin or through inhalation (pulmonary form).

Complications

Sporotrichosis can lead to arthritis, osteomyelitis and, rarely, pneumonitis. Chronic meningitis can develop in the absence of skin or lung lesions.

Assessment findings

The patient's history may reveal exposure through occupation or hobbies, such as farming or gardening.

Lymphangitis sporotrichosis is the most common form. During inspection, look for characteristic skin lesions, usually on the patient's hands or fingers. Each lesion begins as a small, painless, movable, subcutaneous nodule. It then grows progressively larger, discolors and, eventually, ulcerates. Later, more lesions form along the adjacent lymph node chain. (See [Viewing sporotrichosis.](#))

Plague sporotrichosis appears as a nontender, red maculopapular granuloma at the site of infection. A patient with osteoarticular sporotrichosis may complain of pain, especially in the knees, wrists, ankles, and elbows, with progression over months or years. A patient with pulmonary sporotrichosis may report a productive cough, anorexia, fatigue, weight loss and, possibly, dyspnea and hemoptysis.

During your assessment, you may note low-grade fever in a patient with either extracutaneous form.

In the patient with osteoarticular sporotrichosis, you may observe edema and decreased mobility in involved joints.

Diagnostic tests

Culture of *S. schenckii* in sputum, pus, or bone drainage confirms the diagnosis. Histologic identification is difficult. Despite pulmonary symptoms, few definitive

abnormalities appear on a chest X-ray.

Demineralization of bone is evident on X-ray for osteoarticular sporotrichosis. Draining sinuses appear over joints and lesions. Pulmonary sporotrichosis presents as a single, chronic, cavitary lesion of the upper lobe of the lung. *S. schencki* is difficult to obtain from cerebrospinal fluid.

Treatment

The cutaneous lymphatic form of the disease usually responds to application of a saturated solution of potassium iodide, usually continued for 1 month after lesions heal. The extracutaneous form responds to I.V. amphotericin B but may require several weeks of treatment.

Viewing sporotrichosis

Ulceration, swelling, and crusting of nodules on fingers is characteristic of sporotrichosis.

Nursing diagnoses

- u Altered nutrition: Less than body requirements
- u Body image disturbance
- u Fatigue
- u Impaired physical mobility
- u Impaired skin integrity
- u Pain

Key outcomes

- u The patient will exhibit improved or healed lesions or wounds.
- u The patient will report increased comfort.
- u Complications will be avoided or minimized.
- u The patient will voice feelings about changed body image.
- u The patient will exhibit increased mobility.
- u The patient will experience no further weight loss.

Nursing interventions

- u Keep lesions clean, and carefully dispose of contaminated dressings.
- u Keep the patient as comfortable as possible, and apply heat to affected joints to relieve pain, if ordered.
- u Administer anti-inflammatory agents as ordered.
- u If the patient is receiving I.V. amphotericin B, infuse it slowly. Rapid infusion may cause circulatory collapse.
- u Monitor vital signs during the infusion. Watch for decreased urine output, and check laboratory test results for elevated blood urea nitrogen, serum creatinine, and potassium levels.
- u If joint involvement impairs the patient's mobility, encourage warm soaks, progressive movement, and range-of-motion exercises, unless contraindicated. Refer the patient to a physical therapist, if needed.

Patient teaching

- u Inform the patient that the illness is infectious but not contagious.
- u Teach the patient about drug therapy, and tell him to immediately report adverse effects.
- u To help prevent sporotrichosis, advise horticulturists, agricultural workers, and home gardeners to wear gloves while working.
- u Encourage the patient to return for follow-up appointments.

Viruses

Several hundred different viruses may infect humans and are spread chiefly by humans themselves. Diagnosis often remains difficult. Viral diseases aren't susceptible to antibiotics, but sometimes antibiotics are used to prevent complications.

ADENOVIRAL INFECTIONS

Adenoviruses cause acute, self-limiting, febrile infections, with inflammation of the respiratory or ocular mucous membranes or both. Infections occur throughout the year, but are most common from fall to spring. Adenovirus accounts for 3% to 5% of acute respiratory infections in children and 2% in civilian adults.

Of the many known adenovirus types, only a few result in epidemics. Types 1, 2, 3, and 5 are frequent in children; types 4 and 7 (also types 3, 14, and 21) are associated with outbreaks in military corps. Nearly 100% of adults have serum antibody titers to several types.

Causes

Transmission occurs by direct inoculation into the eye by fecal-oral contamination (adenoviruses may persist in the GI tract for years after infection) or by inhalation of an infected droplet. The incubation period usually is less than 1 week. Although the acute illness lasts less than 5 days, it may be followed by prolonged asymptomatic reinfection.

Complications

Acute conjunctivitis, sinusitis, pharyngitis, bronchiolitis, and pneumonia are potential complications of adenoviral infections. In patients who are immunosuppressed, disseminated disease and pneumonia may be caused by adenovirus.

Assessment findings

Clinical features vary with the type of infection. In children, the most common clinical syndrome is an acute upper respiratory tract infection with rhinitis. Types 3 and 7

are associated with pharyngoconjunctival fever, which is a febrile illness often occurring in summer camps. Other symptoms include bilateral conjunctivitis with bulbar and palpebral conjunctiva having a granular appearance, low-grade fever for 3 to 5 days, rhinitis, sore throat, and cervical adenopathy. Febrile pharyngitis without conjunctivitis can also occur due to the adenovirus.

In adults, types 4 and 7 often affect military recruits. Symptoms include a prominent sore throat, gradual onset of fever reaching 102° F (39° C) on the second to third day, cough, coryza, and regional lymphadenopathy. Examination may reveal pharyngeal edema, infection, and tonsillar enlargement with little or no exudate.

Adenovirus may also cause an acute diarrheal illness (types 40 and 41) in young children and hemorrhagic cystitis (types 11 and 21). Epidemic keratoconjunctivitis (types 8, 19, and 37) is associated with contaminated ophthalmic solutions.

Diagnostic tests

Definitive diagnosis requires isolation of the virus from respiratory or ocular secretions or from fecal smears. During epidemics, typical symptoms alone allow the doctor to make a diagnosis. Because adenoviral illnesses resolve quickly, serum antibody titers aren't useful for diagnosis. Blood tests show lymphocytosis in children. A chest X-ray may show patchy infiltrates in pneumonia.

Treatment

No specific drugs are effective against adenoviruses, so treatment is mainly supportive. Pharyngoconjunctival fever lasts 1 to 2 weeks and resolves spontaneously. Ocular infections may require cortico-steroids and direct supervision by an ophthalmologist. Infants with pneumonia should be hospitalized to monitor for and treat symptoms that can cause death; those with keratoconjunctivitis require hospitalization to treat symptoms that can cause blindness. Live vaccines have been successful against types 4 and 7 in military recruits.

Nursing diagnoses

⌞ Altered nutrition: Less than body requirements ⌞ Diarrhea ⌞ Fatigue ⌞ Hyperthermia ⌞ Impaired gas exchange ⌞ Impaired skin integrity ⌞ Pain ⌞ Risk for fluid volume deficit ⌞ Risk for infection

Key outcomes

- ⌞ The patient's temperature will return to within normal limits.
- ⌞ The patient's respiratory rate will be maintained within 5 breaths of baseline.
- ⌞ The patient will cough effectively.
- ⌞ The patient's fluid volume will remain adequate.
- ⌞ The patient will verbally report having an increased energy level.
- ⌞ The patient will express a feeling of comfort and relief from pain.

Nursing interventions

- ⌞ During the acute stage, monitor the patient's respiratory status and intake and output. Provide respiratory care measures for the infant hospitalized with pneumonia.
- ⌞ Check the patient's eyes for redness, itching, and drainage.
- ⌞ Plan care to provide rest periods.
- ⌞ Ensure adequate fluid and nutritional intake.
- ⌞ Administer ordered medications to relieve symptoms.

Patient teaching

- ⌞ Explain supportive care measures, such as bed rest, adequate fluid intake, analgesics, and antipyretics.
- ⌞ To help minimize the incidence of adenoviral disease, teach the patient proper hand-washing techniques to reduce fecal-oral transmission.
- ⌞ Inform the patient, patient groups, and other health care workers that keratoconjunctivitis can be prevented by avoiding swimming pools during epidemics of keratoconjunctivitis, by adequately chlorinating swimming pools, and by sterilizing ophthalmic instruments.

COLORADO TICK FEVER

Colorado tick fever is a benign infection that occurs in the Rocky Mountain region of the United States. The infection is acquired between March and November in the mountainous western region at altitudes of 4,000' to 10,000' (1,200 to 3,000 m). Colorado tick fever apparently confers long-lasting immunity against reinfection.

Causes

Colorado tick fever results from the Colorado tick fever virus, an arbovirus. A hard-shelled wood tick called *Dermacentor andersonii* transmits the disease to humans. After the adult tick acquires the virus from biting an infected rodent, the tick becomes permanently infected. The virus's incubation period is 3 to 6 days.

Complications

Rare complications of Colorado tick fever include pericarditis, myocarditis, epididymitis, orchitis, atypical pneumonia, and meningoencephalitis, a potentially fatal disorder.

Assessment findings

The patient's history may include a known tick bite or recent exposure to ticks or tick-infested areas. Soon after exposure, he may report the abrupt onset of chills; severe aching of the back, arms, and legs; lethargy; and headache with eye movement. He may experience photophobia, abdominal pain, nausea, and vomiting. He also may complain of a fever that begins abruptly, with temperature increasing to 104° F (40° C). The fever may subside after 2 to 3 days and then recur for another 2 to 3 days.

Inspection may reveal conjunctival infection, altered level of consciousness (with central nervous system involvement), and a maculopapular or, less commonly, petechial rash.

Diagnostic tests

A complete blood count demonstrating leukopenia, thrombocytopenia, and serologic findings or viral isolation confirms the diagnosis. Infection of erythroblasts and other marrow cells by the fever virus causes the appearance of erythrocytes containing the virus; these are present for several weeks. This is detected in smears stained by immunofluorescence.

Treatment

After correct removal of the tick, supportive treatment relieves symptoms, combats secondary infection, and maintains fluid balance.

Nursing diagnoses

u Altered skin integrity u Hyperthermia u Pain u Risk for fluid volume deficit

Key outcomes

- u The patient will remain afebrile.
- u The patient's vital signs will remain stable.
- u The patient will exhibit improved or healed lesions or wounds.
- u The patient will express a feeling of comfort and relief from pain.
- u The patient's fluid volume will remain adequate.

Nursing interventions

- u Carefully remove the tick by grasping it with forceps or gloved fingers and pulling gently. Be careful not to crush the tick's body. Keep it for identification. Thoroughly wash the wound with soap and water. If the tick's head remains embedded, surgical removal is necessary. Give a tetanus-diphtheria booster as ordered.
- u Be alert for secondary infection.
- u Monitor the patient's intake, output, and body weight daily for evidence of fluid and electrolyte imbalance. Replace fluids and electrolytes as needed.
- u Help the patient with personal hygiene and self-care during the acute stage of the illness.
- u Relieve pain and reduce fever with antipyretic, analgesic medications such as acetaminophen. Discourage using aspirin because of its potential to cause bleeding. Also provide or suggest tepid sponge baths.

Patient teaching

- u To prevent Colorado tick fever, educate patients to avoid tick-infested areas. If this isn't possible, recommend wearing protective clothing, using insect repellants, frequently checking for ticks, and removing them before they attach and feed.
- u Teach patients and caregivers the correct technique for removing a tick. If the technique fails and the tick can't be removed, tell the patient to seek medical attention immediately.
- u Alert patients and caregivers to the signs and symptoms of Colorado tick fever and the need for medical attention before symptoms advance and prostration and dehydration occur.

COMMON COLD

The common cold is an acute, usually afebrile, viral infection that causes inflammation of the upper respiratory tract. It's the most common infectious disease and is more prevalent in children, adolescent boys, and women. In temperate climates, it occurs more often in the colder months; in the tropics, during the rainy season.

Colds usually are benign and self-limiting, but they cause more lost time from school or work than any other illness. Morbidity from acute respiratory illness accounts for 30% to 50% of time lost from work by adults and 60% to 80% of time lost from school by children.

Causes

About 90% of colds stem from a viral infection of the upper respiratory tract passages and consequent mucous membrane inflammation. Some colds result from *Mycoplasma*. More than 100 viruses can cause the common cold. Major offenders include rhinoviruses, coronaviruses, myxoviruses, adenoviruses, coxsackieviruses, and echoviruses.

A cold is communicable for 2 to 3 days after the onset of symptoms. Transmission occurs through airborne respiratory droplets or through contact with contaminated objects, including hands. Children acquire new strains from their schoolmates and pass them on to family members. Contrary to popular belief, fatigue or drafts don't increase susceptibility.

Complications

Secondary bacterial infection may occur, causing sinusitis, otitis media, pharyngitis, or lower respiratory tract infection.

Assessment findings

The patient's history may reveal exposure to others with the common cold. After an incubation period of 1 to 4 days, the patient initially complains of nasal congestion, headache, and burning, watery eyes. He also may report chills, myalgia, arthralgia, malaise, lethargy, and a hacking, nonproductive, or nocturnal cough. Most patients are afebrile, although fever may occur, especially in children.

Clinical features develop more fully as the cold progresses. By the second day (in addition to initial symptoms), the patient may report a copious nasal discharge that often irritates the nose, adding to his discomfort. About 3 days after onset, major symptoms diminish, but the “stuffed up” feeling often persists for a week. Reinfection (with productive cough) is common, but complications are rare.

Inspection may reveal a reddened nose and eyes and nasal discharge. The nasal and pharyngeal mucous membranes may exhibit increased erythema, and the patient's voice may have a nasal quality. The skin around the nose may be excoriated because of frequent nose blowing.

Diagnostic tests

No explicit diagnostic test exists to isolate the specific organism responsible for the common cold. Despite infection, white blood cell count and differential are within normal limits. Diagnosis must rule out allergic rhinitis, measles, rubella, and other disorders that produce similar early symptoms.

A temperature higher than 100° F (37.8° C), severe malaise, anorexia, tachycardia, exudate on the tonsils or throat, petechiae, and tender lymph glands may point to a more serious disorder and require additional diagnostic tests.

Treatment

Because the common cold has no cure, the primary treatment—aspirin or acetaminophen, fluids, and rest—is purely symptomatic. Aspirin and acetaminophen ease myalgia and headache; fluids help loosen accumulated respiratory secretions and maintain hydration; and rest combats fatigue and weakness. Because aspirin has been associated with Reye's syndrome in children, acetaminophen is the drug of choice for a child with a cold and fever.

Decongestants can relieve nasal congestion. Throat lozenges relieve soreness, and steam encourages expectoration. Nasal douching, sinus drainage, and antibiotics are necessary except in complications or chronic illness. Pure antitussives relieve severe coughs but are contraindicated with productive coughs when cough suppression is harmful. The role of vitamin C remains controversial. In infants, saline nose drops and mucus aspiration with a bulb syringe may be beneficial.

No preventive measures currently are available. Vitamin therapy, interferon administration, and experimental vaccines are under investigation.

Nursing diagnoses

u Fatigue u Hyperthermia u Impaired skin integrity u Ineffective airway clearance u Ineffective breathing pattern u Pain u Risk for infection

Key outcomes

- u The patient will be free from pain.
- u The patient will express feeling of comfort in maintaining air exchange.
- u The patient will cope effectively.
- u Patient's temperature will return to normal.
- u Patient's respiratory secretions will remain clear and odorless.
- u The patient will verbally express increased energy.

Nursing interventions

- u Administer antipyretics and analgesics as ordered.
- u Refer the patient for medical care if he has a persistent high fever, changes in level of consciousness, or significant respiratory symptoms.

Patient teaching

- u Emphasize that antibiotics don't cure the common cold.
- u Tell the patient to stay in bed for the first few days, use a lubricant on his nostrils to decrease irritation, relieve throat irritation with sugarless hard candy or cough drops, increase fluid intake, and eat light meals.
- u A warm bath or heating pad can reduce aches and pains but won't hasten a cure. Suggest a hot or cold steam vaporizer to relieve nasal congestion. Commercial expectorants are available, but their effectiveness is questionable.
- u Advise against overuse of nose drops or sprays because these may cause rebound congestion.
- u To help prevent colds, warn the patient to minimize contact with people who have them. To avoid spreading colds, tell him to wash his hands often, cover his mouth and nose when he coughs or sneezes, avoid sharing towels and drinking glasses, and properly dispose of used tissues.

CYTOMEGALOVIRUS INFECTION

Cytomegalovirus (CMV) is also called generalized salivary gland disease and cytomegalic inclusion disease. CMV is a herpesvirus that occurs world-wide. The disease is transmitted by human contact. Once infected, a person carries the virus for life. It usually remains latent, but reactivation occurs when t-lymphocyte-mediated immunity is compromised, as in organ transplantation, lymphoid neoplasms, and certain acquired immunodeficiencies.

Causes

The infection results from the cytomegalovirus, a deoxyribonucleic acid virus belonging to the herpes family. CMV has been found in the saliva, urine, semen, breast milk, feces, blood, and vaginal and cervical secretions of infected people.

Transmission occurs through direct contact with secretions and excretions, through blood transfusions, transplacentally, and through transplanted organs. CMV in cervical secretions can infect a sexual partner or an infant during passage through the birth canal. CMV is present in the semen of homosexual men and may be transmitted through sexual activity; such transmission hasn't yet been proved in heterosexual men.

The disease probably spreads through the body in lymphocytes or mononuclear cells to the lungs, liver, GI tract, eyes, and central nervous system (CNS), where it often produces inflammatory reactions.

Complications

Immunosuppressed patients, such as those with acquired immunodeficiency syndrome, may develop opportunistic infections, such as pneumonia, hepatitis, ulceration of the GI tract, retinitis, and encephalopathy.

Congenital CMV can lead to stillbirth, neonatal retinitis, microcephaly, mental retardation, seizures and, later, hearing loss. The infant also can develop thrombocytopenia and hemolytic anemia.

Assessment findings

The adult patient's history may reveal an immunosuppressive condition. He may complain of mild, nonspecific clinical symptoms, such as fatigue, myalgia, and headache, or he may have no symptoms.

Other immunosuppressed patients may suffer extensive organ involvement. For example, a patient with CMV pneumonia may complain of a nonproductive cough and dyspnea with hypoxia. A patient with CMV colitis may report explosive watery diarrhea. A patient with CMV ulcerative disease may have GI bleeding, and a patient with CMV retinitis may complain of blurred vision and scotoma, which can progress to blindness in one or both eyes. (See [CMV infection in immunosuppressed patients.](#))

Fever is common. In an immunocompetent patient with CMV mononucleosis, 3 or more weeks of irregular high fever may be the only symptom.

Inspection findings vary in immunosuppressed patients. With respiratory involvement, you may note tachypnea, shortness of breath, cyanosis, and coughing but seldom sputum production. With liver involvement, you may note jaundice and spider angiomas.

Inspection of an infant with congenital CMV infection may reveal signs of central nervous system damage, such as mental retardation and hearing loss, or jaundice, a petechial rash, seizures, and respiratory distress.

Palpation in all CMV patients may reveal splenomegaly and hepatomegaly.

Diagnostic tests

Isolating the virus or demonstrating increasing serologic titers allows diagnosis of CMV. Complement fixation studies, hemagglutination inhibition antibody tests and, in congenital infections, indirect immunofluorescent tests for CMV immunoglobulin M antibody may be performed. Chest X-ray typically shows bilateral, diffuse, white infiltrates.

Treatment

Although antiviral therapy for herpesviruses has had encouraging results, CMV is more difficult to prevent and treat than other herpesviruses. Ganciclovir and, less frequently, high-dose acyclovir prove helpful for certain patients, although relapse may occur. Immunoglobulin specific to CMV has been helpful in transplant recipients. The second line of therapy is foscarnet.

Nursing diagnoses

- u Activity intolerance
- u Altered nutrition: Less than body requirements
- u Diarrhea
- u Fatigue
- u Hyperthermia
- u Impaired gas exchange
- u Ineffective breathing pattern
- u Ineffective family coping
- u Pain
- u Risk for infection
- u Risk for injury

Key outcomes

- u The patient's temperature will remain within normal limits.
- u The patient will demonstrate skill in conserving energy while carrying out daily activities to tolerance level.
- u The patient will verbally report having an increased energy level.
- u The patient will articulate factors that intensify pain and modify behavior accordingly.
- u The patient's respiratory rate will be maintained within 5 breaths of baseline.
- u The patient will express a feeling of comfort while maintaining air exchange.

Nursing interventions

- u Institute standard precautions before coming into contact with the patient's blood or other body fluids. Secretion precautions are especially important for infants known to be shedding CMV.
- u Administer medications to treat symptoms as needed.
- u Monitor intake and output. Offer nutritionally adequate meals. If the patient has diarrhea, replace fluids.
- u Provide emotional support and counseling to the parents of a child with severe CMV infection. Help them find support systems, and coordinate referrals to other health care professionals.
- u Monitor a patient with splenomegaly for signs of rupture, and protect him from excess activity and injury.
- u For the patient with impaired vision, provide a safe environment and encourage optimal independence. Make referrals to community resources as needed.
- u For the patient with respiratory involvement, frequently assess ventilation status, and administer oxygen and assist ventilation as needed. Position the patient in a semi-Fowler's or sitting position to facilitate ventilation.

CMV infection in immunosuppressed patients			
The table below lists immunosuppressed patients, their risk factors for cytomegalovirus (CMV) infection, associated disorders, and prevention tips.			
TYPE OF PATIENT	RISK FACTORS	ASSOCIATED DISORDERS	PREVENTION
Fetus	Primary maternal infection in early pregnancy	Cytomegalic inclusion disease	Avoidance of exposure
Organ transplant recipient	Seropositive donor, seronegative recipient; intensive immunosuppression, particularly with antilymphocyte globulins, cyclosporine	Febrile leukopenia, pneumonia, GI disease	Donor matching, CMV immunoglobulin, ganciclovir or high-dose acyclovir
Bone marrow transplant recipient	Graft-vs-host disease, older age, seropositive recipient, viremia	Pneumonia, GI disease	Ganciclovir or high-dose acyclovir
Patient with acquired immunodeficiency syndrome	Less than 100 CD4 + cells per microliter; CMV seropositivity	Retinitis, GI disease, neurologic disease	Trials under way with newer drugs; to date none has proven effective

Patient teaching

- u Advise women health care workers trying to get pregnant to have CMV titers drawn to identify their risk of contracting the infection. A study done by the Centers for Disease Control and Prevention showed that 50% of pregnant women exposed to CMV also had fetal exposure, with 20% of the fetuses contracting the infection.
- u Urge the patient (especially if the patient is a child, who may be unconcerned with personal hygiene) to wash his hands thoroughly to help prevent contagion.
- u Tell parents—especially the mother, if she's of childbearing age—to wear gloves when coming into contact with secretions or changing diapers of a baby with congenital CMV. They should dispose of diapers and soiled articles properly and wash their hands thoroughly.
- u Warn an immunosuppressed or pregnant patient to avoid contact with any person who has confirmed or suspected CMV infection.
- u Tell an immunosuppressed patient who is CMV-seronegative to carry this information with him and to relay it to any caregiver. This way, he won't be given CMV-positive blood.

EBOLA VIRUS INFECTION

One of the most frightening viruses to come out of the African subcontinent, the Ebola virus first appeared in 1976. More than 400 people in Zaire and the neighboring Sudan were killed by the hemorrhagic fever that it caused. Ebola virus has been responsible for several outbreaks in the years since then, including one that occurred in Zaire in the summer of 1995.

An unclassified ribonucleic acid (RNA) virus, Ebola is morphologically similar to the Marburg virus. Both viruses cause headache, malaise, myalgia, and high fever, progressing to severe diarrhea, vomiting, and internal and external hemorrhage.

Ebola-zaire

The illustration below shows Ebola-Zaire, one of three strains of the Ebola virus that cause hemorrhagic illness in humans.

Four strains of the Ebola virus are known to exist: Ebola-Zaire, Ebola-Sudan, Ebola-Ivory Coast, and Ebola-Reston. All four types are structurally similar, although they have different antigenic properties. However, Ebola-Reston causes illness only in monkeys, not in humans as do the other three. (See [Ebola-Zaire.](#))

The prognosis for Ebola virus infection is extremely poor, with mortality as great as 90%. The incubation period ranges from 2 to 21 days.

Causes

Ebola virus infection is caused by an RNA virus that is passed from person to person by direct contact with infected blood, body secretions, or organs. Nosocomial and community-acquired transmission can occur. Contaminated needles can also cause the infection. Transmission through semen may occur up to 7 weeks after clinical recovery. The virus remains contagious even after the patient has died.

Complications

As the infection progresses, severe complications, including liver and kidney dysfunction, dehydration, and hemorrhage, may develop. In pregnant women, the Ebola virus leads to abortion, disseminated intravascular coagulation, azotemia, and massive hemorrhage. Death usually results during the second week of illness from organ failure or hemorrhage.

Assessment findings

The patient's health history usually reveals contact with an infected person. However, no clear line of infection may be apparent at the beginning of an Ebola virus outbreak. The patient usually complains of flu-like symptoms (such as headache, malaise, myalgia, fever, cough, and sore throat), which first appear within 3 days of infection.

As the virus spreads through the body, inspection reveals bruising as capillaries rupture and dead blood cells infiltrate the skin. A maculopapular eruption appears after the fifth day of infection. The patient may also display melena, hematemesis, epistaxis, and bleeding gums. In the final stages of the disease, the skin blisters and sloughs off, blood seeps from all body orifices, and the patient begins vomiting his liquefied internal organs.

Diagnostic tests

Specialized laboratory tests reveal specific antigens or antibodies and may show the isolated virus. As with other types of hemorrhagic fever, tests also demonstrate leukopenia as early as the first day, with leukocyte counts as low as 1,000/μL and neutrophilia by the fourth day. In addition, atypical lymphocytes and neutrophils with Pelger Huet anomaly may appear, along with thrombocytopenia with fewer than 10,000 cells/μL between days 6 and 12. Hypofibrinogenemia and microangiopathic hemolytic anemia may also be evident.

Treatment

No cure exists for Ebola virus infection; treatment consists mainly of intensive supportive care. Administration of I.V. fluids helps offset the effects of severe dehydration. The patient may receive replacement of plasma heparin before the onset of clinical shock.

Experimental treatments include administration of plasma that contains Ebola virus-specific antibodies. Although this treatment has resulted in diminished levels of the Ebola virus in the body, further evaluation is needed.

Throughout treatment, the patient should remain in isolation. If diagnostic tests indicate that the patient is free from the virus—which typically occurs 21 days after onset in those few who survive—the patient can be released.

Nursing diagnoses

u Activity intolerance u Altered nutrition: Less than body requirements u Fatigue u Fear u Hyperthermia u Impaired skin integrity u Pain u Risk for fluid volume deficit u Risk for infection u Risk for injury

Key outcomes

- u The patient will remain afebrile.
- u The patient's vital signs will remain stable.
- u The patient's electrolyte levels will stay within normal range.
- u The patient's fluid volume will remain adequate.
- u The patient will exhibit improved or healed lesions or wounds.
- u The patient will verbally report having an increased energy level.
- u The patient's white blood cell count and differential will stay within normal range.
- u The patient will remain free from complications.

Nursing interventions

- u Follow the guidelines for standard precautions published by the Centers for Disease Control and Prevention when assessing a patient who may have Ebola virus infection. More extreme precautions are called for as the disease progresses. (See [Preventing the spread of Ebola virus.](#))
- u Watch for any changes in the rate and pattern of the patient's respirations.
- u Closely monitor the patient's fluid and electrolyte balance.
- u Monitor the patient's intake and output, looking for signs of dehydration.
- u Check the results of complete blood count and coagulation studies for signs of blood loss and coagulopathy.
- u Assess the patient daily for petechiae, ecchymoses, and oozing blood. Note and document the size of ecchymoses at least every 24 hours.
- u Test stools, urine, and vomitus for occult blood.
- u Protect all areas of petechiae and ecchymoses from further injury.
- u Watch for frank bleeding, including GI bleeding and, in women, menorrhagia. Note and document the amount of bleeding every 24 hours or more often.
- u Monitor the patient's family and other close contacts for fever and other signs of infection.
- u Provide emotional support for the patient and family during the course of this devastating disease. Encourage the patient and family to ask questions and discuss any concerns they have about the disease and its treatment.

WARNING

Preventing the spread of ebola virus

When caring for a patient in the early stages of Ebola virus infection, practicing standard precautions will generally prevent its transmission. As the disease progresses, however, the patient develops diarrhea and begins vomiting and hemorrhaging, greatly increasing the risk of the disease spreading through contact with infected blood and body fluids. The Centers for Disease Control and Prevention recommends the following guidelines to help prevent the spread of this deadly disease:

- u Keep the patient in isolation throughout the course of the disease.
- u If possible, place the patient in a negative-pressure room at the beginning of hospitalization to avoid the need for transfer as the disease progresses.
- u Restrict nonessential staff members from entering the patient's room.
- u Make sure that anyone who enters the patient's room wears gloves and a gown to prevent contact with any surface in the room that may have been soiled.
- u Use barrier precautions to prevent skin or mucous membrane exposure to blood or other body fluids, secretions, or excretions when caring for the patient. If you must come within 3' (1 m) of the patient, also wear a face shield or surgical mask and goggles or eyeglasses with side shields.
- u Make sure any patient who dies of the disease is promptly buried or cremated: Precautions to prevent contact with the patient's body fluids and secretions should continue even after the patient's death.

Patient teaching

- u Teach the patient's family about Ebola virus infection.
- u Explain the importance of reporting any signs of bleeding.
- u Explain the purpose of any diagnostic tests and procedures that the patient may undergo.

HENITAL WARTS

A common sexually transmitted disease, genital warts are papillomas that consist of fibrous tissue overgrowth from the dermis and thickened epithelial coverings. Also known as venereal warts and condylomata acuminata, these growths are one of the most common sexually transmitted diseases in the United States.

Causes

Genital warts result from infection with one of the more than 60 known strains of human papillomavirus. The virus is transmitted by sexual contact and incubates for 1 to 6 months (the average is 2 months) before warts erupt.

Complications

During pregnancy, genital warts in the vaginal and cervical walls may grow so large that they impede vaginal delivery. Other complications include possible genital tract dysplasia or cancer. (Studies show an association between human papillomavirus types 11, 16, and 18 and cervical dysplasia and cancer.)

Assessment findings

The patient's health history may include reported unprotected sexual contact with a partner with a known infection, a new partner, or many partners.

On examination, you'll observe warts growing on the moist genital surfaces, such as the subpreputial sac, the urethral meatus and, less commonly, on the penile shaft or scrotum in male patients and on the vulva and vaginal and cervical walls in female patients. In both sexes, papillomas spread to the perineum and the perianal area. On inspection, you may find warts that begin as tiny red or pink swellings. These warts may grow as large as 4" (10.2 cm) and may become pedunculated. Multiple swellings have a cauliflower-like appearance. Most patients report no symptoms; a few complain of itching or pain. Infected lesions become malodorous.

Diagnostic tests

Dark-field microscopy of wart-cell scrapings shows marked epidermal cell vascularization. This differentiates genital warts from condylomata lata associated with second-stage syphilis.

Another test involves applying 5% acetic acid (white vinegar) to the warts, which turn white if they are papillomas.

Treatment

Many cases of genital warts resolve spontaneously. Frequently used therapies include cryosurgery, application of caustic agents, electrodesiccation, surgical excision, and laser ablation. Topical antimetabolites, such as 5-fluorouracil, have also been used. Topical podophyllin agents may also be used. Topical interferon benefits condylomata acuminata. Vaccine preparations show promise in preventing papillomavirus.

Nursing diagnoses

- u Altered sexuality patterns u Altered skin integrity u Body image disturbance u Pain u Risk for infection u Risk for injury

Key outcomes

- u The patient will remain free from all signs and symptoms of infection.
- u The patient will express a feeling of comfort and relief from pain.
- u The patient will exhibit improved or healed lesions or wounds.
- u The patient will acknowledge the change in body image.
- u The patient will voice feelings about potential or actual changes in sexuality.
- u The patient and spouse or partner will resume effective communication patterns.

Nursing interventions

- u Use standard precautions when examining the patient, collecting a specimen, or performing associated procedures.
- u Provide a nonthreatening, nonjudgmental atmosphere that encourages the patient to verbalize feelings about perceived changes in sexual identity and behavior.

Patient teaching

- u Tell the patient to remove podophyllum resin with soap and water 4 to 6 hours after applying it to warts.
- u Recommend sexual abstinence or condom use during intercourse until healing is complete.
- u Advise the patient to inform his sexual partners about the risk of genital warts and of the need for evaluation.
- u Urge the patient and his sexual partners to be tested for human immunodeficiency virus infection and other sexually transmitted diseases.
- u Emphasize that genital warts can recur and that the virus can mutate, causing infection with warts of a different strain.
- u Remind the patient to report for weekly treatments until all warts are removed. Then instruct him to schedule a checkup 3 months after all warts are gone.
- u Encourage female patients to have a Papanicolaou test every 6 months.

HANTAVIRUS PULMONARY SYNDROME

Hantavirus pulmonary syndrome is a viral disease that was first reported in May 1993. It occurs mainly in the southwestern United States. The syndrome, which causes flulike symptoms and rapidly progresses to respiratory failure, is known for its high mortality; the mortality rate is 40% with good management. The hantavirus strain that causes disease in Asia and Europe—mainly hemorrhagic fever and renal disease—is distinctly different from the one currently found in North America. (See [Sin Nombre virus](#).)

Causes

A member of the Bunyaviridae family, the genus *Hantavirus* (first isolated in 1977) is responsible for hantavirus pulmonary syndrome. Disease transmission is associated with exposure to infected rodents, which are the primary reservoir for this virus. Data suggest that deer mice are the main source, but pinion mice, brush mice, and western chipmunks living in close proximity to humans in rural areas are also carriers. Hantavirus infections have been documented in people whose activities are associated with rodent contact, such as farming, hiking or camping in rodent-infested areas, and occupying rodent-infested dwellings.

Infected rodents manifest no apparent illness. However, they shed the virus in their stool, urine, and saliva. Human infection may occur from inhalation, ingestion (of contaminated food or water, for example), contact with rodent excrement, or rodent bites. Other means of transmission—from person to person or by mosquitos, fleas, or other arthropods—haven't been reported.

Complications

Hantavirus pulmonary syndrome can very quickly progress to respiratory failure, possibly leading to death.

Assessment findings

Noncardiogenic pulmonary edema distinguishes this syndrome. Common chief complaints include myalgia, fever, headache, nausea, vomiting, and cough. Respiratory distress typically follows the onset of a cough. Fever, hypoxia and, in some patients, serious hypotension typifies the facility course.

Other signs and symptoms include an increasing respiratory rate (28 breaths/minute or more) and an increased heart rate (120 beats/minute or more). During the next few hours, the patient rapidly decompensates to severe hypoxemia and respiratory failure. Most patients are extubated during the next 48 hours of hospitalization and discharged within a few days.

Sin nombre virus

This illustration shows the Sin Nombre virus, the most common cause of hantavirus pulmonary syndrome in the United States and Canada. It exists primarily in western states and provinces.

Diagnostic tests

Despite ongoing efforts to identify clinical and laboratory features that distinguish hantavirus pulmonary syndrome from other infections with similar features, diagnosis currently rests mainly on clinical suspicion in conjunction with a process of elimination developed by the Centers for Disease Control and Prevention (CDC) with the Council of State and Territorial Epidemiologists. *Note:* The CDC and state health departments can perform definitive testing for hantavirus exposure and antibody formation. (See [Screening for hantavirus pulmonary syndrome](#).)

Laboratory studies usually reveal an elevated white blood cell count with a predominance of neutrophils, myeloid precursors, and atypical lymphocytes. Tests also show an elevated hematocrit level, a decreased platelet count, an elevated partial thromboplastin time, and a normal fibrinogen level. Usually, laboratory findings demonstrate only minimal abnormalities in renal function, with serum creatinine levels no higher than 2.5 mg/dl.

Screening for hantavirus pulmonary syndrome

The Centers for Disease Control and Prevention (CDC) has developed a screening procedure to track cases of hantavirus pulmonary syndrome. The screening criteria identify potential and actual cases.

Potential cases

For a diagnosis of possible hantavirus pulmonary syndrome, a patient must have one of the following:

- a febrile illness (temperature equal to or above 101° F [38.3° C])
- infection occurring in a previously healthy person and characterized by unexplained adult respiratory distress syndrome
- bilateral interstitial pulmonary infiltrates that develop within 1 week of hospitalization and cause respiratory compromise that requires supplemental oxygen
- an unexplained respiratory illness that results in death and autopsy findings that demonstrate non-cardiogenic pulmonary edema without an identifiable specific cause of death.

Exclusions

Of the patients who meet the criteria for having potential hantavirus pulmonary syndrome, the CDC excludes those who have any of the following:

- a predisposing underlying medical condition (for example, severe underlying pulmonary disease, solid tumors or hematologic cancers, congenital or acquired immunodeficiency disorders) or a medical condition such as rheumatoid arthritis or organ transplantation that requires immunosuppressive drug therapy (for example, steroids or cytotoxic chemotherapy)
- an acute illness that provides a likely explanation for the respiratory illness. For example, a recent major trauma, burn, or surgery; a recent seizure disorder or history of aspiration; bacterial sepsis; another respiratory disorder such as respiratory syncytial virus in young children; influenza; or pneumonia caused by *Legionella*.

Confirmed cases

Cases of confirmed hantavirus pulmonary syndrome must include the following:

- at least one serum or tissue specimen that shows evidence of hantavirus infection
- in a patient with a compatible clinical illness, serologic evidence (presence of hantavirus-specific immunoglobulin M or rising titers of immunoglobulin G), polymerase chain reaction for hantavirus ribonucleic acid, or a positive immunohistochemistry test for the hantavirus antigen.

Chest X-rays eventually show bilateral diffuse infiltrates in almost all patients (findings consistent with adult respiratory distress syndrome).

Treatment

Management during the first few hours is critical, requiring intubation and aggressive respiratory management. Treatment consists of maintaining adequate oxygenation, monitoring vital signs, and intervening to stabilize the patient's heart rate and blood pressure.

Drug therapy includes administration of vasopressors, such as dopamine or epinephrine, for hypotension. Fluid volume replacement may also be necessary, although precautions must be taken not to overhydrate the patient.

Recent investigational drug therapy involves ongoing clinical trials with ribavirin.

Nursing diagnoses

- Altered health maintenance ▫ Fatigue ▫ Hyperthermia ▫ Impaired gas exchange ▫ Ineffective breathing pattern ▫ Pain ▫ Risk for fluid volume deficit ▫ Risk for infection

Key outcomes

- The patient's respiratory rate will be maintained within 5 breaths of baseline.
- The patient will express a feeling of comfort while maintaining air exchange.
- The patient will cough effectively.
- The patient will expectorate mucus.
- The patient's fluid volume will remain adequate.
- The patient's temperature will remain within normal limits.
- The patient will verbally report having an increased energy level.

Nursing interventions

- Assess the patient's respiratory status and arterial blood gas values often.
- Monitor serum electrolyte levels and correct imbalances as appropriate.
- Maintain a patent airway by suctioning. Ensure adequate humidification, and check mechanical ventilator settings frequently.
- If the patient is hypoxic, assess his neurologic status frequently as well as his heart rate and blood pressure.
- Administer drug therapy and monitor the patient's response.
- Provide I.V. fluid therapy based on results of hemodynamic monitoring.
- Provide emotional support for the patient and family members.
- Report cases of hantavirus pulmonary syndrome to your state health department.
- Provide patients with prevention guidelines. (Until more is known about hantavirus pulmonary syndrome, preventive measures currently focus on rodent control.)

Patient teaching

- Teach the patient about his disorder, and answer any questions he might have.
- Fully discuss all treatments, procedures, and diagnostic tests with the patient, and explain why they have been ordered.

HERPANGINA

This infectious disease characteristically produces vesicular lesions on the mucous membranes of the soft palate, tonsillar pillars, and throat. Herpangina usually affects children under age 10 but seldom occurs in neonates (who are protected by maternal antibodies). It occurs slightly more often in late summer and fall and can be sporadic, endemic, or epidemic.

Causes

Herpangina is typically caused by coxsackievirus A. Herpangina is transmitted by fecal-oral transfer and has a 2- to 9-day incubation period. (See [Understanding enteroviruses.](#))

Complications

Dehydration is possible.

Assessment findings

The patient history usually is unremarkable, although the patient may seek treatment during a known outbreak of herpangina, especially in warm months. After the incubation period, the patient or his parents may report the following signs and symptoms: a sore throat and pain on swallowing (the primary symptoms), transient headache, anorexia, vomiting, malaise, diarrhea, and pain in the stomach, back of the neck, legs, and arms. A temperature of 100° to 104° F (37.8° to 40° C) occurs suddenly and persists for 1 to 4 days.

PATHOPHYSIOLOGY

Understanding enteroviruses

Enteroviruses inhabit the GI tract. Included among them are 3 known polioviruses, 23 group A coxsackieviruses, 6 group B coxsackieviruses, and 34 echoviruses.

They usually infect humans as a result of ingesting stool-contaminated material. They cause a wide range of diseases, such as aseptic meningitis, myocarditis, pericarditis, gastroenteritis, poliomyelitis, and hand-foot- and-mouth disease.

Enteroviruses can appear in the pharynx, stool, blood, cerebrospinal fluid, and central nervous system tissue. Infections from these microorganisms are more prevalent in the summer and fall.

After initial symptoms, you may observe up to 12 grayish-white papulovesicles on the soft palate. Less commonly, you may see lesions on the tonsils, uvula, tongue, and larynx. These lesions grow from about 1 to 2 mm in diameter to large, punched-out ulcers surrounded by small, inflamed margins. Usually all signs and symptoms subside in 4 to 7 days.

Diagnostic tests

The virus may be isolated from mouth washings or stool. Elevated specific antibody titers confirm herpangina, but these tests seldom are done. Other laboratory test findings are normal except for slight leukocytosis.

Treatment

Symptomatic treatment to relieve discomfort includes measures to reduce fever, prevent seizures, and promote hydration.

Nursing diagnoses

- u Altered nutrition: Less than body requirements
- u Altered oral mucous membrane
- u Hyperthermia
- u Impaired swallowing
- u Pain
- u Risk for fluid volume deficit

Key outcomes

- u The patient will exhibit improved or healed lesions or wounds.
- u The patient will express a feeling of comfort and relief from pain.
- u The patient won't exhibit complications related to trauma to oral mucous membranes.
- u The patient will remain afebrile.
- u The patient will achieve adequate nutrient intake.
- u The patient's fluid volume will remain adequate.

Nursing interventions

- u Although herpangina doesn't require isolation precautions, practice careful hand washing and dispose of excretions properly.
- u Provide adequate fluids, enforce bed rest, give tepid sponge baths, and administer prescribed antipyretic and analgesic medications such as acetaminophen. Serve soft or pureed foods that minimize oral irritation.

Patient teaching

- u Teach parents effective infection-control measures.
- u Instruct caregivers in techniques to promote patient comfort and recovery.

HERPES SIMPLEX

Herpes simplex virus (HSV) is a common infection that occurs subclinically in about 85% of patients. In the rest, it causes localized lesions. HSV may be latent for years, but after the initial infection, the patient becomes a carrier susceptible to recurrent attacks. The outbreaks may be provoked by fever, menses, stress, heat, cold, lack of sleep, sun exposure, and contact with reactivated disease (for example, by kissing or by sharing cosmetics). In recurrent infections, the patient usually has no constitutional signs and symptoms. (See [Understanding the genital herpes cycle.](#))

HSV infection generally isn't serious in an otherwise healthy adult; in a neonate or an immunocompromised patient, such as one with acquired immunodeficiency syndrome (AIDS), it can produce severe illness. In fact, serious HSV infections occur commonly in patients with AIDS.

HSV infection occurs worldwide and equally in males and females. Lower socioeconomic groups are infected more often, probably because of crowded living conditions.

Causes

Herpesvirus hominis, a widespread infectious agent, causes two serologically distinct HSV types. Type 1 (HSV-1) is transmitted primarily by contact with oral secretions. It mainly affects oral, labial, ocular, or skin tissues. Type 2 (HSV-2), transmitted primarily by contact with genital secretions, mainly affects genital structures. Infection with HSV-1 occurs more frequently and earlier in life than infection with HSV-2. More than 90% of adults have antibodies to HSV-1 by age 40; in lower socioeconomic groups, most persons acquire HSV-1 infection before age 20. Antibodies to HSV-2 aren't routinely detected before puberty. (See [Recognizing herpetic whitlow](#))

Although HSV most frequently occurs in the structures mentioned, it may infect any epithelial tissue. The incubation period varies, depending on the infection site. The average incubation for infection is 1 to 26 days.

Complications

Primary (or initial) HSV infection during pregnancy can lead to abortion, premature labor, microcephaly, and uterine growth retardation. Congenital herpes transmitted during vaginal birth may produce a subclinical neonatal infection or severe infection with seizures, chorioretinitis, skin vesicles, and hepatosplenomegaly.

In infants, HSV-1 can cause life-threatening nonepidemic encephalitis. Primary HSV infection is a leading cause of gingivostomatitis in children ages 1 to 3.

Blindness may result from ocular infection. Females with HSV may be at increased risk for cervical cancer. Urethral stricture may result from recurrent genital herpes.

Perianal ulcers, colitis, esophagitis, pneumonitis, and various neurologic disorders, resulting from HSV infection, are serious complications in patients with AIDS and other immunocompromised conditions. Viremia can occur, with multiple-organ involvement.

Assessment findings

The patient's history may reveal oral, vaginal, or anal sexual contact with an infected person or other direct contact with lesions. With recurrent infection, the patient may identify various precipitating factors.

In *primary perioral HSV*, the patient may have generalized or localized infection. The patient with generalized infection usually reports a sore throat, fever, increased salivation, halitosis, anorexia, and severe mouth pain. If pain prevents adequate fluid intake, you also may note such signs as dehydration and poor skin turgor. After a brief prodromal tingling and itching, typical primary lesions erupt.

Examination of the pharyngeal and oral mucosa may disclose edema and small vesicles on an erythematous base. These vesicles eventually rupture, leaving a painful ulcer that is followed by yellow crusting. Vesicles most commonly occur on the tongue, gingiva, and cheeks, but any part of the oral mucosa may be involved. Palpation reveals tender cervical adenopathy. A generalized infection usually runs its course in 4 to 10 days.

With *primary genital HSV*, the patient usually complains first of malaise, dysuria, dyspareunia and, in females, leukorrhea. Then fluid-filled vesicles appear.

In examining a female patient, you may detect vesicles on the cervix (the primary infection site) and, possibly, on the labia, perianal skin, vulva, and vagina. In male patients, vesicles develop on the glans penis, foreskin, and penile shaft. Extragenital lesions may be seen on the mouth or anus. Ruptured vesicles appear as extensive, shallow, painful ulcers, with redness, marked edema, and characteristic oozing, yellow centers. Lesions may persist for several weeks. Palpation may reveal tender inguinal adenopathy.

The patient with *recurrent perioral or genital HSV* also may report prodromal symptoms (pain, tingling, or itching) at the site. Typically, the disease course is shorter than that of the primary infection. Recurrent perioral infection usually triggers no systemic symptoms, but the outer lip may be affected and painful. A male patient with recurrent genital herpes usually has less severe systemic symptoms and less local involvement. A female patient may have more symptoms and report severe discomfort. Palpation may reveal tender cervical adenopathy.

The patient with a *primary ocular infection* may report localized signs and symptoms, such as photophobia and excessive tearing. Follicular conjunctivitis or blepharitis with vesicles on the eyelid, eyelid edema, and chemosis also may occur. Systemic signs and symptoms may include lethargy and fever. The infection usually is unilateral, healing in 2 to 3 weeks. Recurrent ocular infections may cause decreased visual acuity and even permanent vision loss. Palpation may reveal regional adenopathy.

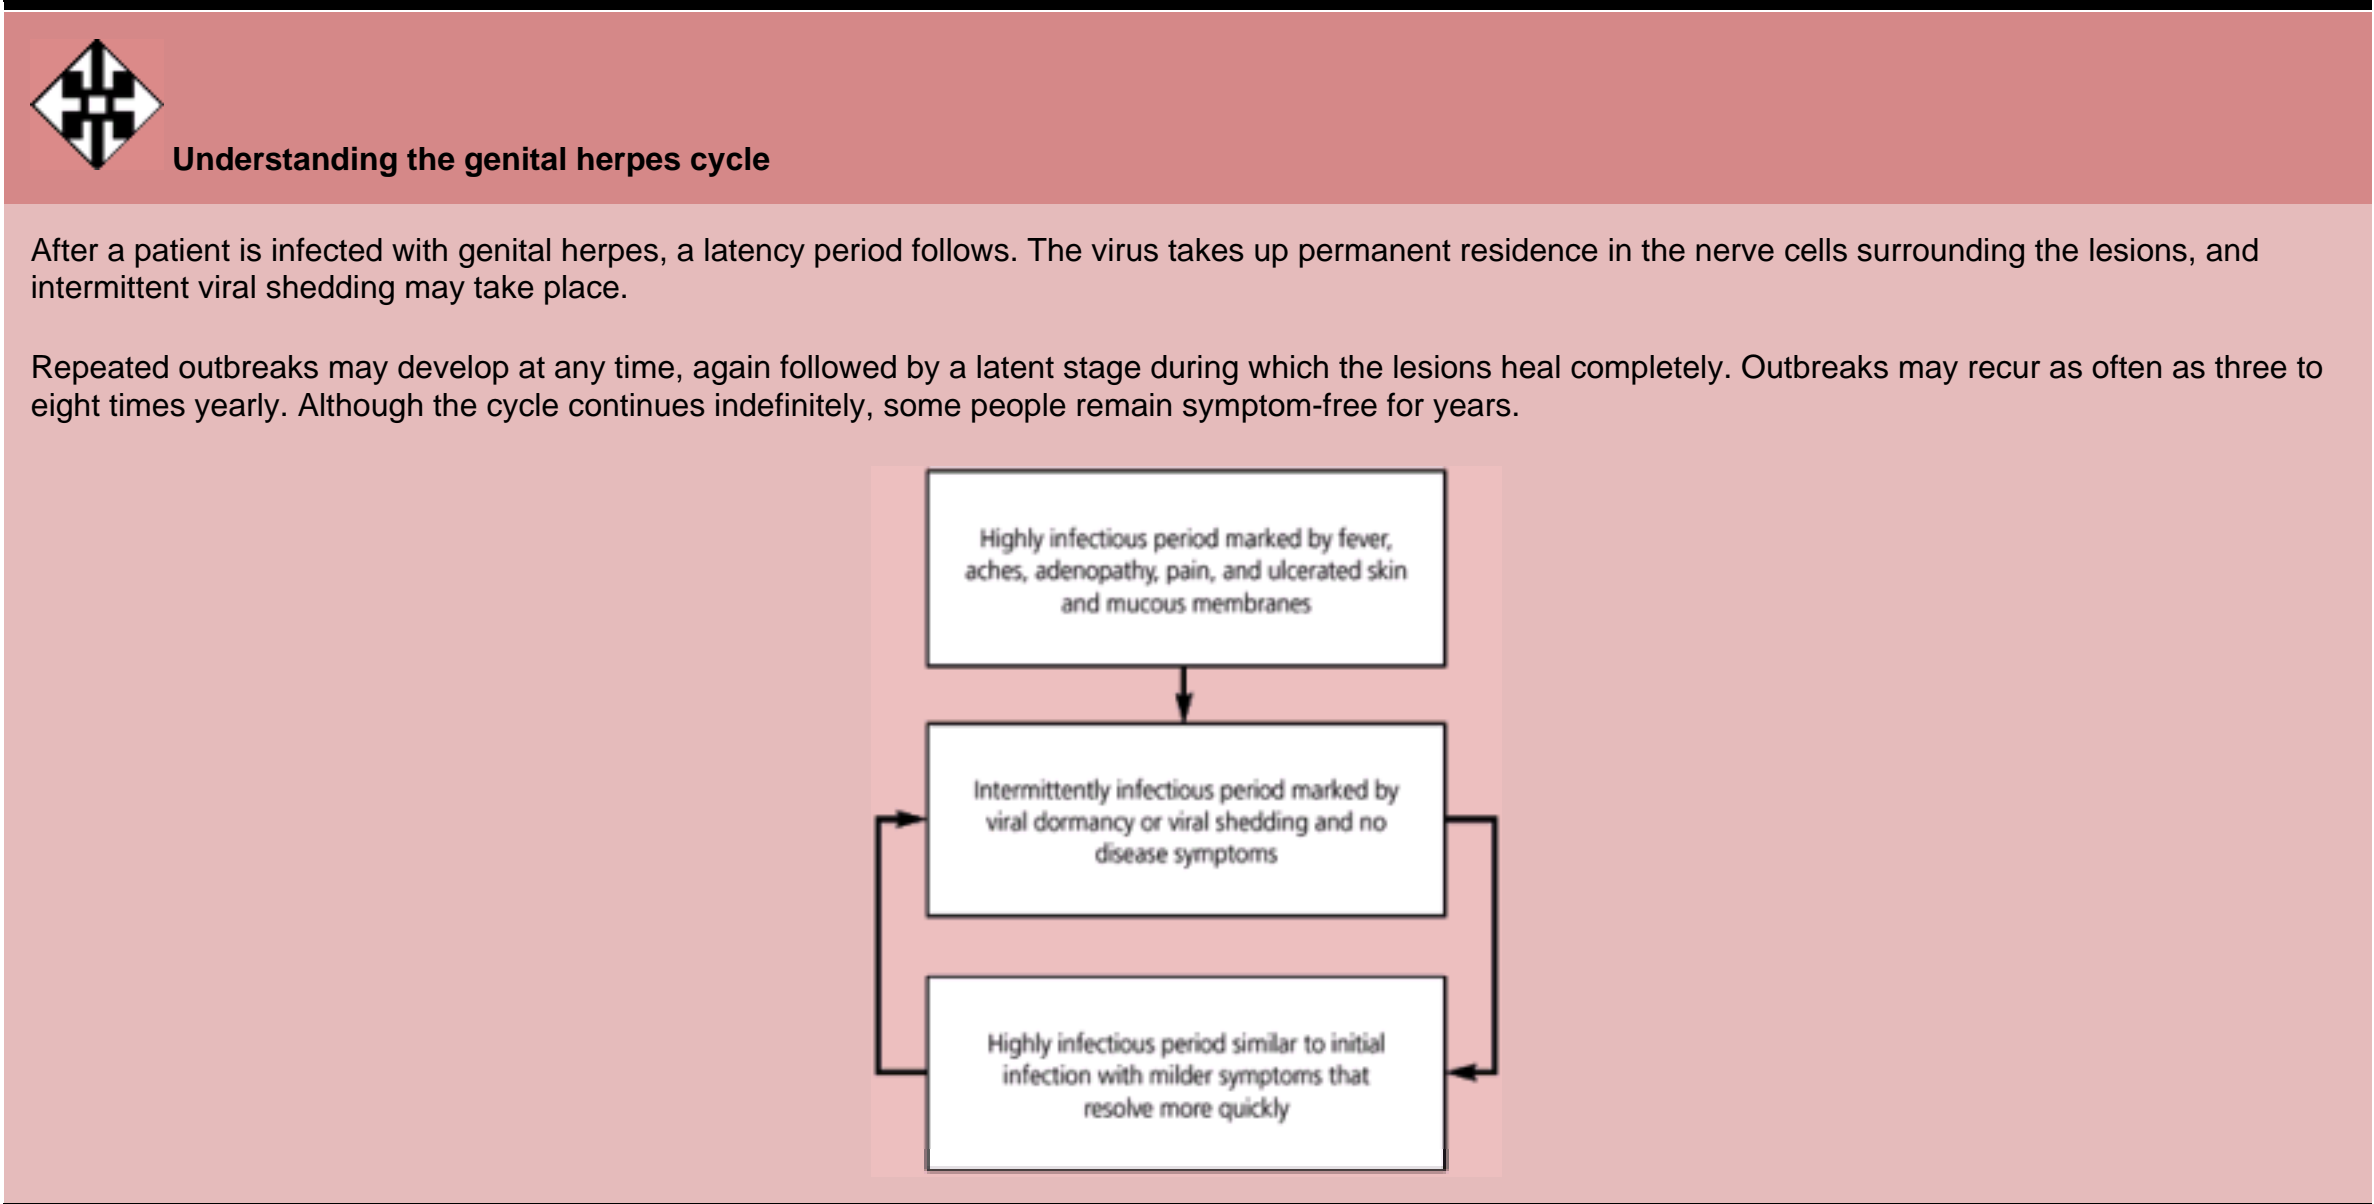

Diagnostic tests

Confirmation of HSV infection requires isolating the virus from local lesions and a histologic biopsy. In primary infection, an increase in antibodies and moderate leukocytosis may support the diagnosis.

Treatment

Symptomatic and supportive therapy is the rule. Generalized primary infection usually requires antipyretic and analgesic medications to reduce fever and pain. Anesthetic mouthwashes, such as viscous lidocaine, may reduce the pain of gingivostomatitis, enabling the patient to consume food and fluids and thus promote hydration. (Avoid offering alcohol-based mouthwashes, which can increase discomfort.) A bicarbonate-based mouth rinse may be used for oral care. Drying agents, such as calamine lotion, may soothe labial and skin lesions. Avoid using petrolatum-based salves or dressings because they promote viral spread and slow healing.

PATHOPHYSIOLOGY

Refer patients with eye infections to an ophthalmologist. Topical corticosteroids are contraindicated in active infection, but ophthalmic medications, such as

idoxuridine, trifluridine, and vidarabine, may be effective.

Acyclovir is a major agent for combating genital herpes, particularly primary infection. Other medications include ganciclovir, famciclovir, and valacyclovir. The drug may reduce symptoms, viral shedding, and healing time. And although it's mostly ineffective in treating recurrent attacks, it may be prescribed to treat and suppress HSV in immuno-compromised patients and those with severe and frequent recurrences. The drug is available in topical, oral, and I.V. form (usually reserved for severe infection).

Recognizing herpetic whitlow

Herpetic whitlow is a finger infection caused by the microorganism that causes herpes simplex virus (HSV). It commonly affects nurses, usually only in one finger. Typical signs and symptoms in the affected finger begin with tingling followed by:

- pain, redness, and swelling
- vesicular eruptions bordered by red halos
- vesicular ulceration or coalescence—related effects include satellite vesicles, fever, chills, malaise, and a red streak up the arm.

Healing occurs in 2 to 3 weeks. In health care workers, the infecting organism usually is HSV-1. In others, the infection usually is secondary to HSV-2 infection.

Nursing diagnoses

▫ Altered oral mucous membrane ▫ Altered sexuality patterns ▫ Impaired skin integrity ▫ Impaired social interaction ▫ Pain ▫ Powerlessness ▫ Risk for infection ▫ Risk for injury ▫ Social isolation

Key outcomes

- The patient will remain free from all signs and symptoms of infection.
- The patient will exhibit improved or healed lesions or wounds.
- The patient will express a feeling of comfort and relief from pain.
- The patient won't exhibit complications related to trauma to oral mucous membranes.
- The patient will voice feelings about potential or actual changes in sexuality.
- The patient and spouse or partner will resume effective communication patterns.

Nursing interventions

- Observe standard precautions. For the patient with extensive cutaneous, oral, or genital lesions, institute drainage and secretion precautions.
- Instruct caregivers with active oral or cutaneous infections not to care for a patient in a high-risk group until the caregiver's lesions crust and dry. Also, insist that the caregiver wear protective coverings, including a mask and gloves.
- Administer pain medications and prescribed antiviral agents as ordered.
- As appropriate, refer the patient to a support group such as the Herpes Resource Center.

Patient teaching

- Tell the patient with cold sores not to kiss infants or people with eczema. Tell the patient with genital herpes to wash his hands carefully after using the bathroom or touching his genitalia, to avoid spreading the infection to infants or other susceptible people.
- Instruct the patient with oral lesions to use lip balm with sunscreen to avoid reactivating lesions.
- Encourage the patient to get adequate rest and nutrition and to keep his lesions dry, except for applying prescribed medications.
- Teach the patient how to apply medications, using aseptic technique.
- Urge the patient with genital herpes to avoid sexual intercourse during the active disease stage before lesions completely heal.
- Instruct the patient with genital herpes to inform any sexual partner of his condition. Advise patients and partners to be screened for other sexually transmitted diseases, including human immunodeficiency virus infection.
- If the patient is pregnant, explain the potential risk to the infant during vaginal delivery. Answer her questions about cesarean delivery if she has an HSV outbreak when labor begins and if her membranes haven't ruptured.
- Advise the female patient with genital herpes to have a Papanicolaou test yearly if results have been normal. If results have been abnormal, advise her to be tested more frequently.
- Instruct the patient with herpetic whitlow not to share towels or eating utensils with others. Educate facility staff members and other susceptible people about the risk of contracting the disease.
- Accept the patient's feelings of powerlessness as normal. Help him to identify and develop coping mechanisms, strengths, and resources for support.
- Provide a nonthreatening, nonjudgmental atmosphere to encourage the patient with genital herpes to voice his feelings about perceived changes in sexuality and behavior. Provide him and his partner with current information about the disease and treatment options. Offer to refer them for appropriate counseling, as needed.

HERPES ZOSTER

Herpes zoster (shingles) is an acute unilateral and segmental inflammation of the dorsal root ganglia. It produces localized vesicular skin lesions confined to a dermatome. The patient with shingles may have severe neuralgic pain in the areas bordering the inflamed nerve root ganglia. (See [Tracking herpes zoster.](#))

The infection is found primarily in adults between ages 50 and 70. The prognosis is good, and most patients recover completely unless the infection spreads to the brain. Herpes zoster is more severe in the immunocompromised patient but seldom is fatal. Patients who have received a bone marrow transplant are especially at risk for the infection.

Causes

The varicella-zoster virus, a herpesvirus, causes shingles. For unknown reasons and by an unidentified process, the disease erupts when the virus reactivates after dormancy in the cerebral ganglia (extramedullary ganglia of the cranial nerves) or the ganglia of posterior nerve roots. Although the process is unclear, the virus may multiply as it reactivates, and antibodies remaining from the initial infection may neutralize it. Without opposition from effective antibodies, the virus continues to multiply in the ganglia, destroys neurons, and spreads down the sensory nerves to the skin.

Herpes zoster may be more prevalent in people who had chickenpox at a very young age.

Complications

Herpes zoster ophthalmicus may result in vision loss. Complications of generalized infection may involve acute urine retention and unilateral paralysis of the diaphragm. In postherpetic neuralgia (most common in elderly patients), intractable neurologic pain may persist for years, and scars may be permanent. In rare cases, herpes zoster may be complicated by generalized central nervous system (CNS) infection, muscle atrophy, motor paralysis (usually transient), acute transverse myelitis, and ascending myelitis.

Assessment findings

The typical patient reports no history of exposure to others with the varicella-zoster virus. He may complain of fever, malaise, pain that mimics appendicitis, pleurisy, musculoskeletal pain, or other conditions. In 2 to 4 days, he may report severe, deep pain; pruritus; and paresthesia or hyperesthesia (usually affecting the trunk and occasionally the arms and legs). Pain, described as intermittent, continuous, or debilitating, usually lasts from 1 to 4 weeks.

During examination of the patient within 2 weeks after his initial symptoms, you may observe small, red, nodular skin lesions spread unilaterally around the thorax or vertically over the arms or legs. Instead of nodules, you may see vesicles filled with clear fluid or pus. About 10 days after they appear, these vesicles dry, forming scabs. The lesions are most vulnerable to infection after rupture; some even become gangrenous. (See [A look at herpes zoster.](#))

During palpation, you may detect enlarged regional lymph nodes.

Herpes zoster may involve the cranial nerves (especially the trigeminal and geniculate ganglia or the oculomotor nerve). With geniculate involvement, you may observe vesicle formation in the external auditory canal and ipsilateral facial palsy. The patient may complain of hearing loss, dizziness, and loss of taste. With trigeminal involvement, the patient may complain of eye pain. He also may have corneal and scleral damage and impaired vision. Rarely, oculomotor involvement causes conjunctivitis, extraocular weakness, ptosis, and paralytic mydriasis.

Diagnostic tests

Vesicular fluid and infected tissue analyses typically show eosinophilic intranuclear inclusions and varicella virus. Differentiation of herpes zoster from localized herpes simplex requires staining antibodies from vesicular fluid and identification under fluorescent light. Usually, though, the locations of herpes simplex and herpes zoster lesions are distinctly different.

With CNS involvement, results of a lumbar puncture indicate increased pressure, and cerebrospinal fluid analysis demonstrates increased protein levels and, possibly, pleocytosis.

Treatment

Oral acyclovir therapy accelerates healing of lesions and resolution of zoster-associated pain. Famciclovir is also very effective, as is valacyclovir. In the immunocompromised patient, herpes zoster should be treated with I.V. acyclovir. Therapeutic goals include relief of itching with antipruritics (such as calamine lotion) and relief of neuralgic pain with analgesics (such as aspirin, acetaminophen or, possibly, codeine). Tricyclic antidepressants help relieve neuritic pain. A similar goal involves preventing secondary infection by applying a demulcent and skin protectant (such as collodion or tincture of benzoin) to unbroken lesions.

Tracking herpes zoster

The herpes zoster virus infects the nerves that innervate the skin, eyes, and ears. Each nerve (tagged for its corresponding vertebral source) emanates from the spine, banding and branching around the body to innervate a skin area called a dermatome. The herpes zoster rash erupts along the course of the affected nerve fibers, covering the skin in one or several of the dermatomes (as shown).

The thoracic (T) and lumbar (L) dermatomes are the most commonly affected, but others, such as those covering the cervical (C) and sacral (S) areas, can also be affected. Dermatome levels can vary and overlap.

If bacteria infect ruptured vesicles, treatment includes an appropriate systemic antibiotic. Herpes zoster affecting trigeminal and corneal structures calls for instillation of idoxuridine ointment or another antiviral agent.

To help a patient cope with the intractable pain of postherpetic neuralgia, a systemic corticosteroid, such as cortisone or corticotropin, may be ordered to reduce inflammation. The doctor also may order tranquilizers, sedatives, or tricyclic antidepressants with phenothiazines.

As a last resort for pain relief, transcutaneous peripheral nerve stimulation, patient-controlled analgesia, or a small dose of radiotherapy may be considered.

Nursing diagnoses

- u Body image disturbance
- u Impaired skin integrity
- u Impaired social interaction
- u Pain
- u Risk for infection

Key outcomes

- u The patient will exhibit improved or healed lesions or wounds.
- u The patient will express a feeling of comfort and relief from pain.
- u The patient will remain free from all signs and symptoms of infection.
- u The patient will acknowledge change in body image.
- u The patient will participate in decision-making about his care.
- u The patient will demonstrate effective social interaction skills in both one-on-one and group settings.

Nursing interventions

- u Administer topical therapies as directed. If the doctor orders calamine, apply it liberally to the patient's lesions. Avoid blotting contaminated swabs on unaffected skin areas. Be prepared to administer drying therapies, such as oxygen, if the patient has severe disseminated lesions. Use silver sulfadiazine, as ordered, to soften and debride infected lesions.
- u Give analgesics exactly as scheduled to minimize severe neuralgic pain. For a patient with postherpetic neuralgia, consult with a pain specialist, and follow his

- recommendations to maximize pain relief without risking tolerance to the analgesic.
- u Maintain meticulous hygiene to prevent spreading the infection to other parts of the patient's body.
 - u If the patient has open lesions, follow contact isolation precautions to prevent the spread of infection to immunocompromised patients.

A look at herpes zoster

These characteristic herpes zoster lesions are fluid-filled vesicles that dry and form scabs after about 10 days.

Patient teaching

- u To decrease discomfort from oral lesions, tell the patient to use a soft toothbrush, eat soft foods, and use a saline- or bicarbonate-based mouthwash and oral anesthetics.
- u Stress the need for rest during the acute phase.
- u Reassure the patient that herpes zoster isn't contagious (except to immunocompromised patients), but stress the need for meticulous hygiene to prevent spreading infection to other body parts.
- u Reassure the patient that herpetic pain eventually will subside. Suggest diversionary or relaxation activities to take his mind off the pain and pruritus.

INFECTIOUS MONONUCLEOSIS

Mononucleosis is an acute infectious disease that causes fever, sore throat, and cervical lymphadenopathy, the hallmarks of the disease. It also causes hepatic dysfunction, increased lymphocytes and monocytes, and development and persistence of heterophil antibodies. The disease primarily affects young adults and children, although in children, it's usually so mild that it's often overlooked.

ADVANCED PRACTICE

Differentiating mononucleosis

Mononucleosis needs to be differentiated from acute infection with cytomegalovirus (CMV), toxoplasma, human immunodeficiency virus, human herpesvirus 6, and hepatitis virus as well as drug hypersensitivity reactions. CMV often affects older patients, causing less severe sore throat, splenomegaly, and lymphadenopathy. In addition, rubella, acute infectious lymphocytosis in children, and lymphoma or leukemia share some of the same features as infectious mononucleosis.

The prognosis is excellent, and major complications are uncommon.

Causes

Infectious mononucleosis is caused by the Epstein-Barr virus (EBV), a member of the herpes group. Apparently, the reservoir of EBV is limited to humans.

EBV is spread by contact with oral secretions. It's frequently transmitted from adults to infants and among young adults by kissing. It has also been transmitted during bone marrow transplantation and blood transfusion.

Complications

Although major complications are rare, mononucleosis may cause splenic rupture, aseptic meningitis, encephalitis, hemolytic anemia, pericarditis, and Guillain-Barré syndrome.

Assessment findings

The patient's history may reveal contact with a person who has infectious mononucleosis.

After an incubation period of about 4 to 6 weeks in young adults, the patient may experience prodromal symptoms. He usually reports headache, malaise, profound fatigue, anorexia, myalgia and, possibly, abdominal discomfort. After 3 to 5 days, he develops a sore throat, which he may describe as the worst he's ever had, and dysphagia related to adenopathy. He usually has a fever, typically with a late afternoon or evening peak of 101° to 102° F (38.3° to 38.9° C).

Your inspection commonly reveals exudative tonsillitis, pharyngitis and, sometimes, palatal petechiae, periorbital edema, maculopapular rash that resembles rubella, and jaundice.

On palpation, you'll probably note that nodes are mildly tender. You'll usually find cervical adenopathy with slight tenderness, but the patient also may have inguinal and axillary adenopathy. You may detect splenomegaly and, less commonly, hepatomegaly.

Auscultation of the chest usually is normal. (See [Differentiating mononucleosis.](#))

Diagnostic tests

The following abnormal laboratory test results confirm infectious mononucleosis:

- u An increase in white blood cell (WBC) count of 10,000 to 20,000/mm³ during the second and third weeks of illness. Lymphocytes and monocytes account for 50% to 70% of the total WBC count; 10% of the lymphocytes are atypical.
- u A fourfold increase in heterophil antibodies (agglutinins for sheep red blood cells) in serum drawn during the acute phase and at 3- to 4-week intervals.
- u Antibodies to EBV and cellular antigens shown on indirect immunofluorescence. Such testing usually is more definitive than heterophil antibodies but may not be necessary because the vast majority of patients are heterophil-positive.
- u Abnormal liver function studies.

Treatment

Infectious mononucleosis isn't easily prevented, and it's resistant to standard antimicrobial treatment. Thus, therapy is essentially supportive: relief of symptoms, bed rest during the acute febrile period, and aspirin or another salicylate for headache and sore throat.

If severe throat inflammation causes airway obstruction, steroids can relieve swelling and prevent a tracheotomy. Splenic rupture, marked by sudden abdominal pain, requires splenectomy. About 20% of patients with infectious mononucleosis also have streptococcal pharyngotonsillitis and should receive antibiotic therapy for at least 10 days.

Nursing diagnoses

- u Activity intolerance
- u Altered nutrition: Less than body requirements
- u Fatigue
- u Hyperthermia
- u Impaired skin integrity
- u Impaired social interaction
- u Pain
- u Risk for fluid volume deficit

Key outcomes

- u The patient's temperature will remain within normal limits.
- u The patient will demonstrate skill in conserving energy while carrying out daily activities to tolerance level.
- u The patient will verbally report having an increased energy level.
- u The patient's fluid volume will remain adequate.
- u The patient will articulate factors that intensify pain and modify behavior accordingly.
- u The patient will express needs and communicate whether needs are met.

Nursing interventions

- u Administer medications to treat symptoms as needed.
- u Provide warm saline gargles for symptomatic relief of sore throat.
- u Provide adequate fluids and nutrition.
- u Plan care to provide frequent rest periods.

Patient teaching

- u Explain that convalescence may take several weeks, usually until the patient's WBC count returns to normal.
- u Stress the need for bed rest during the acute illness. Warn the patient to avoid excessive activity, which could lead to splenic rupture.
- u If the patient is a student, tell him that he can continue less demanding school assignments and see his friends but that he should avoid long, difficult projects until after recovery.
- u To minimize throat discomfort, encourage the patient to drink milk shakes, fruit juices, and broths, and to eat cool, bland foods. Advise using warm saline gargles, analgesics, and antipyretics as needed.

INFLUENZA

Also called the gripe or the flu, influenza is an acute, highly contagious infection of the respiratory tract.

Although it affects all age-groups, the highest incidence occurs in school-age children. The greatest severity is in young children, elderly people, and those with chronic diseases. In these groups, influenza may even lead to death.

Influenza occurs sporadically or in epidemics (usually during the colder months). Epidemics usually peak within 2 to 3 weeks after initial cases and last 2 to 3 months.

Causes

Influenza results from three types of virus. Type A, the most prevalent, strikes every year, with new serotypes causing epidemics every 3 years. Type B also strikes annually but only causes epidemics every 4 to 6 years. Type C is endemic and causes only sporadic cases.

The infection is transmitted by inhaling a respiratory droplet from an infected person or by indirect contact, such as drinking from a contaminated glass. The virus then invades the epithelium of the respiratory tract, causing inflammation and desquamation. (See [How influenza viruses multiply.](#))

One remarkable feature of the influenza virus is its capacity for antigenic variation—that is, its ability to mutate into different strains so that no immunologic resistance is present in those at risk. Antigenic variation is characterized as *antigenic drift* (minor changes that occur yearly or every few years) and *antigenic shift* (major changes that lead to pandemics).

Complications

The most common complication of influenza is pneumonia, which can be primary influenza viral pneumonia or secondary to bacterial infection. Influenza also may cause myositis, exacerbation of chronic obstructive pulmonary disease, Reye's syndrome and, rarely, myocarditis, pericarditis, transverse myelitis, and encephalitis.

Assessment findings

The patient's history usually reveals recent exposure to a person with influenza. Most patients say that they didn't receive the influenza vaccine during the past season.

After an incubation period of 24 to 48 hours, flu symptoms appear. The patient may report sudden onset of chills, fever (101° to 104° F [38.3° to 40° C]), headache, malaise, myalgia (particularly in the back and limbs), photophobia, a nonproductive cough and, occasionally, laryngitis, hoarseness, rhinitis, and rhinorrhea. Fever usually is higher in children, who also may show signs of croup. These signs usually subside in 3 to 5 days, but cough and weakness may persist. Some patients (especially elderly people) may feel tired and listless for several weeks.

PATHOPHYSIOLOGY

How influenza viruses multiply

An influenza virus, classified as type A, B, or C, contains the genetic material ribonucleic acid (RNA), which is covered and protected by protein. The RNA is arranged in genes that carry the instruction for viral replication. This genetic material has an extraordinary ability to mutate, causing the generation of new serologically distinct strains of influenza virus. Being a virus, the pathogen can't reproduce or carry out chemical reactions on its own. It needs a host cell.

After attaching to the host cell, the viral RNA enters the host cell and uses host components to replicate its genetic material and protein, which are then assembled into the new virus particles. These newly produced viruses can burst forth to invade other healthy cells.

The viral invasion destroys the host cells, impairing respiratory defenses, especially the mucociliary transport system, and predisposing the patient to secondary bacterial infection.

1 Virus attaches to host.

2 Virus RNA enters host cell.

3 Virus RNA replicates within host cell.

4 New virus particles are assembled and released.

Inspection initially may reveal red, watery eyes; erythema of the nose and throat without exudate; and clear nasal discharge.

As the disease progresses, respiratory findings become more apparent. The patient frequently coughs and looks tired. If pulmonary complications occur, tachypnea, cyanosis, and shortness of breath may be noted.

With bacterial pneumonia, you'll see purulent or bloody sputum.

Palpation may reveal cervical adenopathy and tenderness, especially in children. Auscultation may disclose transient gurgles or crackles. With pneumonia, breath sounds may be diminished in areas of consolidation.

Diagnostic tests

At the beginning of an influenza epidemic, many patients are misdiagnosed with other respiratory disorders. Because signs and symptoms of influenza aren't pathognomonic, isolation of the influenza virus through inoculation of chicken embryos (with nasal secretions from infected patients) is essential at the first sign of an epidemic. In addition, nose and throat cultures and increased serum antibody titers help confirm the diagnosis.

When an epidemic is confirmed, diagnosis requires only observation of clinical signs and symptoms. Uncomplicated cases show decreased white blood cells with an increase in lymphocytes.

Treatment

The patient with uncomplicated influenza needs bed rest, adequate fluid intake, acetaminophen or aspirin to relieve fever and muscle pain (children should only receive acetaminophen), and guaifenesin or another expectorant to relieve nonproductive coughing. Prophylactic antibiotics aren't recommended; they have no effect on the influenza virus.

The antiviral agent amantadine has effectively reduced the duration of influenza A infection. In influenza complicated by pneumonia, the patient needs supportive care (fluid and electrolyte replacements, oxygen, and assisted ventilation) and treatment of bacterial superinfection with appropriate antibiotics. No specific therapy exists for cardiac, central nervous system, or other complications.

Nursing diagnoses

u Altered health maintenance u Fatigue u Hyperthermia u Ineffective breathing pattern u Pain u Risk for fluid volume deficit u Risk for infection

Key outcomes

- u The patient will maintain his current health status.
- u The patient will verbally report having an increased energy level.
- u The patient's temperature will remain within normal limits.
- u The patient will express a feeling of comfort and relief from pain.
- u The patient's fluid volume will remain adequate.
- u The patient's respiratory rate will be maintained within 5 breaths of baseline.

Nursing interventions

- u Administer analgesics, antipyretics, and decongestants as ordered.
- u Watch for signs and symptoms of developing pneumonia, such as crackles, increased fever, chest pain, dyspnea, and coughing accompanied by purulent or bloody sputum.
- u Follow respiratory and blood and body fluid precautions.
- u Provide cool, humidified air, but change the water daily to prevent *Pseudomonas* superinfection.
- u Encourage the patient to rest in bed and drink plenty of fluids. Administer I.V. fluids as ordered.
- u Administer oxygen therapy, if warranted.

- u Help the patient to gradually return to his normal activities.

Patient teaching

- u Influenza usually doesn't require hospitalization. Teach the home patient about supportive care measures and signs and symptoms of serious complications.
- u Advise the patient to use mouthwash or warm saline gargles to ease sore throat.
- u Teach the patient the importance of increased fluids to prevent dehydration.
- u Suggest a warm bath or a heating pad to relieve myalgia.
- u Advise the patient to use a vaporizer to provide cool, moist air but to clean the reservoir and change the water every 8 hours.
- u Teach the patient how to dispose of tissues properly and proper hand-washing technique to prevent the virus from spreading.
- u Discuss influenza immunization. Suggest that high-risk patients and health care workers get an annual inoculation at the start of flu season (late autumn). Explain that each year's vaccine is based on the previous year's virus and usually is about 75% effective.

Tell a patient receiving the vaccine about possible adverse effects (discomfort at the vaccination site, fever, malaise and, rarely, Guillain-Barré syndrome).

Remember that the vaccine isn't recommended for pregnant women unless they have chronic diseases and are highly susceptible to influenza. The vaccine also shouldn't be given to anyone who's allergic to eggs, feathers, or chickens because it's made from chicken embryos. (Amantadine is an effective alternative for these people.)

MUMPS

Mumps (also called infectious or epidemic parotitis) is an acute inflammation of one or both parotid glands. The disease seldom occurs in infants under age 1 because of passive immunity from maternal antibodies. About 50% of cases occur in young adults, with the remainder occurring in young children or immunocompromised adults.

ADVANCED PRACTICE

Differentiating mumps

Bilateral parotid swelling can occur in conditions other than mumps. These conditions include parainfluenza virus type 3, coxsackieviruses, and influenza A virus; metabolic disease, such as diabetes mellitus and uremia; and drugs, such as phenylbutazone and thiouracil. Unilateral parotid swelling can occur from a tumor, cyst, obstruction, or stricture. Chronic parotid swelling can occur in sarcoidosis, Sjögren's syndrome, and infection with human immunodeficiency virus. Suppurative parotitis, caused by *S. aureus*, is usually unilateral. In addition, testicular torsion can produce a painful scrotal mass resembling mumps orchitis; other viruses (such as entero-viruses) can cause aseptic meningitis that is clinically indistinguishable from that caused by the mumps virus.

Peak incidence takes place during late winter and early spring. The prognosis for complete recovery is good, although some patients, especially postpubertal males, have serious complications. One attack of mumps (even with only unilateral infection) usually confers lifelong immunity.

Causes

A paramyxovirus found in the saliva of an infected person causes mumps. Transmitted by droplets or by direct contact, the virus can be detected in the saliva 6 days before to 9 days after the parotid glands swell. The disease probably is also communicable before the onset of symptoms. The incubation period ranges from 14 to 18 days.

Complications

Epididymo-orchitis occurs in about 25% of postpubertal males who contract mumps. This complication results in testicular swelling and tenderness, scrotal erythema, lower abdominal pain, nausea, vomiting, fever, and chills. Swelling and tenderness may last for several weeks. Epididymitis may precede or accompany orchitis. About 50% of men with mumps-induced orchitis exhibit testicular atrophy, with sterility occurring only when both testes are affected.

Mumps meningitis occurs in about 10% of mumps victims and affects male patients three to five times more often than female patients. Symptoms include fever, meningeal irritation (nuchal rigidity, headache, and irritability), vomiting, drowsiness, and a cerebrospinal fluid (CSF) lymphocyte count from 500 to 2,000/mm³.

Less common complications include pancreatitis, transient sensorineural hearing loss, transverse myelitis, arthritis, myocarditis, pericarditis, oophoritis, pancreatitis, diabetes mellitus, arthritis, thyroiditis, and nephritis.

Assessment findings

The typical patient history points to inadequate immunization and exposure to someone with mumps within the preceding 2 to 3 weeks. The clinical features of mumps vary widely. Up to 50% of susceptible people have subclinical illness without symptoms. In apparent disease, mumps usually begins with prodromal symptoms that last for 24 hours. In addition to complaining of myalgia, anorexia, malaise, headache, an earache aggravated by chewing, and pain when drinking sour or acidic liquids, the patient may report a temperature of 101° to 104° F (38.3° to 40° C).

Inspection may reveal swelling and tenderness of the parotid glands and simultaneous (or a little later) swelling of one or more other salivary glands. Diagnosis usually is made after the characteristic signs and symptoms develop, especially parotid gland enlargement with a history of exposure to mumps. (See [Differentiating mumps](#), and [Parotid inflammation in mumps](#).)

Diagnostic tests

Glandular swelling confirms the diagnosis. Serologic testing to detect the mumps antibodies can verify the diagnosis if the patient's glands don't swell. If comparisons between a saliva, urine, or CSF specimen obtained during the acute phase of illness and another specimen obtained 3 weeks later show a fourfold increase in antibodies, the patient probably had mumps. Serum amylase levels also may be elevated.

Treatment

Appropriate treatment includes analgesics for pain, antipyretics for fever, and adequate fluid intake to prevent dehydration from fever and anorexia. If the patient can't swallow, treatment may include I.V. fluid replacement.

Nursing diagnoses

- u Altered nutrition: Less than body requirements
- u Anxiety
- u Body image disturbance
- u Fluid volume deficit
- u Hyperthermia
- u Impaired swallowing
- u Pain
- u Risk for infection

Key outcomes

- u The patient and family members will communicate understanding of special dietary needs.
- u The patient will remain afebrile.
- u The patient will express a feeling of comfort and relief from pain.
- u The patient's fluid volume will remain adequate.
- u The patient will achieve adequate nutritional intake.
- u The patient will express his feelings about his changed body image.

Nursing interventions

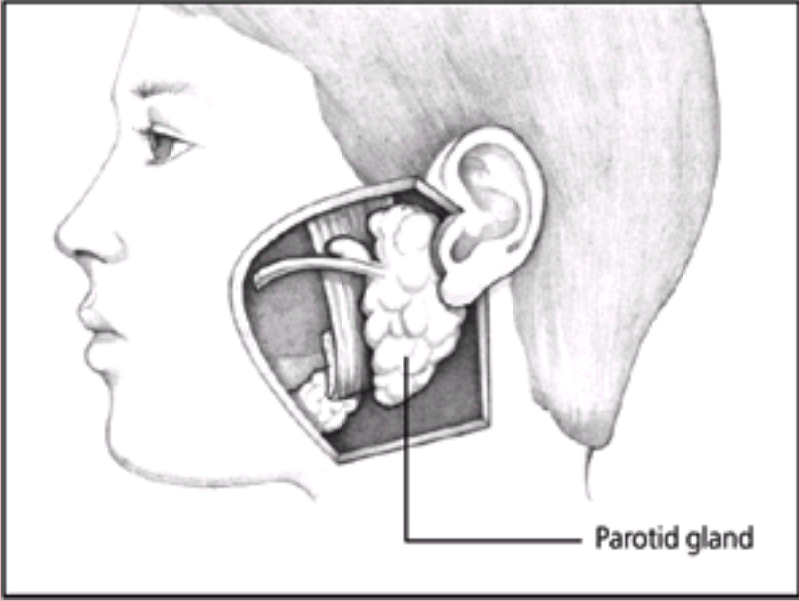

- u Give analgesics, and apply warm or cool compresses to the neck area to relieve pain. Give antipyretics and tepid sponge baths for fever. Increase fluids to prevent dehydration. Provide a high-calorie, nutritionally sound diet. Avoid spicy, irritating foods that trigger salivation or require a lot of chewing.
- u Closely observe the patient for complications, especially for signs of central nervous system involvement, such as an altered level of consciousness and nuchal rigidity.
- u Until symptoms subside, consider implementing respiratory isolation because the mumps virus remains in the patient's saliva throughout the disease course. Provide comfort measures; if the patient has scrotal swelling, support the scrotum with a small pillow or make an adhesive tape bridge to place between the thighs. Use a nonadhesive material for the portion that will elevate and support the scrotum.
- u Report all cases of mumps to local public health authorities.

Patient teaching

- u Encourage bed rest during the febrile period.
- u To minimize pain and anorexia, recommend eating bland, nonirritating foods that require minimal chewing.
- u Advise administering antipyretics and tepid sponge baths to reduce fever and increasing fluids to prevent dehydration.
- u List complications to watch for and report to the doctor.
- u Urge parents to have children immunized with live attenuated mumps vaccine at age 15 months—or older, if applicable. Among those susceptible to mumps and its complications are nonimmunized males who are approaching or past puberty. Explain that immunity to mumps is usually lifelong after acquiring the disease and that immunity is long-term if the patient is immunized.

Parotid inflammation in mumps

The mumps virus (paramyxovirus) attacks the parotid glands—the main salivary glands. Inflammation causes characteristic swelling and discomfort associated with eating, drinking, swallowing, and talking.

- u Reassure the patient with epididymo-orchitis that even if testicular atrophy occurs, it won't cause impotence. Also inform him that sterility occurs only with bilateral orchitis.

PARAINFLUENZA

Widespread in infants and children and rare in adults, parainfluenza resembles influenza but is milder and seldom fatal. This self-limiting disease causes both upper and lower respiratory tract illness and is more common in children in the winter and spring.

Causes

Parainfluenza refers to any of a group of respiratory illnesses caused by paramyxoviruses, a subgroup of the myxoviruses. It's transmitted by direct contact or by inhalation of contaminated airborne droplets, and it has an incubation period of about 3 to 6 days.

Paramyxoviruses occur in four forms—Para 1 to 4—that are linked to several diseases: croup (Para 1, 2, and 3), acute febrile respiratory illnesses (1, 2, and 3), the common cold (1, 3, and 4), pharyngitis (1, 3, and 4), bronchitis (1 and 3), and bronchopneumonia (1 and 3). Para 3 is the second most common infecting organism that causes lower respiratory tract infections in children (respiratory syncytial virus infection ranks first). Para 4 seldom causes symptomatic infections in humans.

By age 8, most children demonstrate antibodies to Para 1 and Para 3. Most adults have antibodies to all four types as a result of childhood infections and subsequent multiple exposures. Reinfection usually is less severe and affects only the upper respiratory tract.

Complications

Possible complications include croup, bronchiolitis, and pneumonia. Bacterial complications are uncommon.

Assessment findings

The patient may complain of signs and symptoms that are similar to those of other respiratory diseases: nasal discharge, cough, hoarseness, sore throat, chills, and muscle pain. A temperature over 100° F (37.8° C) for 2 or 3 days is common.

Inspection may reveal pharyngeal erythema (with little or no exudate). Other findings depend on whether complications develop. For example, nasal flaring and sternal retractions indicate respiratory distress; listlessness may indicate hypoxemia.

Palpation may reveal the absence of cervical adenopathy. Chest auscultation usually detects rhonchi or, in croup, stridor of the upper airways.

Diagnostic tests

Parainfluenza usually is clinically indistinguishable from similar viral infections. Isolation of the virus and serum antibody titers differentiate parainfluenza from other

respiratory illness, but they seldom are done.

Treatment

Parainfluenza may require no treatment, or it may require bed rest, antipyretics, analgesics, and antitussives, depending on the severity of symptoms. Vaporizers are helpful in mild croup. Admittance to a facility seldom is necessary unless complications, such as croup or pneumonia, develop.

WARNING If acute respiratory distress develops, humidified oxygen and intermittent racemic epinephrine should be administered. High-dose systemic glucocorticoids also may be helpful.

Nursing diagnoses

u Activity intolerance u Fatigue u Fluid volume deficit u Hyperthermia u Impaired gas exchange u Ineffective airway clearance u Pain u Risk for infection

Key outcomes

- u The patient's respiratory rate will be maintained within 5 breaths of baseline.
- u The patient will express a feeling of comfort while maintaining air exchange.
- u The patient will cough effectively.
- u The patient will expectorate mucus.
- u The patient's fluid volume will remain adequate.
- u The patient will verbally report having an increased energy level.

Nursing interventions

- u Administer analgesics, antipyretics, and antitussives as ordered.
- u Encourage adequate rest and fluid intake.
- u Promote careful hand washing.

Patient teaching

- u Instruct the patient or family members about the need for bed rest, antipyretics, analgesics, and antitussives, as well as the need for adequate fluids and for performing careful hand washing.
- u Teach the patient or parents about the various signs and symptoms of complications. Tell them to call the doctor if these occur because additional treatment will be needed.
- u Vaccines are available for high-risk groups. For information, the patient can contact the doctor or local health department.

POLIOMYELITIS

Poliomyelitis—also called polio and infantile paralysis—is an acute communicable disease caused by the poliovirus. Most patients present with minor illness (fever, malaise, headache, sore throat, and vomiting), but a few develop aseptic meningitis and paralytic illness.

In the United States, only 5 to 10 cases of the disease are reported annually. These cases are associated with the use of oral poliovirus vaccine, with infants frequently developing signs and symptoms after the first dose of the vaccine. Most of the other cases develop in individuals who haven't received vaccines and are in close contact with infected individuals.

Causes and pathophysiology

The poliovirus (an enterovirus) is found worldwide and is transmitted from person to person by direct contact with infected oropharyngeal secretions or stool.

The virus usually enters the body through the alimentary tract, multiplies in the oropharynx and lower intestinal tract, and then spreads to regional lymph nodes and blood. Factors that increase the probability of paralysis include pregnancy, old age, unusual physical exertion at or just before the clinical onset of poliomyelitis, and localized trauma, such as a recent tonsillectomy, tooth extraction, or inoculation.

Most major cases in the United States are related to the oral poliovirus vaccine (OPV) and occur in children under age 4. Infection occurs 3 to 6 days after administration of OPV and usually is associated with the first dose of the vaccine.

Complications

Possible complications include respiratory failure, pulmonary edema, pulmonary embolism, urinary tract infection, urolithiasis, atelectasis, pneumonia, cor pulmonale, soft-tissue and skeletal deformities, and paralytic ileus.

In polio survivors, latent poliomyelitis can lead to muscle spasticity and weakness 20 to 30 years after the initial infection. Delayed poliomyelitis also can affect respiratory muscles, leading to hypoxemia. It's thought that the syndrome is due to loss of motor neurons that compensate for neurons lost in the original infection.

Assessment findings

Today, most cases of polio are so minor that the patient doesn't even visit the doctor. Inapparent, or subclinical, poliomyelitis (95% of all cases) has no symptoms. Abortive poliomyelitis (4% to 8% of all cases) is over in about 72 hours, with the patient experiencing only a slight fever, malaise, headache, sore throat, and vomiting.

The third type, major poliomyelitis, is most likely to be reported. It involves the central nervous system (CNS) and takes two forms: nonparalytic and paralytic. In children, the course often is biphasic, with the onset of major illness occurring after recovery from the minor illness stage.

The most perilous paralytic form, bulbar paralytic poliomyelitis, occurs when the virus affects the medulla of the brain. This type usually weakens the muscles supplied by the cranial nerves (particularly the ninth and tenth).

A patient with nonparalytic poliomyelitis complains of moderate fever, headache, vomiting, lethargy, irritability, and pains in the neck, back, arms, legs, and abdomen.

Paralytic poliomyelitis usually develops within 5 to 7 days after the onset of fever. The patient complains of symptoms similar to those of nonparalytic poliomyelitis and then develops weakness and paralysis. The patient also may report related signs and symptoms, such as paresthesia, urine retention, constipation, and abdominal distention.

The patient with bulbar paralytic poliomyelitis may complain of facial weakness, dysphasia, difficulty in chewing, inability to swallow or expel saliva, regurgitation of food through the nasal passages, and dyspnea.

Your examination of the patient with nonparalytic poliomyelitis may reveal muscle tenderness and spasms in the extensors of the neck and back and sometimes in the hamstring and other muscles. (These spasms may be observed during maximum range-of-motion exercises.) This type of polio usually lasts about 1 week, with meningeal irritation persisting for about 2 weeks.

Examination of the patient with paralytic poliomyelitis may show asymmetrical weakness and flaccid paralysis of various muscles. The patient displays Hoyne's sign—his head falls back when he's supine and his shoulders are elevated. This patient is unable to raise his legs a full 90 degrees. The extent of paralysis depends on the level of the spinal cord lesions, which may be cervical, thoracic, or lumbar.

In both nonparalytic and paralytic polio, you may observe resistance to neck flexion—the patient extends his arms behind him for support (“tripod”) when he sits up.

Diagnostic tests

Isolation of the poliovirus from throat washings early in the disease and from stools throughout the disease confirms the diagnosis. If the patient has a central nervous system infection, cerebrospinal fluid cultures may aid diagnosis. Coxsackievirus and echovirus infections must be ruled out. Convalescent serum antibody titers four times greater than acute titers support a diagnosis of poliomyelitis.

Treatment

Poliomyelitis calls for supportive treatment, including analgesics to ease headache, back pain, and leg spasms. Morphine is contraindicated because of the danger of additional respiratory depression. Moist heat applications also may reduce muscle spasm and pain.

Bed rest is necessary until extreme discomfort subsides. It also helps prevent increased paralysis. Patients with paralytic polio may be bedridden for a long time and then require long-term rehabilitation using physical therapy, braces, and corrective shoes. Orthopedic surgery also may be necessary.

Bladder involvement may require catheterization, and respiratory muscle involvement may require mechanical ventilation. Postural drainage and suction may be sufficient to manage pooling of secretions in patients with nonparalytic polio.

Nursing diagnoses

⌞ Activity intolerance ⌞ Altered family processes ⌞ Altered growth and development ⌞ Altered urinary elimination ⌞ Impaired gas exchange ⌞ Impaired physical mobility ⌞ Impaired skin integrity ⌞ Ineffective airway clearance ⌞ Ineffective breathing pattern ⌞ Ineffective individual coping ⌞ Risk for aspiration ⌞ Risk for infection

Key outcomes

- ⌞ The patient will express a feeling of comfort while maintaining air exchange.
- ⌞ The patient will verbally report having an increased energy level.
- ⌞ Complications will be minimized or prevented.
- ⌞ The patient will demonstrate age-appropriate skills and behaviors to the extent possible.
- ⌞ The patient and family members will agree to seek help from peer support groups or professional counselors to increase adapting and coping behaviors.

Nursing interventions

- ⌞ Observe for signs of paralysis and other neurologic damage, which can occur rapidly. Maintain a patent airway, and look for respiratory weakness and difficulty swallowing. Endotracheal intubation commonly is performed at the first sign of respiratory distress, and the patient is placed on a ventilator.
- ⌞ Perform a brief neurologic assessment at least once a day, but don't demand any vigorous muscle activity. Encourage a return to mild activity as soon as possible.
- ⌞ Frequently check blood pressure, especially if the patient has bulbar poliomyelitis. This form of the disease can cause hypertension or shock.
- ⌞ Watch for signs of stool impaction, caused by dehydration and intestinal inactivity. To prevent this, give enough fluids to ensure an adequate daily urine output of low specific gravity (1.5 to 2 L/day for adults).
- ⌞ Monitor the bedridden patient's food intake to make sure he's receiving an adequate, well-balanced diet. Provide tube feeding when needed.
- ⌞ To prevent pressure ulcers, provide good skin care, reposition the patient often, and keep the bed linens dry.
- ⌞ Assess bladder distention. Muscle paralysis may cause bladder weakness or transient bladder paralysis with urine retention.
- ⌞ Have the patient wear high-top sneakers or use a footboard to prevent footdrop. To alleviate discomfort, use foam rubber pads and sandbags or light splints as ordered.
- ⌞ To control the spread of infection, wash your hands thoroughly after contact with the patient or any of his excretions.
- ⌞ Provide emotional support to the patient and family members. Long-term support and encouragement are essential for maximum rehabilitation.
- ⌞ When caring for a paralytic patient, help set up an interdisciplinary rehabilitation program with physical and occupational therapists and doctors. A psychiatrist also may help the patient and family members accept the patient's physical disabilities.
- ⌞ Report all polio cases to local public health authorities.

Patient teaching

- ⌞ Inform the ambulatory patient about the need for careful hand washing.
- ⌞ Warn any facility worker who hasn't been vaccinated against polio to avoid contact with the patient.
- ⌞ Instruct the patient or caregivers about measures needed to manage symptoms and prevent complications.
- ⌞ Help the patient establish a support system of family, friends, or health care workers to assist him at home.
- ⌞ Encourage parents to have children vaccinated against polio. Reassure them that the risk of vaccine-related disease is small.

RABIES

Rabies (hydrophobia) is an acute central nervous system (CNS) infection. It usually is transmitted by an animal bite and is almost always fatal after symptoms occur. Fortunately, immunization that begins soon after infection may prevent fatal CNS invasion. (See [Schedules for rabies prophylaxis.](#))

Increased domestic animal control and vaccination in the United States have reduced cases of rabies in humans. Consequently, most human rabies can be traced to dog bites that occurred in other countries or bites from wild animals, such as raccoons.

Causes

Rabies is caused by the rabies virus, a rhabdovirus. The rabies virus is transmitted to a human from the bite of an infected animal through the skin or mucous membranes. The virus begins replicating in the striated muscle cells at the entry site and spreads along the nerve pathways to the spinal cord and brain, where it replicates. Finally, it moves through the nerves into other tissues, including the salivary glands. Airborne droplets and infected tissue transplants occasionally can transmit the virus. The incubation period is hours to weeks.

Complications

Untreated rabies can lead to life-threatening complications, including respiratory failure, peripheral vascular collapse, and central brain failure.

If intensive support is used, a number of late complications can occur: inappropriate secretion of antidiuretic hormone, diabetes insipidus, cardiac arrhythmias, vascular instability, adult respiratory distress syndrome, GI bleeding, thrombocytopenia, and paralytic ileus. Recovery is very rare and, when it occurs, gradual.

Assessment findings

The patient usually seeks treatment after an animal bite or after open wound contact with an infected animal's saliva. The patient initially complains of local or

radiating pain or burning and a sensation of cold, pruritus, and tingling at the bite site. He also may report prodromal symptoms, such as malaise, headache, anorexia, nausea, sore throat, and a persistent loose cough.

In this patient, you may observe nervousness, anxiety, irritability, hyperesthesia, photophobia, sensitivity to loud noises, and excessive salivation, lacrimation, and perspiration. He also may have a slight fever, with his body temperature ranging from 100° to 102° F (37.8° to 38.9° C).

About 2 to 10 days after prodromal signs and symptoms begin, an excitation phase occurs, marked by intermittent hyperactivity, anxiety, apprehension, pupillary dilation, shallow respirations, and altered level of consciousness. With cranial nerve dysfunction, you may see ocular palsies, strabismus, asymmetrical pupillary dilation or constriction, absence of corneal reflexes, facial muscle weakness, and hoarseness. During this phase, the patient's temperature increases to about 103° F (39.4° C).

Schedules for rabies prophylaxis
<p>The most important treatment consideration for the person exposed to rabies is immunization to prevent full-blown disease. If the patient never had a rabies immunization, he will need passive immunization with rabies immune globulin (RIG) and active immunization with human diploid cell vaccine (HDCV), rabies vaccine absorbed (RVA), or purified chick embryo cell vaccine (PCEC). Treatment with both should begin on the day of exposure.</p> <p>If the patient received HDCV, RVA or PCEC, and if he has an adequate rabies antibody titer, he won't need RIG vaccine. Nevertheless, he will need a booster dose of HDCV, RVA or PCEC.</p> <p>Review these schedules for people receiving rabies vaccine.</p> <p>For passive immunization</p> <p>The typical inoculation dose for the patient receiving RIG is 20 IU/kg. If anatomically feasible, the full dose should be infiltrated around the wound and the remaining volume should be administered I.M. at an anatomical site distant from vaccine administration.</p> <p>For active immunization</p> <p>The patient receiving HDCV, RVA, or PCEC will have five I.M. injections (1 ml each), usually in the deltoid muscle. Follow the first injection with doses at 3, 7, 14, and 28 days later.</p> <p>Nursing considerations</p> <ul style="list-style-type: none">u Be sure to prepare RIG and HDCV in separate syringes.u Never combine vaccines.u Avoid injecting RIG and HDCV in the same site. Doing so will inactivate the vaccine. With active immunization, check the antibody titer after the last inoculation and at 2 to 4 weeks. Expect rapid fluorescent focus inhibition test findings to show an antibody titer of at least 1:5. This indicates growing immunity.

About 50% of patients exhibit hydrophobia during which forceful, painful pharyngeal muscle spasms expel fluids from the mouth, causing dehydration and, possibly, apnea, cyanosis, and death. Swallowing difficulty causes frothy drooling. Soon, the sight, sound, or thought of water triggers uncontrollable pharyngeal muscle spasms and excessive salivation. During this phase, you may observe nuchal rigidity and seizures (possibly accompanied by cardiac arrhythmias or arrest).

First aid for animal bites
<p>Follow these steps when caring for a person bitten by an animal:</p> <ul style="list-style-type: none">u Wash the bite vigorously with soap and water for at least 10 minutes to remove the animal's saliva. As soon as possible, flush the wound with a viricidal agent and then rinse with clear water.u Apply a sterile dressing when you're sure the wound is clean. If possible, don't suture the patient's wound, and don't immediately stop the bleeding (unless it's massive) because blood flow helps to clean the wound.u Question the patient about the animal bite. Ask if he provoked the animal (if so, chances are it isn't rabid). Also ask him to identify the animal or its owner (because the animal may need to be confined for observation).

Between excitatory and hydrophobic episodes, the patient usually remains cooperative and lucid. After about 3 days, excitation and hydrophobia subside, and progressive paralysis, leading to coma, begins.

Palpating the peripheral pulses may detect tachycardia or bradycardia when the patient has signs of severe systemic disease. Hypotension usually accompanies coma.

Diagnostic tests

No tests can confirm the rabies diagnosis in humans before onset. In the United States, the rapid fluorescent focus inhibition test (RFFIT) is the standard measure for rabies neutrality antibody. The results of this in vitro cell culture neutralization test are available within 24 hours. The Centers for Disease Control and Prevention considers complete neutralization at the 1:5 level by RFFIT an adequate antibody titer.

The rabies virus also may be isolated from certain infected tissue or secretions in animals or humans. Histologic examination of brain tissue from human rabies victims typically shows perivascular inflammation of the gray matter, neuronal degeneration, and characteristic cytoplasmic inclusion bodies (Negri bodies).

Treatment

Immunization as soon as possible after exposure and meticulous wound care are the treatments for rabies.

Before performing wound care, remember to put on gloves to avoid contact with infected blood. Thoroughly wash all wounds and abrasions with soap and water. Check the patient's immunization status, and administer tetanus-diphtheria prophylaxis, if needed. Take measures to control bacterial infection as ordered. If the wound requires suturing, special techniques may be used to ensure proper wound drainage. (See [First aid for animal bites.](#))

Although no specific drugs are available to treat rabies, postexposure prophylaxis usually is successful in preventing disease when used appropriately during the rabies incubation period. Treatment is mainly supportive, with special attention given to the cardiovascular and respiratory systems.

Nursing diagnoses

u Altered nutrition: Less than body requirements u Anxiety u Decreased cardiac output u Hyperthermia u Impaired swallowing u Impaired tissue integrity u Ineffective breathing pattern u Risk for fluid volume deficit u Risk for infection

Key outcomes

- u The patient will remain afebrile.
- u The patient will express a feeling of comfort while maintaining air exchange.
- u The patient's respiratory rate will be maintained within 5 breaths of baseline.
- u The patient will show no signs of aspiration pneumonia.
- u The patient will achieve adequate nutritive intake.
- u The patient's vital signs will remain stable.

Nursing interventions

- u When injecting rabies vaccine, rotate injection sites on the upper arm or thigh. Don't use the buttocks. Watch for and symptomatically treat redness, itching, pain, and tenderness at the injection site.
- u If rabies develops, begin aggressive supportive care. Monitor cardiac, neurologic, and pulmonary function. Administer I.V. fluids as ordered.
- u Isolate the patient, as needed. Wear a gown, gloves, mask, and protective eyeglasses when handling saliva and articles contaminated with saliva. Take precautions to avoid being bitten by the patient during the excitation phase.
- u Keep the patient's room dark and quiet.
- u Establish communication with the patient and his family. Provide psychological support to help them cope with the patient's symptoms and probable death.

Patient teaching

- u Reassure the patient receiving prophylactic rabies vaccine that this will prevent rabies. Tell him how many times and on what dates he'll need to be vaccinated. Discuss possible adverse effects, such as redness and tenderness at the injection site.
- u If the patient has rabies, explain the need for isolation precautions to him and his family. Also explain the probable course of the disease and any treatments.
- u To help prevent this disease, urge any patient to have household pets immunized. Warn people not to try to touch wild animals, especially if they appear ill or docile (a possible sign of rabies).
- u Assist in the prophylactic administration of rabies vaccine to high-risk people, such as farm workers, forest rangers, spelunkers (cave explorers), veterinarians, and other animal handlers.

RESPIRATORY SYNCYTIAL VIRUS INFECTION

Respiratory syncytial virus infection occurs almost exclusively in infants and young children. It's the leading cause of lower respiratory tract infections, pneumonia, tracheobronchitis, and bronchiolitis in this age group. It's also a suspected cause of the fatal respiratory diseases of infancy.

Rates of illness are highest among infants age 1 to 6 months; incidence peaks between 2 and 3 months. Those in day-care settings are especially susceptible. This virus creates annual epidemics during winter and spring.

Causes

Respiratory syncytial virus infection results from a subgroup of the myxoviruses that resemble paramyxovirus. The organism is transmitted from person to person by respiratory secretions and has an incubation period of 4 to 5 days.

Reinfection is common, producing milder symptoms than the primary infection. School-age children, adolescents, and young adults with mild reinfections are probably the sources of infection for infants and young children.

Complications

Young children, especially infants, are at increased risk for severe infection. Common complications include pneumonia, bronchiolitis, tracheobronchitis, and otitis media. Acute complications include apnea and respiratory failure.

Assessment findings

Signs and symptoms vary in severity. The patient may complain of nasal congestion, coughing, wheezing, malaise, sore throat, earache, dyspnea, and fever. Although uncommon, signs of central nervous system infection, such as weakness, irritability, and nuchal rigidity, also may be observed.

Inspection usually reveals inflamed mucous membranes in the nose and throat. Other findings are variable. For example, with otitis media, you may see a hyperemic eardrum on otoscopic examination; with severe respiratory distress, you may note nasal flaring, retraction, cyanosis, and tachypnea. With a lower respiratory tract infection, you may hear or auscultate wheezes, rhonchi, and crackles.

Diagnostic tests

Cultures of nasal and pharyngeal secretions may show respiratory syncytial virus; however, the virus is very labile, so cultures aren't always reliable.

Serum antibody titers may be elevated, but in infants under age 4 months, maternal antibodies may impair test results.

Two serologic techniques that give rapid results are indirect immunofluorescence and the enzyme-linked immunosorbent assay (ELISA). However, these tests are an impractical diagnostic tool because serum specimens aren't obtained until 4 weeks after the onset of illness. They're mainly used for epidemiologic studies.

Treatment

Appropriate treatment aims to support respiratory function, maintain fluid balance, and relieve symptoms. Ribavirin, a broad-spectrum antiviral agent, is being used successfully to treat infants with severe lower respiratory tract infection caused by the respiratory syncytial virus. The aerosol form of the drug is given by way of tent, oxygen hood, mask, or ventilator for 2 to 5 days, 12 to 18 hours a day. With this drug therapy, patients show less severe symptoms and improvements in arterial oxygen saturation.

Nursing diagnoses

- u Activity intolerance
- u Altered nutrition: Less than body requirements
- u Fatigue
- u Impaired gas exchange
- u Impaired social interaction
- u Ineffective airway clearance
- u Ineffective family coping
- u Risk for aspiration
- u Risk for fluid volume deficit
- u Risk for infection

Key outcomes

- u The patient's respiratory rate will be maintained within 5 breaths of baseline.
- u The patient will express a feeling of comfort while maintaining air exchange.
- u The patient will cough effectively.
- u The patient will expectorate mucus.
- u The patient's fluid volume will remain adequate.

- u The patient will demonstrate effective social interactions in both one-on-one and group settings.

Nursing interventions

- u Monitor the patient's respiratory status. Observe the rate and pattern; watch for nasal flaring or retraction, cyanosis, pallor, and dyspnea; and listen or auscultate for wheezes, rhonchi, or other signs of potential respiratory distress. Monitor arterial blood gases and arterial oxygen saturation.
- u Maintain a patent airway, and be especially watchful during periods of acute dyspnea. Perform percussion, and provide drainage and suction, when necessary. Administer oxygen as ordered. If appropriate, use a croup tent to provide a high-humidity atmosphere. Semi-Fowler's position may help prevent aspiration of secretions.
- u Carefully monitor intake and output. Observe for signs of dehydration, such as decreased skin turgor. Encourage the intake of high-calorie fluids, and administer I.V. fluids as needed.
- u Promote bed rest. Plan your nursing care to allow uninterrupted rest.
- u Hold, talk to, and play with infants and young children. Offer diversional activities suited to the child's condition and age. Encourage parents to visit often and to cuddle their child.
- u To prevent nosocomial infection on pediatric units, don't care for infants with respiratory syncytial virus infection if you have a respiratory illness yourself. Place infants with this infection on contact isolation (those infected with the same organism can share a room). Enforce strict hand washing for staff members and visitors, and impose oral secretions precautions.

Patient teaching

- u Describe respiratory syncytial virus infection transmission methods to parents, and caution against taking infants into crowds.
- u Explain all procedures and treatments to parents and, when appropriate, to children.
- u If the patient is being cared for at home, explain the need for adequate rest, fluids, and nourishment.
- u Teach the parents about drugs the child is taking and about adverse effects that should be reported.
- u Teach the parents what signs and symptoms of serious complications to watch for and report.

ROSEOLA INFANTUM

Roseola infantum (Exanthema subitum) is an acute, benign infection that affects infants and young children, typically between ages 6 months to 3 years.

Roseola affects both sexes equally and occurs year-round, mostly in spring and fall. Overt roseola is the most common exanthem in children under age 2; inapparent roseola (febrile illness without a rash) may affect the rest.

Causes

Human herpesvirus 6 is thought to cause roseola. The mode of transmission may be saliva and, possibly, genital secretions. The incubation period lasts from 10 to 15 days.

Complications

Encephalopathy and thrombocytopenic purpura are rare complications.

Assessment findings

The patient's history is unremarkable. The parents of a child with roseola usually report an abruptly increasing, unexplainable fever that peaks between 103° and 105° F (39.4° and 40.6° C) for 3 to 5 days and then drops suddenly. Parents also report these symptoms: anorexia, irritability, and listlessness, although the child doesn't seem particularly ill. (Seizures may accompany a high fever.)

Accompanying the abrupt drop in temperature is a maculopapular, nonpruritic rash that blanches with pressure. This rash, which is profuse on the child's trunk, arms, and neck and mild on the face and legs, fades within 24 hours.

Diagnostic tests

Roseola infantum is usually diagnosed clinically; the causative organism is present in saliva.

Treatment

Because roseola is self-limiting, treatment is supportive and symptomatic: antipyretic medications to lower fever and, if necessary, anticonvulsants to relieve seizures.

Nursing diagnoses

- u Altered nutrition: Less than body requirements
- u Fluid volume deficit
- u Hyperthermia
- u Impaired skin integrity

Key outcomes

- u The patient will remain afebrile.
- u The patient will exhibit improved or healed lesions or wounds.
- u The patient's fluid volume will remain adequate.
- u The patient will achieve adequate nutritive intake.
- u Intake will be equivalent to output.

Nursing interventions

- u Give tepid sponge baths and administer antipyretics, as ordered, to reduce fever.
- u Monitor fluid intake and output. Replace fluids and electrolytes as needed.
- u Institute seizure precautions and monitor for seizures.

Patient teaching

- u Teach parents how to lower the child's fever by giving tepid sponge baths, dressing the child in lightweight clothing, keeping the environment at a comfortable temperature, and administering antipyretics as ordered.
- u Stress the need for adequate fluid intake to promote hydration. Advise parents that strict bed rest isn't necessary.
- u Tell parents to keep the child's skin clean and dry.
- u Reassure parents that brief febrile seizures won't cause brain damage and will stop as the fever subsides. If the doctor prescribes phenobarbital to control seizures, explain that this medication may cause drowsiness. However, if it causes stupor, instruct the parents to call the doctor immediately.

ROTAVIRUS

Rotavirus is the most common cause of severe diarrhea among children. The disease is characterized by vomiting and watery diarrhea for 3 to 8 days, commonly with

fever and abdominal pain.

In the United States and other countries with a temperate climate, the disease has a winter seasonal pattern, with annual epidemics occurring from November to April. The highest rates of illness occur among infants and young children; most children in the United States are infected by age 2. Rotavirus is responsible for the hospitalization of approximately 55,000 children each year in the United States and the death of more than 600,000 children annually worldwide, as reported by the Centers for Disease Control and Prevention (CDC).

Causes

The primary mode of transmission is fecal-oral, although some have reported low titers of virus in respiratory tract secretions and other body fluids. Due to the endurance of the virus in the environment, transmission can occur through ingestion of contaminated water or food and contact with contaminated surfaces.

Billions of rotavirus particles are passed in the stool of the infected individual. Small numbers of the rotavirus can lead to infection if a baby puts fingers or other objects contaminated with the virus into the mouth. Young children can pass it on to siblings and parents.

Immunity after infection is incomplete, but recurrent infections tend to be less severe than the original infection.

Complications

Complications include severe dehydration, shock, and skin breakdown due to severe vomiting and diarrhea. This can be detrimental in the immunocompromised patient and can also complicate other conditions, such as cystic fibrosis. About 1 child in 40 with rotavirus gastroenteritis requires hospitalization for I.V. fluids.

Assessment findings

The incubation period for rotavirus disease is approximately 2 days. Rotavirus gastroenteritis commonly starts with a fever, nausea, and vomiting, followed by diarrhea. The illness can range from mild to severe and last from 3 to 9 days. Diarrhea and vomiting may result in dehydration.

ASSESSMENT TIP Look for the following signs to assess for dehydration in an infected patient:

- u 5% to 6% dehydration: heart rate 10% to 15% above baseline, slightly dry mucous membranes, concentration of the urine, poor tear production
- u 7% to 8% dehydration: increased severity of above, decreased skin turgor, oliguria, sunken eyeballs, sunken anterior fontanelle
- u greater than 9% dehydration: pronounced severity of above signs, decreased blood pressure, delayed capillary refill (greater than 2 seconds), acidosis (large base deficit).

Diagnostic tests

The diagnosis is determined by rapid antigen detection of rotavirus in stool specimens.

Rotavirus is the most common diagnosis for young children with acute diarrhea, but other causes may include bacteria (*Salmonella*, *Shigella*, *Campylobacter* are most common), parasites (*Giardia* and *Cryptosporidium* are most common), localized infection elsewhere, antibiotic-associated adverse effects (such as those related to treatment for *Clostridium difficile*), and food poisoning. Noninfectious causes include overfeeding (particularly of fruit juices), irritable bowel syndrome, celiac disease, milk protein intolerance, lactose intolerance, cystic fibrosis, and inflammatory bowel syndrome.

Treatment

For a person with a healthy immune system, rotavirus gastroenteritis is a self-limited illness, lasting only days. Treatment is nonspecific and consists of oral rehydration therapy to prevent dehydration.

Nursing diagnoses

- u Activity intolerance
- u Altered nutrition: Less than body requirements
- u Fatigue
- u Hyperthermia
- u Impaired skin integrity
- u Pain
- u Risk for fluid volume deficit

Key outcomes

- u Patient will remain afebrile.
- u Vital signs will remain stable.
- u Electrolyte levels will stay within normal range.
- u Fluid volume will remain adequate.
- u Patient will exhibit improved or healed lesions or wounds.
- u Patient will verbally express increased energy.

Nursing interventions

- u Enforce strict hand washing and careful cleaning of all equipment, including the child's toys. This measure is most important in preventing the spread of the rotavirus.
- u Help the patient maintain adequate hydration. Remember that dehydration occurs rapidly in infants and young children. Ice pops, gelatin dessert, and ice chips may be included in the diet to maintain hydration.
- u Breast-fed infants should continue to nurse without restrictions. Lactose-free soybean formulas may be used for infants who are bottle-fed.
- u Carefully monitor intake and output (including stools).
- u Clean the perineum thoroughly to prevent skin breakdown.

Patient teaching

- u Instruct parents about proper hand-washing techniques for themselves and the infant; provide instructions about diaper changing and cleaning all affected surfaces.
- u Teach parents and caregivers how to measure intake and output. Tell them to notify their doctor about any increased diarrhea or dehydration.

RUBELLA

Commonly called German measles, rubella is an acute, mildly contagious viral disease that produces a distinctive rash and lymphadenopathy.

Rubella is worldwide in distribution. It flourishes during spring. Since the introduction of live attenuated vaccine in 1969, there have been no epidemics, and limited outbreaks have been reported in schools and workplaces. It occurs most commonly among children ages 5 to 9, adolescents, and young adults.

The incubation period is 18 days with a duration of 12 to 23 days. The disease is self-limiting and the prognosis is excellent, except for congenital rubella, which can have disastrous consequences.

Causes

The rubella virus, a togavirus, is transmitted through contact with the blood, urine, stools, or nasopharyngeal secretions of infected people. It's communicable from

about 10 days before until 5 days after the rash appears. Rubella can also be transmitted transplacentally. Humans are the only known hosts for the virus.

Complications

Rubella can cause arthritis, which usually is transient and mainly affects women; hemorrhagic problems, seen more often in children; and, less commonly, encephalitis, myocarditis, thrombocytopenia, and hepatitis. Complications associated with congenital rubella are serious and may be fatal.

Assessment findings

The patient's history may reveal inadequate immunization, exposure to someone with rubella infection within the past 2 to 3 weeks, or recent travel to an endemic area without reimmunization.

Children usually don't have prodromal symptoms, but adolescents and adults may report headache, malaise, anorexia, coryza, sore throat, and cough before the rash appears. Some adults also report symptoms of polyarthralgias and polyarthritis.

In all patients, the rash may be accompanied by a low-grade fever (99° to 101° F [37.2° to 38.3° C]), which usually disappears after the first day of the rash. In rare instances, a patient's temperature may reach 104° F (40° C).

Examination reveals an exanthematous, maculopapular, mildly pruritic rash that typically begins on the face and then spreads rapidly, often covering the trunk and extremities within hours. Small, red, petechial macules on the soft palate (Forschheimer spots) may precede or accompany the rash.

By the end of the second day, the rash begins to fade in the opposite order in which it appeared. The facial rash subsides, but the trunk rash may be confluent and hard to distinguish from a scarlet fever rash. It usually disappears on the third day but may persist for 4 to 5 days, sometimes accompanied by mild coryza and conjunctivitis. The rapid appearance and disappearance of the rubella rash distinguishes it from rubeola.

Palpation detects suboccipital, postauricular, and postcervical lymph node enlargement, a hallmark of rubella.

Diseases that mimic rubella include toxoplasmosis, scarlet fever, modified measles, roseola, fifth disease (erythema infection due to the parvovirus B19), and enteroviral infection.

Diagnostic tests

Clinical signs and symptoms usually are sufficient to make a diagnosis, so laboratory tests seldom are done. Cell cultures of the throat, blood, urine, and cerebrospinal fluid, along with convalescent serum that shows a fourfold increase in antibody titers, confirm the diagnosis. Rubella-specific immunoglobulin M (IgM) antibody also can be determined by laboratory testing.

Congenital rubella can be diagnosed by determining the presence of rubella-specific IgM antibody in cord blood.

Treatment

Because the rubella rash is self-limiting and only mildly pruritic, it doesn't require topical or systemic medication. Treatment consists of antipyretics and analgesics for fever and joint pain. Bed rest isn't necessary, but the patient should be isolated until the rash disappears.

Immunization with the live rubella virus vaccine (RA 27/3), the only rubella vaccine available in the United States, is necessary for prevention. The vaccine should be given with measles and mumps vaccines at age 15 months and a second dose during childhood.

Nursing diagnoses

u Activity intolerance u Hyperthermia u Impaired skin integrity u Ineffective family coping (with congenital rubella): Compromised u Pain u Risk for infection

Key outcomes

- u The patient will remain afebrile.
- u The patient will remain free from all signs and symptoms of infection.
- u The patient will perform self-care activities to tolerance level.
- u The patient will exhibit improved or healed lesions or wounds.
- u Family members will identify their needs.
- u The patient will express a feeling of comfort and relief from pain.

Nursing interventions

- u Make the patient with active rubella as comfortable as possible. Keep the skin clean and dry.
- u Administer antipyretics and analgesics as ordered.
- u If the patient is a child, give him books to read or games to play to keep him occupied.
- u Institute isolation precautions until 5 days after the rash disappears. An infant with congenital rubella needs to be isolated for 3 months, until three throat cultures are negative.
- u Ensure that only hospital workers who aren't at risk for rubella provide patient care. If ordered, administer immune globulin to anyone seeing the patient who hasn't been immunized.
- u Report confirmed cases of rubella to local public health officials. (See [Preventing rubella.](#))
- u Provide the parents of an infant with congenital rubella with support, counseling, and referrals, as needed.

Patient teaching

- u Explain to the hospitalized patient or his family why respiratory isolation is necessary.
- u Warn family members and visitors that rubella can be devastating to an unborn baby. Be sure the patient understands how important it is to avoid exposing pregnant women to this disease.

PREVENTION

Preventing rubella

Know how to manage rubella immunization before giving the vaccine. First, ask about allergies, especially to neomycin. If the patient has this allergy or if he's had a reaction to any immunization in the past, check with the doctor before giving the vaccine.

If the patient is a woman of childbearing age, ask her if she's pregnant. If she is or thinks she may be, don't give the vaccine.

Give the vaccine at least 3 months after any administration of immune globulin or blood. These substances may have antibodies that could neutralize the vaccine.

Don't vaccinate an immunocompromised patient, a patient with immunodeficiency diseases, or a patient receiving immunosuppressant, radiation, or corticosteroid therapy. Instead, administer immune serum globulin, as ordered, to prevent or reduce infection.

- u Warn women who receive the rubella vaccine to use an effective means of birth control for at least 3 months after immunization.
- u After giving the vaccine, warn about possible mild fever, slight rash, transient arthralgia (in adolescents), and arthritis (in elderly people). If the patient is an adult, suggest treating fever with aspirin or acetaminophen. Tell the parents of a child receiving the vaccine not to give him aspirin because of the danger of Reye's syndrome.
- u Advise the patient to apply warmth to the injection site on and off for 24 hours after immunization to help the body absorb the vaccine. If swelling persists after 24 hours, suggest a cold compress to promote vasoconstriction and prevent antigenic cyst formation.
- u Explain congenital rubella to the parents of an infant with that disease.

RUBEOLA

Also called morbilli and commonly called measles, rubeola is an acute, highly contagious infection that causes a characteristic rash. Measles is one of the most common and most serious communicable childhood diseases.

Although the measles vaccine has reduced the number of cases in children, most cases involve preschool children. (See [Administering measles vaccine.](#))

In temperate zones, incidence is highest in late winter and early spring. Before the measles vaccine, epidemics occurred every 2 to 5 years in large urban areas.

In the United States, the prognosis usually is excellent, but mortality is highest among children under age 2 and adults. Patients with impaired cell-mediated immunity are at high risk for severe or even fatal measles. Mortality is as high as 10% in developing countries.

Causes

Measles is caused by the rubeola virus, a paramyxovirus. It's spread by direct contact or by contaminated airborne respiratory droplets. The portal of entry is the upper respiratory tract.

Complications

Severe infection may lead to secondary bacterial infection and to autoimmune reaction or organ invasion by the virus. This can result in otitis media, cervical adenitis, laryngitis, laryngotracheitis, pneumonia, and encephalitis.

Subacute sclerosing panencephalitis, a rare and invariably fatal complication, may develop several years after measles. This complication is less common in patients who have received the measles vaccine.

Immunosuppressive measles encephalitis is an opportunistic infection that afflicts immunocompromised patients and occurs from 5 weeks to 6 months after measles. It causes progressive neurologic deterioration and can be fatal.

Assessment findings

The patient's history may reveal inadequate immunization and exposure to someone with measles within the past 10 to 14 days. Greatest communicability occurs 1 to 2 days before the onset of symptoms until 4 days after the rash appears.

The patient may complain of photophobia, malaise, anorexia, coryza, hoarseness, and a hacking cough. His temperature also may be elevated during this phase, peaking to 103° to 105° F (39.4° to 40.6° C).

Throughout the disease, symptoms vary in severity. They're usually mild in patients with partial immunity, in infants with transplacental antibodies, and in children. More severe symptoms and complications may develop in young infants, adolescents, adults, and immunocompromised patients.

PREVENTION

Administering measles vaccine

Follow these steps whenever you administer measles vaccine:

- u Warn the patient or his parents that possible adverse effects of measles vaccine include anorexia, malaise, rash, mild thrombocytopenia or leukopenia, and fever. These reactions usually occur within 7 to 10 days.
- u Ask about known allergies, especially to neomycin, because each dose contains a small amount of this drug. A patient who is allergic to eggs may receive the vaccine because it contains only minimal amounts of albumin and yolk components.
- u Ask a woman patient of childbearing age if she's pregnant. If she is or thinks she might be, don't give the vaccine.
- u Caution a woman patient to use reliable birth control methods for at least 3 months after vaccination.
- u Don't vaccinate a child who has untreated tuberculosis, immunodeficiency, leukemia, or lymphoma or who is receiving immunosuppressants. Instead, recommend that he receive gamma globulin if he's exposed to measles. (Gamma globulin won't prevent measles but will lessen its severity.)

An older, nonimmunized child who has been exposed to measles for more than 5 days also may require gamma globulin, but be sure to immunize him 3 months later.

- u Delay vaccination for 8 to 12 weeks after administration of whole blood, plasma, or gamma globulin; measles antidotes in these components may neutralize the vaccine.
- u Watch for signs of anaphylaxis for 30 minutes after vaccination. Keep epinephrine 1:1,000 handy.
- u Advise the patient to apply a warm compress to the vaccination site to facilitate absorption of the vaccine. If swelling occurs within 24 hours after vaccination, tell the patient to apply cold compresses to promote vasoconstriction and prevent antigenic cyst formation.

Other considerations

One bout of measles usually renders immunity (a second infection is rare and may represent misdiagnosis). Infants under age 4 months may be immune because of circulating maternal antibodies.

Under normal conditions, measles vaccine isn't administered to children younger than age 15 months. However, during an epidemic, infants as young as 6 months may receive the vaccine; then they will need reimmunization at age 15 months. An alternate approach calls for administration of gamma globulin to infants between ages 6 and 15 months who are likely to be exposed to measles. The risk of measles substantially increases after age 12 for people who received the vaccine at age 15 months. Because of this, the American Academy of Pediatrics recommends a second dose of measles vaccine before junior high school.

During the prodromal phase, your examination may reveal periorbital edema and red, irritated conjunctiva. At the end of the prodromal phase, you may see Koplik's spots, the hallmark of the disease. These are tiny, bluish-gray specks surrounded by a red halo that appear on the oral mucosa opposite the molars and occasionally bleed.

About 5 days after Koplik's spots appear, you may note that the patient's temperature increases sharply, spots slough off, and a slightly pruritic rash appears. This rash starts as faint macules behind the ears and on the neck and cheeks. The macules become papular and erythematous, rapidly spreading over the face, neck, eyelids, arms, chest, back, abdomen, and thighs. When the rash reaches the feet (2 to 3 days later), it begins to fade in the same sequence it appeared, leaving a brown discoloration that disappears in 7 to 10 days.

The disease climax occurs 2 to 3 days after the rash appears. At this time, your assessment may reveal a severe cough, puffy red eyes, and rhinorrhea. About 5 days after the rash appears, other symptoms disappear and communicability ends.

At any point in the disease, palpation may reveal lymphadenopathy.

If the patient received the killed measles vaccine instead of the live, attenuated vaccine currently used, he may develop signs and symptoms of atypical measles. On examination, the patient appears acutely ill, with a fever and a maculopapular rash that is most obvious in the arms and legs. He may have pulmonary involvement and no skin lesions.

Diagnostic tests

Several tests may be ordered to differentiate measles from rubella, roseola infantum, enterovirus infection, toxoplasmosis, and drug eruptions. If necessary, measles virus may be isolated from the blood, nasopharyngeal secretions, and urine during the febrile period. Serum antibodies appear within 3 days after onset of the rash and reach peak titers 2 to 4 weeks later.

Treatment

The patient should receive antipyretics to control fever. Vaporizers and a warm environment help reduce respiratory irritation, but cough preparations and antibiotics are usually ineffective. Therapy also must combat complications.

Nursing diagnoses

u Altered nutrition: Less than body requirements u Altered oral mucous membrane u Fatigue u Hyperthermia u Impaired skin integrity u Risk for infection u Sensory or perceptual alterations (visual)

Key outcomes

- u The patient will remain afebrile.
- u The patient will remain free from all signs and symptoms of infection.
- u The patient will exhibit improved or healed lesions or wounds.
- u The patient will perform self-care activities to tolerance level.
- u The patient and family members will communicate understanding of special dietary needs.
- u The patient will not exhibit complications related to trauma to oral mucous membranes.

Nursing interventions

- u Institute respiratory isolation measures for 4 days after the onset of the rash. Also follow standard blood and body fluid precautions.
- u Encourage bed rest during the acute period.
- u Administer saline eyedrops for irritation and antipyretics for fever.
- u If you're using a vaporizer, clean it and change the water every 8 hours.
- u If ordered, administer immune globulin to provide passive immunization to people at high risk who come in contact with the patient.
- u To prevent the spread of disease, administer measles vaccine.
- u Report measles cases to local health authorities.

Patient teaching

u Teach the patient or his parents supportive measures. Stress the need for isolation, bed rest, and increased fluids. The skin should be kept clean and dry. Eye irritation can be soothed by removing crusts and secretions with warm water. If photophobia occurs, advise darkening the room or using sunglasses. Fever can be reduced with antipyretics and tepid sponge baths.

- u If a vaporizer is used, remind the patient or his parents to clean it and change the water every 8 hours.
- u Warn parents to watch for and report the early signs and symptoms of complications.

VARICELLA

Chickenpox, the common name for varicella, is an acute, highly contagious infection that can occur at any age but is most common in children ages 5 to 9. Congenital varicella may affect infants whose mothers had acute infections in their first or early second trimester. Neonatal infection is rare, probably because of transient maternal immunity.

Chickenpox occurs worldwide and is endemic in large cities. Outbreaks occur sporadically and with varying severity, usually in areas with large groups of susceptible children. It affects all races and both sexes equally. Seasonal distribution varies; in temperate areas, incidence is higher during late winter and spring.

Most children recover completely. However, potentially fatal complications may affect children receiving corticosteroids, antimetabolites, or other immunosuppressants, and those with leukemia, other malignant diseases, or immunodeficiency disorders. Congenital and adult varicella also may have severe effects.

The varicella zoster virus is thought to become latent until the sixth decade of life, or later, when herpes zoster may present as a dermatomal vesicular rash (shingles) that usually causes severe pain.

Causes

Chickenpox is caused by the varicella-zoster herpesvirus—the same virus that, in its latent stage, causes herpes zoster (shingles). Transmission occurs through direct contact (primarily with respiratory secretions, less often with skin lesions) and indirect contact (through airwaves).

The incubation period lasts from 13 to 17 days. The disease is communicable from 48 hours before lesions erupt until after the vesicles are crusted over.

Complications

Severe pruritus with this rash may provoke scratching, which can lead to infection, scarring, impetigo, furuncles, and cellulitis. Rare complications include Reye's syndrome, pneumonia, myocarditis, bleeding disorders, arthritis, nephritis, hepatitis, and acute myositis. (See [Chickenpox and Reye's syndrome.](#))

Congenital varicella causes hypoplastic deformity and limb scarring, retarded growth, and central nervous system and eye problems.

Assessment findings

The patient's history reveals exposure within the past 2 to 3 weeks to someone with chickenpox.

During the prodromal phase, the patient complains of malaise, headache, and anorexia. When lesions develop, he also may report pruritus.

Your examination may reveal a temperature of 101° to 103° F (38.3° to 39.4° C), which usually persists for 3 to 5 days but, in the immunocompromised patient, may last for more than 7 days.

Within 24 hours of the prodromal phase onset, you may observe the rash, beginning as crops of small, erythematous macules on the trunk or scalp. The macules progress to papules and then clear vesicles on an erythematous base (so-called dewdrops on rose petals). The vesicles become cloudy and break easily; then scabs form. The rash spreads to the face and, rarely, to the extremities.

New vesicles continue to appear for 3 to 4 days, so the rash contains a combination of red papules, vesicles, and scabs in various stages. Shallow ulcers may develop on mucous membranes of the mouth, conjunctivae, and genitalia.

Inspection of an immunocompromised patient reveals more numerous lesions. These often are hemorrhagic and take longer to heal. (See [Differentiating chickenpox.](#))

Diagnostic tests

Although diagnosis usually doesn't require laboratory tests, the virus can be isolated from vesicular fluid within the first 3 to 4 days of the rash. Giemsa stain distinguishes the varicella-zoster virus from the vaccinia-variola virus. Serum samples contain antibodies 7 days after onset of symptoms. Serologic testing is useful in differentiating rickettsial pox from varicella.

Treatment

Chickenpox calls for strict isolation until all the vesicles have crusted over. Children can go back to school if just a few scabs remain; at this stage, chickenpox is no longer contagious. Congenital chickenpox requires no isolation.

WARNING

Chickenpox and Reye's syndrome

If Reye's syndrome develops in a patient with chickenpox, signs and symptoms usually appear in the later stages of the disease. In the hospitalized patient, watch for such signs and symptoms as vomiting, restlessness, irritability, and a progressively decreased level of consciousness—all associated with progressive cerebral edema. The patient eventually develops encephalopathy, characterized by elevated serum ammonia and transaminase levels, bleeding diathesis, and hyperglycemia.

If the patient is to be cared for at home, teach the signs and symptoms of Reye's syndrome to his parents. Also, because aspirin use has been linked to the development of Reye's syndrome, warn parents not to give aspirin to their child.

Treatment consists of local or systemic antipruritics, such as calamine lotion, diphenhydramine or another antihistamine, or cool sponge baths with baking soda.

The patient doesn't need antibiotics unless bacterial infection develops. Salicylates are contraindicated because of their link with Reye's syndrome. Instead, the patient can receive acetaminophen as an analgesic and antipyretic. Antiviral drugs and corticosteroids aren't used to treat immunocompetent patients.

Immunosuppressed patients may need special treatment. I.V. acyclovir is recommended for these individuals for both chickenpox and herpes zoster. It reduces visceral complications but has no effect on the healing of lesions. When given up to 72 hours after exposure to chickenpox, varicella-zoster immune globulin may provide passive immunity.

Nursing diagnoses

- u Body image disturbance
- u Hyperthermia
- u Impaired skin integrity
- u Risk for fluid volume imbalance
- u Risk for infection
- u Social isolation

Key outcomes

- u The patient's temperature will remain within normal limits.
- u The patient will verbally report having an increased energy level.
- u The patient will exhibit improved or healed lesions or wounds.

ADVANCED PRACTICE

Differentiating chickenpox

Other viral infections can mimic chickenpox. Examples are disseminated herpes simplex virus infection in patients with atopic dermatitis and disseminated vesiculopapular lesions sometimes associated with coxsackievirus infection, echovirus infection, or atypical measles. Chickenpox is more vesiculopustular in appearance than these disorders. Rickettsiae pox can also be confused with chickenpox, but it causes a “herald spot” at the site of the mite bite, and the individual develops a more pronounced headache.

- u The patient and family members will demonstrate the skin care regimen.
- u The patient will express his feelings about his changed body image.
- u The patient will interact with family and peers, decreasing feelings of isolation.

Nursing interventions

- u Observe an immunocompromised patient for manifestations of complications, such as pneumonitis and meningitis, and report them immediately.
- u Provide skin care comfort measures. Use calamine lotion or cornstarch to relieve itching. Sponge baths or showers may increase comfort (tub baths may encourage the spread of the vesicles).
- u If ordered, administer acetaminophen. Also administer varicella-zoster immune globulin, if ordered, to lessen the severity of the disease. Institute strict isolation measures until all skin lesions have crusted.
- u To help prevent the spread of chickenpox, don't admit a child exposed to chickenpox to a unit that contains children who receive immunosuppressants or who have leukemia or immunodeficiency disorders.

Patient teaching

- u Explain that the patient will probably receive treatment at home if he's immunocompetent.
- u Teach the child and his family how to correctly apply topical antipruritic medications. Stress the importance of good hygiene.
- u Tell the patient not to scratch the lesions. Because the need to scratch may be overwhelming, tell parents to trim their child's fingernails, tie mittens on his hands or, possibly, use sedatives.
- u Warn the parents to watch for and immediately report signs of complications. Severe skin pain, burning, or purulent discharge may indicate a serious secondary infection and require prompt medical attention.
- u Caution the parents not to give the child aspirin because of its association with Reye's syndrome.
- u To manage a fever, instruct the parents to give acetaminophen and tepid sponge baths, to dress the child in light clothing, and to maintain a cool environment.

WEST NILE ENCEPHALITIS

West Nile encephalitis is an infectious disease that primarily causes inflammation, or encephalitis, of the brain. The etiology stems from the West Nile virus (WNV), a flavivirus commonly found in humans, birds, and other vertebrates in Africa, West Asia, and the Middle East. This disease is part of a family of vector-borne diseases that also includes malaria, yellow fever, and Lyme disease.

The virus was first documented in the Western Hemisphere in August 1999, when a virus found in numerous dead birds in the New York, New Jersey, and Connecticut region was identified by genetic sequencing as WNV. Scientists in the United States first discovered the rare strain in and around the Bronx Zoological Park and believe imported birds may have carried the disease, which spread by mosquitoes that fed on the infected birds.

In temperate areas of the world, West Nile encephalitis cases occur mainly in late summer or early fall. In climates where temperatures are milder, West Nile encephalitis can occur year-round.

As of mid-November 1999, health officials at the Centers for Disease Control and Prevention (CDC) reported 56 cases of WNV infection (31 confirmed and 25 probable), including 7 deaths.

The risk of contracting West Nile encephalitis is greater for residents of areas where active cases have been identified. Individuals older than age 50 and those with compromised immune systems have the greatest risk. At this time, there is no documented evidence that a pregnant woman's fetus is at risk due to an infection with WNV. The mortality rate for West Nile encephalitis ranges from 3% to 15%; the mortality rate is higher in the elderly population.

Causes

WNV is transmitted to humans by the bite of a mosquito (primarily the *Culex* genus), that is infected with the virus. They are considered the primary vector for WNV and the source of the August 1999 outbreak in New York, New Jersey, and Connecticut. Mosquitoes become infected by feeding on birds contaminated with the virus. The mosquitoes may then transmit the virus to humans and animals when taking a blood meal.

Ticks infected with WNV have been found in Africa and Asia only. The role of ticks in the transmission and maintenance of the virus remains uncertain; to date, ticks haven't been considered a vector for transmission in the United States.

The CDC has reported that there is no evidence that a person can contract the virus by handling live or dead infected birds. However, people should be instructed to use gloves or double plastic bags to place the carcass of any dead bird or animal in a garbage can; the finding should be reported to the nearest Emergency Management Office.

Complications

Complications due to WNV include progression to coma, tremors, occasional convulsions, paralysis and, rarely, death.

Assessment findings

The incubation period for West Nile encephalitis is 5 to 15 days after exposure. Most patients bitten by an infected mosquito develop no symptoms at all. Only 1 in

300 people who are bitten by an infected mosquito actually get sick.

Mild infections with the virus are most common and cause fever, headache, and body aches, often accompanied by rash and swollen lymph glands. Headache, high fever, neck stiffness, stupor, and disorientation can occur with severe infections.

Diagnostic tests

The enzyme-linked immunosorbent assay (ELISA), the MAC-ELISA, is the test of choice for obtaining a rapid definitive diagnosis. The major advantage of MAC-ELISA lab analysis is the high probability of an accurate diagnosis of WNV infection. An accurate diagnosis is possible only when serum or cerebrospinal fluid specimens are obtained while the patient is still hospitalized with acute illness.

When developing a differential diagnosis, another condition to consider is St. Louis encephalitis, which causes similar symptoms. Inflammation of the brain can be caused by numerous viral and bacterial infections, so all data must be examined to make a definitive diagnosis.

Treatment

There is no specific therapy to treat West Nile encephalitis and no known cure. Treatment is generally aimed at controlling the specific symptoms. Supportive care measures such as I.V. fluids, fever control, and respiratory support are rendered when necessary.

There is no vaccine at present to prevent the transmission of West Nile encephalitis.

Nursing diagnoses

u Altered tissue perfusion (cardiopulmonary) u Fluid volume deficit u Hyperthermia u Impaired tissue integrity u Pain

Key outcomes

- u The patient's collateral circulation will be maintained.
- u Hemodynamic stability will be maintained.
- u The patient's cardiac output will remain adequate.
- u The patient will remain afebrile.
- u The patient's fluid volume will remain adequate.

Nursing interventions

- u Obtain an extensive history of the patient's whereabouts in the last 2 to 3 weeks (especially around bodies of water, such as lakes and ponds), presence of dead birds, and recent mosquito bites.
- u Perform a comprehensive physical assessment and report signs of fever, headache, lymphadenopathy, and maculopapular rash.
- u Perform a complete neurologic examination and report any signs of confusion, lethargy, weakness, or slurred speech.
- u Maintain adequate hydration with I.V. fluids.
- u Monitor strict intake and output.
- u Administer fever-control measures.
- u Provide respiratory support measures when applicable.
- u West Nile encephalitis isn't transmitted from person to person, but use standard precautions when handling blood or other body fluids.
- u Report any suspected cases of West Nile encephalitis to the state Department of Health.

PREVENTION

Preventing West Nile virus

To reduce the risk of becoming infected with West Nile encephalitis, advise patients to:

- u stay indoors at dawn, dusk, and in the early evening.
- u wear long-sleeved shirts and long pants whenever they are outdoors.
- u apply insect repellent sparingly to exposed skin. (Effective repellents contain 20% to 30% DEET [N,N-diethyltoluamide]. DEET in high concentrations [greater than 30%] can cause adverse effects, particularly in children; avoid products containing more than 30% DEET.)

Patient teaching

- u Repellents can irritate the eyes and mouth, so avoid applying repellent to the hands of children. Insect repellents shouldn't be applied to children under age 3.
- u Spray clothing with repellents containing DEET because mosquitoes can bite through thin clothing.
- u Whenever you use an insecticide or insect repellent, be sure to read and follow the manufacturer's directions for use, as printed on the product.
- u *Note:* Vitamin B and ultrasonic devices aren't effective in preventing mosquito bites. (See [Preventing West Nile virus.](#))

Rickettsiae

Rickettsiae are parasitic microorganisms that grow only inside living cells. They're named for Howard Taylor Ricketts, who discovered them. These small, modified forms of bacteria cause Rocky Mountain spotted fever and other rickettsial diseases.

ROCKY MOUNTAIN SPOTTED FEVER

Rocky Mountain spotted fever is an acute infectious, febrile, and rash-producing illness that is associated with outdoor activities, such as camping and hiking. Rocky Mountain spotted fever is endemic throughout the continental United States. The disease is particularly prevalent in children ages 5 to 9; the mortality rate is 5% due to delayed diagnosis and treatment. Mortality is higher in males than females. As outdoor activities increase in popularity, so does the risk for contracting Rocky Mountain spotted fever—especially in the spring and summer months.

The usual incubation period is 7 days, but it can range from 2 to 12 days.

Causes

The *Rickettsia rickettsi* organism causes Rocky Mountain spotted fever. It's transmitted by the wood tick (*Dermacentor andersoni*) in the western United States and by the dog tick (*D. variabilis*) in the eastern United States. The rickettsial organism enters humans or small animals with the prolonged bite (4 to 6 hours) of an adult tick.

This disease occasionally is acquired through inhalation or through contact of abraded skin with tick excreta or tissue juices. (This is why a person shouldn't crush a

tick between the fingers when removing it.) In most tick-infested areas, 1% to 5% of the ticks harbor *R. rickettsia*.

Complications

Complications can include lobar pneumonia, pneumonitis, otitis media, parotitis, disseminated intravascular coagulation (DIC), and shock. Systemic and pulmonary microcirculation are compromised, renal failure, meningoencephalitis, and hepatic injury also occur. Death can occur from severe visceral lesions. Death can occur in 2 weeks after onset in untreated cases and in 5 days with fulminant Rocky Mountain spotted fever.

Assessment findings

The patient's history may show recent exposure to ticks or tick-infested areas or a known tick bite.

The patient typically complains of symptoms that begin abruptly, including a persistent fever with temperature ranging between 102° and 104° F (38.9° to 40° C); generalized, excruciating headache; and aching in the bones, muscles, joints, and back. He also may report anorexia, nausea, and vomiting.

A rash is evident in 14% of patients on the first day and in 49% by the third day. In 2 to 5 days, eruptions begin at the wrists, ankles, or forehead and spread to the remainder of the extremities and trunk. Within 2 days, the rash covers the entire body (including the scalp, palms, and soles). It consists of erythematous macules 1 to 5 mm in diameter. The pink foci of vasodilation are leaky with local edema. The lesions then become maculopapules that blanch on pressure. As more severe vascular damage occurs, frank hemorrhage occurs at the center of the maculopapule, creating a petechia that doesn't blanch on pressure.

CULTURAL TIP Petechiae are difficult to see in dark-skinned individuals. Lesions may be easier to see by examining the conjunctiva, oral mucosa, or lighter-pigmented areas, such as the abdomen, gluteal folds, and inner forearm.

The patient may have a bronchial cough, a rapid respiratory rate (up to 60 breaths/minute), insomnia, restlessness and, in extreme cases, delirium and circulatory collapse. Urine output decreases considerably, and the urine, which appears dark, contains albumin.

At disease onset, palpation may reveal a strong pulse, which gradually becomes rapid (possibly reaching 150 beats/minute) and thready. The rapid pulse rate and hypotension (less than 90 mm Hg systolic) herald imminent death from vascular collapse. Additionally, you may detect hepatomegaly, splenomegaly, and generalized pitting edema. Postauricular adenopathy may be palpated on one side if the tick bit the patient's head. Signs of enterocolitis, meningitis, and pulmonary involvement may become evident. (See [Differentiating Rocky Mountain spotted fever.](#))

Diagnostic tests

The most important factor is a history of exposure to a tick-infested environment. Serologic tests are often negative initially, and treatment shouldn't be delayed until a positive test is obtained. Indirect immunofluorescence assay is the most common test and a diagnostic titer of 64 or greater is detectable between days 7 and 14 of the illness. Latex agglutination may reveal a diagnostic titer of 128 or greater 1 week after onset. The only diagnostic test that is useful during the acute illness is immunohistological examination of a cutaneous biopsy of a rash lesion. Cultivation of rickettsia is feasible but seldom undertaken because necessary equipment isn't available in all facilities, testing can be costly, and the infection could spread to laboratory personnel.

Other laboratory test findings may include a decreased platelet count, white blood cell count, and fibrinogen levels; prolonged prothrombin time and partial thromboplastin time; decreased serum protein levels, especially albumin; hyponatremia and hypo-chloremia associated with increased aldosterone excretion; and abnormal hepatic function.

ADVANCED PRACTICE

Differentiating Rocky Mountain spotted fever

A differential diagnosis is needed to rule out influenza, enterovirus infection, infectious mononucleosis, viral hepatitis, leptospirosis, typhoid fever, gram-negative or gram-positive bacterial sepsis, and other rickettsial diseases. In addition, a multitude of other illnesses and processes can result in a similar rash, making diagnosis and differentiation challenging.

Mild mononuclear pleocytosis with slightly elevated protein content in cerebrospinal fluid is common.

Treatment

In Rocky Mountain spotted fever, treatment requires careful removal of the tick and administration of doxycycline, except for those that are allergic or pregnant. Chloramphenicol or oral tetracycline is an alternative, but neither is recommended for pregnant women or children. The seriously ill patient requires intensive care and careful fluid administration to achieve tissue perfusion without pulmonary edema. Intubation and mechanical ventilation may be required. Hemodialysis, antiseizure medication, and treatment for hemorrhage and thrombocytopenia may be needed.

Nursing diagnoses

⌞ Activity intolerance ⌞ Altered nutrition: Less than body requirements ⌞ Altered tissue perfusion ⌞ Decreased cardiac output ⌞ Fluid volume deficit ⌞ Hyperthermia ⌞ Impaired skin integrity ⌞ Pain ⌞ Risk for infection ⌞ Risk for injury

Key outcomes

- ⌞ The patient's vital signs will remain stable.
- ⌞ Hemodynamic stability will be maintained.
- ⌞ The patient's skin will remain warm and dry.
- ⌞ The patient will remain afebrile.
- ⌞ The patient will exhibit improved or healed lesions or wounds.
- ⌞ The patient's fluid volume will remain adequate.
- ⌞ The patient's white blood cell count and differential will stay within normal range.

Nursing interventions

- ⌞ Administer analgesics as ordered. Avoid giving aspirin, which increases the patient's risk for bleeding.
- ⌞ Monitor vital signs, and watch for profound hypotension and shock. Be prepared to provide oxygen therapy and assisted ventilation for pulmonary complications.
- ⌞ Record intake and output. Watch closely for decreased urine output, a possible indicator of renal failure.
- ⌞ Monitor the I.V. fluid infusion rate hourly. Deliver enough fluids to prevent dehydration, provided the patient has adequate urine output.
- ⌞ Give antipyretic medications, as ordered, and tepid sponge baths to reduce fever.
- ⌞ Provide meticulous mouth and skin care. Offer mentholated lotions to soothe itching resulting from the rash.
- ⌞ Frequently turn the patient to prevent pressure ulcers and pneumonia. Encourage incentive spirometry and deep breathing to reduce the patient's risk for atelectasis.
- ⌞ Plan care to promote adequate rest periods.

- Provide the patient with frequent, small, high-protein, high-calorie meals, or administer tube feeding if necessary.

Patient teaching

- Instruct the patient to report any recurrent symptoms to the doctor at once so that treatment can resume promptly.
- To prevent Rocky Mountain spotted fever, advise the patient to avoid tick-infested areas. If he does frequent these areas, instruct him to inspect his entire body (including his scalp) every 3 to 4 hours for attached ticks. Remind him to wear protective clothing, such as a long-sleeved shirt and slacks firmly tucked into laced boots. Tell him to apply insect repellent to clothes and exposed skin.
- Teach patients and caregivers how to correctly remove ticks with tweezers or forceps and steady traction. Show them how to avoid leaving mouthparts in skin. Instruct them not to handle the tick or tick fragments.

Protozoa

Such diseases as amebiasis, Cryptosporidiosis, giardiasis, malaria, *Pneumocystis carini* pneumonia, toxoplasmosis, and trichomoniasis result from minute but complex unicellular animals known as protozoa. These pathogens are known for their well-defined life cycles.

AMEBIASIS

Also called amoebic dysentery, amebiasis can take the form of either an acute or a chronic protozoal infection. Extraintestinal amebiasis can induce hepatic abscess and infection of the lungs, pleural cavity, pericardium, peritoneum and, rarely, the brain.

Amebiasis occurs worldwide; about 90% of infections are asymptomatic and the rest produce symptoms ranging from amoebic dysentery to abscesses of the liver and other organs. It's the third most common cause of death from paralytic disease, after schistosomiasis and malaria. It's most common in the tropics, subtropics, and other areas with poor sanitation and health practices.

Causes

Amebiasis is caused by *Entamoeba histolytica*. This protozoan has two stages: during the cystic stage, it can survive outside the body; during the trophozoite stage, it can't.

Transmission occurs through ingesting stool-contaminated food or water or through oral-anal sexual practices. The ingested cysts pass through the intestine, where digestive secretions break them down, freeing the motile trophozoites within. The trophozoites then multiply and either invade and ulcerate the mucosa of the large intestine or simply feed on intestinal bacteria. As the trophozoites are carried slowly toward the rectum, they are encysted and then excreted in stool. Humans are the principal carriers.

Complications

Amebiasis can cause chronic, recurrent episodes of diarrhea and abdominal pain, ameboma, megacolon, intussusception, extraintestinal abscesses, and intestinal stricture, hemorrhage, or perforation. Rarely, it causes a brain abscess, which usually is fatal.

Assessment findings

The patient may have a history of recent travel to an area with poor sanitation, sexual practices involving oral-anal contact, eating or drinking suspect food or water, or institutionalization.

The patient's signs and symptoms vary with the severity of the infestation, from no symptoms or only mild diarrhea to fulminating dysentery.

If the patient has *acute amebiasis*, he complains of chills and abdominal cramping; profuse, bloody diarrhea with tenesmus; and diffuse abdominal tenderness (caused by extensive rectosigmoid ulcers). He also develops a sudden high fever, with a temperature of 104° to 105° F (40° to 40.6° C).

A patient with *chronic amebiasis* may report intermittent diarrhea that lasts for 1 to 4 weeks and recurs several times a year. Such diarrhea produces 4 to 8 (or, in severe diarrhea, up to 18) foul-smelling mucus- and blood-tinged stools daily. The patient also may report vague abdominal cramps and, possibly, weight loss. Any fever he has is mild.

During inspection, you may note perianal ulceration and systemic signs of dehydration or anemia. Palpation may reveal diffuse abdominal tenderness and hepatomegaly. On auscultation of the abdomen, you may note hyperactive bowel sounds, particularly in the lower quadrants, when the patient has acute diarrhea.

Diagnostic tests

Isolating *E. histolytica* in fresh stool or in aspirates from abscesses, ulcers, or tissue confirms acute amebiasis. Endoscopy can aid in diagnosis, unless it's contraindicated by fulminant disease.

Other tests that support the diagnosis include:

- indirect hemagglutination test (positive with current or previous infection)
- complement fixation (usually positive only during active disease)
- liver scan, which may reveal abscesses.

Treatment

The patient with amebiasis is treated with metronidazole, the preferred amebicide for intestinal and extraintestinal infection that causes symptoms of acute colitis or liver abscess. Other agents for asymptomatic carriers include diloxamine furoate, iodoquinol, or paromomysin. For liver abscess without intestinal infections, the patient receives metronidazole, tinidazole, imidazole, plus the other agents as listed above for the asymptomatic carrier.

Exploratory surgery is hazardous because it can lead to peritonitis, perforation, and pericecal abscess. Percutaneous drainage of abscesses of the liver may be necessary, but surgery is usually reserved for patients with a perforation or rupture.

Nursing diagnoses

- Altered nutrition: Less than body requirements
- Diarrhea
- Fatigue
- Fluid volume deficit
- Hyperthermia
- Impaired skin integrity
- Pain
- Risk for infection

Key outcomes

- The patient will experience no further weight loss.
- The patient will avoid skin breakdown or infection.
- The patient's vital signs will remain stable.
- The patient will remain afebrile.
- The patient's electrolyte levels will stay within normal range.

- u The patient's elimination pattern will return to normal.
- u The patient will express a feeling of comfort and relief from pain.

Nursing interventions

- u Institute enteric precautions.
- u Obtain a stool specimen for examination. Don't give the patient a soap or hypotonic enema, bismuth, antacids, laxatives, barium preparations, or antibiotics (such as erythromycin or tetracycline) before collecting the sample because they interfere with the test. Send the specimen to the laboratory immediately.
- u Monitor the frequency of the patient's bowel movements and the characteristics of his stools.
- u Keep the patient's perianal area clean. Provide skin care after each bowel movement.
- u Don't use fecal incontinence bags because they may spread disease.
- u Administer amebicide medications as ordered. Monitor the patient for toxic effects.
- u Make sure the patient gets adequate rest, but provide him with diversional activities between rest periods.
- u Assess the patient for signs of dehydration, and administer I.V. fluids as ordered. Encourage him to drink fluids as soon as he can tolerate them.

Patient teaching

- u Teach the patient about amebicide therapy, including precautions he should take and adverse effects of the medication. Explain to the patient taking metronidazole that he should avoid drinking alcohol while taking the drug and for 3 days after he has finished taking it; otherwise, a disulfiram-like reaction could result. Signs and symptoms include confusion, nausea, vomiting, headache, and seizures. Also warn him that the drug may turn his urine dark brown.
- u Encourage the patient to return for follow-up appointments at scheduled intervals.
- u Advise the patient's family and sexual partners to seek medical attention for amebiasis.
- u Teach the patient and his family how to handle infectious material and about the need for careful hand washing. When warranted, teach the patient about safe sexual practices.
- u Advise travelers to endemic areas and campers to boil untreated or contaminated water to prevent the disease.

CRYPTOSPORIDIOSIS

This intestinal infection typically results in acute, self-limited diarrhea. However, in immunocompromised patients, cryptosporidiosis causes chronic, severe, and life-threatening symptoms.

The disease is prevalent in immunocompromised patients, such as malnourished children, patients with hypogammaglobulinemia, and those who receive immunosuppressants for cancer therapy or organ transplantation. It's especially prevalent in patients with acquired immunodeficiency syndrome.

Cryptosporidiosis occurs worldwide. In addition to immunocompromised patients, travelers to foreign countries, medical personnel caring for patients with the disease, and children are at particular risk. It's spread easily in day-care centers and among household contacts and medical providers. Contaminated water, such as in a swimming pool, is a frequent source of infection.

Causes

Cryptosporidiosis is caused by the protozoan *Cryptosporidium*. These small spherules inhabit the microvillus border of the intestinal epithelium. There, the protozoa shed infected oocysts into the intestinal lumen, where they pass into stool. (See [Cryptosporidium oocyst.](#))

These oocysts are particularly hardy, resisting destruction by routine water chlorination. This increases the risk of infection spreading through contact with contaminated water. The disease can also be transmitted via contaminated food and person-to-person contact.

Complications

Complications can be particularly severe in immunocompromised patients. In these patients, profuse, watery diarrhea can lead to severe fluid and electrolyte depletion and malnutrition. Rectal excoriation and breakdown can also result.

If the biliary tract becomes affected, papillary stenosis, sclerosing cholangitis, or cholecystitis can occur.

Assessment findings

Although asymptomatic infections can occur in both normal and immunocompromised patients, the typical patient with cryptosporidiosis develops symptoms after an incubation period of approximately 7 days. (The incubation period may be shorter in an immunocompromised patient.) The patient initially complains of watery, nonbloody diarrhea. He may also report abdominal pain, anorexia, nausea, fever, and weight loss. In the 10% of patients who develop biliary tract involvement, right upper abdominal pain may be severe. Signs and symptoms usually subside within 2 weeks but may recur sporadically for months to years.

The history of an immunocompromised patient typically reveals a more gradual onset of symptoms. Such a patient may also develop more severe diarrhea with daily fluid losses as high as 20 L.

For all patients, auscultation of the abdomen may reveal hyperactive bowel sounds. Palpation may reveal abdominal tenderness.

Diagnostic tests

Cryptosporidiosis often goes undetected as the cause of profuse diarrhea because an acid-fast stain needed to detect the organism isn't routinely used. However, the acid-fast stain as well as microscopic examination of stool samples reveals the presence of oocysts. If too few oocysts are excreted to show up readily under microscopic examination, Sheather's cover-slip flotation method can make detection easier by concentrating the oocysts.

The infecting organisms can also be detected by light and electron microscopy at the apical surfaces of intestinal epithelium obtained through biopsies of the small bowel. Although serologic tests exist, their value in diagnosing acute or chronic infections in immunocompromised patients hasn't been determined.

With biliary tract involvement, studies may reveal an elevated alkaline phosphatase level, gallbladder wall thickening, and dilated bile ducts.

Treatment

Although no treatment currently exists that can eradicate the infecting organism, paromomycin may be partially effective for some patients with human immunodeficiency virus.

Treatment of cryptosporidiosis consists mainly of supportive measures to control symptoms. Such measures include fluid replacement to prevent dehydration as well as administration of analgesics to relieve pain and antidiarrheal and antiperistaltic agents to control diarrhea.

Nursing diagnoses

- u Altered nutrition: Less than body requirements u Anxiety u Diarrhea u Pain u Risk for fluid volume deficit u Risk for impaired tissue integrity u Risk for infection

Key outcomes

- u The patient will experience no further weight loss.
- u The patient will avoid skin breakdown or infection.
- u The patient's vital signs will remain stable.
- u The patient's electrolyte levels will stay within normal range.
- u The patient's elimination pattern will return to normal.
- u The patient will express a feeling of comfort and relief from pain.

Nursing interventions

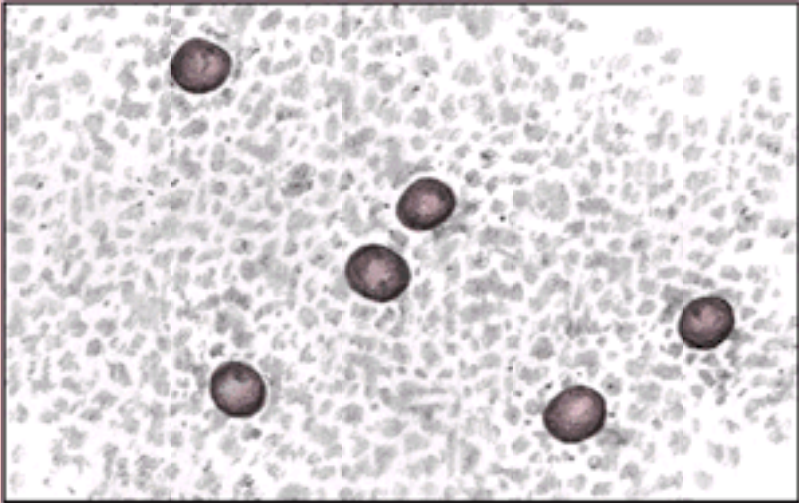

- u Closely monitor the patient's fluid and electrolyte balance.
- u Encourage an adequate intake of fluids, especially those rich in electrolytes.
- u Monitor the patient's intake and output, and weigh him daily to evaluate the need for fluid replacement. Watch him closely for signs of dehydration, and provide fluid replacement as ordered.
- u Administer analgesics, antidiarrheal and antiperistaltic agents, and antibiotics as ordered. Observe the patient for signs of adverse reactions as well as therapeutic effects.
- u Apply perirectal protective cream to prevent excoriation and skin breakdown.
- u Encourage small, frequent meals to help prevent nausea.

Patient teaching

- u Teach the patient about his medications. Make sure he understands how to take the drugs and what adverse reactions to watch for. Stress the importance of calling his doctor immediately if he develops an adverse reaction.
- u Teach the patient and his family to recognize the signs and symptoms of dehydration, including weight loss, poor skin turgor, oliguria, irritability, and dry flushed skin. Tell them to report such findings to the doctor.
- u Teach the patient and family about good personal hygiene, especially proper hand-washing technique. Explain to them how to safely handle potentially infectious material, such as soiled bed sheets.

Cryptosporidium oocyst

This illustration shows the oocyst that causes crypto-sporidiosis.

- u Advise the patient's family members and close contacts to have their stools tested.

GIARDIASIS

Giardiasis, also called Giardia enteritis and lambliasis, is a protozoal infection of the small bowel.

Giardiasis occurs worldwide but is most common in developing countries and other areas where sanitation and hygiene are poor.

In the United States, giardiasis most frequently occurs in travelers who have recently returned from endemic areas, campers who drink nonpurified water from contaminated streams, male homosexuals, patients with congenital IgA deficiency, and children in day-care centers. Children in general are more likely to develop giardiasis than adults, probably because of frequent hand-to-mouth activity. Over the past 10 years, the parasite responsible for the disease has been found in municipal water sources, nursing homes, and day-care centers.

The prognosis is good; with treatment, the patient recovers completely. Without treatment, symptoms continue to wax and wane. Also, giardiasis doesn't confer immunity, so reinfections can occur.

Causes

Giardiasis is caused by the symmetrical flagellate protozoan *Giardia lamblia*, which has two stages: the cystic stage and the trophozoite stage. Ingestion of *G. lamblia* cysts in stool-contaminated water or the fecal-oral transfer of cysts by an infected person results in giardiasis.

PREVENTION

Preventing giardiasis

- u Advise family members and others who may have been in contact with the patient to have their stools tested for *G. lamblia* cysts.
- u Teach the patient and his family about the need for good personal hygiene, particularly proper hand-washing technique, and how to handle infectious material. When warranted, teach the patient about safe sexual practices.
- u Teach travelers to endemic areas not to drink tap or suspect water or to eat uncooked and unpeeled fruits or vegetables, which may have been rinsed in contaminated water. Explain that prophylactic drug therapy isn't recommended.
- u Advise campers to purify all stream and lake water before drinking it.

When cysts enter the small bowel, they release trophozoites, which attach themselves with their sucking disks to the bowel's epithelial surface. This attachment causes superficial mucosal invasion and destruction, inflammation, and irritation. After that, the trophozoites encyst again, travel down the colon, and are excreted. Unformed stool that pass quickly through the intestine may contain trophozoites as well as cysts.

Complications

The mucosal destruction caused by the protozoa decreases food transit time through the small intestine and results in malabsorption. Other complications include dehydration and lactose intolerance. Giardiasis can be life-threatening in patients with hypogammaglobulinemia. It can also complicate conditions such as cystic fibrosis.

Assessment findings

The patient's history may include recent travel to an area with poor sanitation, sexual practices that involve oral-anal contact, drinking suspect water, or institutionalization.

A patient with acute giardiasis may complain of abdominal cramps, bloating, belching, flatus, nausea, and vomiting, accompanied by explosive, pale, loose, greasy, malodorous, and frequent stools (from 2 to 10 daily). In chronic giardiasis, the patient also may complain of fatigue, weight loss, and flatulence. A mild infection may cause no intestinal symptoms.

Auscultation of the abdomen may reveal hyperactive bowel sounds in the right upper and left lower quadrants just before bowel movements, although you may not detect these sounds between episodes. You're most likely to notice alterations 30 minutes to 1 hour after the patient eats.

On palpation, you won't elicit localized tenderness, but you may note general upper and right lower quadrant discomfort and guarding.

Diagnostic tests

An accurate diagnosis depends on examination of a fresh stool specimen for cysts or examination of duodenal aspirate or biopsy for trophozoites.

Treatment

Giardiasis responds readily to metronidazole. Some patients (such as children) may instead be given furazolidone, but it isn't as effective. If the patient has severe diarrhea and oral fluid intake is inadequate, he may need parenteral fluid replacement to prevent dehydration.

Nursing diagnoses

- u Altered nutrition: Less than body requirements
- u Diarrhea
- u Fatigue
- u Fluid volume deficit
- u Impaired skin integrity
- u Pain
- u Risk for infection

Key outcomes

- u The patient will experience no further weight loss.
- u The patient will avoid skin breakdown or infection.
- u The patient's vital signs will remain stable.
- u The patient's electrolyte levels will stay within normal range.
- u The patient's elimination pattern will return to normal.
- u The patient will express a feeling of comfort and relief from pain.

Nursing interventions

- u Institute enteric precautions, and quickly dispose of all fecal material. (Normal sewage systems adequately remove and process infected stool.) Pay strict attention to hand washing, particularly after handling stool. If the patient is a child or an incontinent adult, a private room is needed.
- u Monitor the frequency of the patient's bowel movements and the characteristics of his stools. Keep his perianal area clean, making sure to clean his skin thoroughly after each bowel movement.
- u Make sure the patient takes in adequate fluids. If necessary, administer I.V. fluid therapy. Provide nutritionally adequate foods, and monitor the patient's nutritional intake to prevent malnutrition.
- u Administer medication, as ordered, carefully monitoring for adverse effects. The patient taking metronidazole may have headache, GI upset, a metallic taste in his mouth, and a disulfiram-like reaction if alcohol is ingested. The patient taking furazolidone may experience headache, nausea, vomiting, an allergic reaction, and a disulfiram-like reaction when alcohol is ingested.
- u Report epidemic situations to public health authorities.

Patient teaching

- u Teach the patient about his medication, including precautions he should take and adverse effects. Caution the patient taking metronidazole or furazolidone not to drink alcohol while taking the drug and for 3 days after he has finished taking it. Otherwise, he may experience a disulfiram-like reaction (confusion, nausea, vomiting, headache, and seizures). Also warn him that his urine may turn dark brown.
- u Encourage the patient to return for follow-up appointments because relapses can occur. (See [Preventing giardiasis.](#))

MALARIA

Malaria has been eradicated from North America, Europe, and Russia but, despite efforts, continues to flourish in parts of the tropics. Falciparum malaria is the most severe form of the disease. When treated, malaria seldom is fatal; untreated, it's fatal in 10% of victims, usually as a result of complications.

Untreated primary attacks last from a week to a month or longer. Relapses are common and can recur sporadically for several years. Susceptibility to the disease is universal.

Causes

Malaria is caused by *Plasmodium vivax*, *P. malariae*, *P. falciparum*, and *P. ovale*, all of which are transmitted to humans by mosquito vectors.

Malaria is transmitted by the bite of female *Anopheles* mosquitoes, which abound in humid, swampy areas. When an infected mosquito bites, it injects *Plasmodium* sporozoites into the wound. The infective sporozoites migrate by blood circulation to parenchymal cells of the liver; there they form cystlike structures that contain thousands of merozoites.

On release, each merozoite invades an erythrocyte and feeds on hemoglobin. The erythrocyte eventually ruptures, releasing heme (malaria pigment), cell debris, and more merozoites that, unless destroyed by phagocytes, enter other erythrocytes. At this point, the infected person becomes a reservoir of malaria who infects any mosquito that feeds on him, thus beginning a new cycle of transmission.

As parasites, *P. vivax*, *P. ovale*, and *P. malariae* may persist for years in the liver and are responsible for the chronic carrier state. Because blood transfusions and street-drug paraphernalia also can spread malaria, drug addicts have a higher incidence of the disease.

Complications

Falciparum malaria can cause renal failure, liver failure, heart failure, pulmonary edema, disseminated intravascular coagulation (DIC), circulatory collapse, severe

normocytic anemia, seizures, hypoglycemia, splenic rupture, cerebral dysfunction, and death.

During pregnancy, malaria can lead to premature delivery, spontaneous abortion, stillbirth, and low-birth-weight infants.

Malaria-related immunosuppression could possibly lead to an infection with lymphoma viruses, such as the Epstein-Barr virus (Burkitt's lymphoma).

Assessment findings

The patient's history may reveal travel to an endemic area, a recent blood transfusion, or I.V. drug use.

After an incubation period of 12 to 30 days, the patient may report malaria's prodromal signs and symptoms, such as chills, fever, headache, fatigue, and myalgia interspersed with periods of well-being (the hallmark of the benign form of malaria). Acute attacks (paroxysms) occur when erythrocytes rupture. These attacks have three stages:

- u *cold stage*, lasting for 1 to 2 hours, ranging from chills to extreme shaking
- u *hot stage*, lasting for 3 to 4 hours, characterized by a high fever (up to 107° F [41.7° C]) accompanied by cough, headache, backache, abdominal pain, nausea, vomiting, and delirium

Nursing considerations for antimalarial drugs

Follow these guidelines for administering antimalarial drugs, such as chloroquine, primaquine, pyrimethamine, and quinine.

Chloroquine

- u Perform baseline and periodic ophthalmic examinations, and report blurred vision, increased sensitivity to light, and muscle weakness to the doctor.
- u Consult the doctor about altering therapy if muscle weakness appears.
- u Suggest an audiometric examination before, during, and after therapy.
- u Caution the patient to avoid excessive exposure to the sun to prevent exacerbating drug-induced dermatoses.

Primaquine

- u Give drug with meals or antacids.
- u Discontinue administration if you observe a sudden fall in hemoglobin concentration or in red blood cell or white blood cell count or a marked darkening of urine, suggesting an impending hemolytic reaction.

Pyrimethamine

- u Administer drug with meals to minimize GI distress.
- u Check blood counts (including platelets) twice a week. If signs of folic or folinic acid deficiency develop, reduce the dosage or discontinue administration while the patient receives parenteral folinic acid until blood counts become normal.

Quinine

- u Use with caution in the patient with a cardiovascular condition. Discontinue administration if you see any signs of idiosyncrasy or toxicity, such as headache, epigastric distress, diarrhea, rash, or pruritus in a mild reaction or delirium, seizures, blindness, cardiovascular collapse, asthma, hemolytic anemia, or granulocytosis in a severe reaction.
- u Frequently monitor blood pressure while administering quinine I.V. Rapid administration causes marked hypo-tension.

- u *wet stage*, lasting for 2 to 4 hours, characterized by profuse sweating.

Between paroxysms, the patient typically experiences a period of well-being, except in *P. falciparum* infection.

Inspection reveals pale skin. Rigors can be seen in the cold stage, and flushing, tachypnea, and mental confusion may accompany the hot stage.

Less frequently, inspection findings may include urticaria, jaundice, and petechial rash. Anemia and oliguria may be noted if acute renal failure occurs in the patient with *P. falciparum* infection. If cerebral complications develop, you may note hemiplegia, seizures, altered mental processes, and coma.

CULTURAL TIP When assessing a dark-skinned individual, jaundice is best observed in the sclera closest to the center of the eye. Some patients may have a normal yellow tinge in the sclera. Inspecting the hard palette can help confirm the diagnosis of jaundice if the area appears yellow.

Palpation may reveal moderate splenomegaly and tender hepatomegaly. Lymphadenopathy usually isn't present. Tachycardia accompanies paroxysms. Orthostatic hypotension commonly occurs in the hot stage of paroxysms.

WARNING To decrease the risk of splenic rupture in malaria, avoid vigorous palpation of the spleen. The patient's spleen is enlarged, so it may be extremely fragile. Nevertheless, spontaneous rupture may occur. The spleen is especially prone to rupture in *P. vivax* malaria.

Chest auscultation may reveal scattered crackles.

Diagnostic tests

Unequivocal diagnosis depends on laboratory identification of the parasites in red blood cells of peripheral blood smears. Romanovsky's staining demonstrates the asexual forms of the parasite. Other staining is also useful.

Supplementary laboratory test values that support this diagnosis include decreased hemoglobin (normocytes, normochromic anemia), a normal or decreased white blood cell (WBC) count (as low as 3,000/mm³), and protein and WBCs in urine sediment. In falciparum malaria, serum values reflect DIC: a reduced platelet count (20,000 to 50,000/mm³), prolonged prothrombin time (18 to 20 seconds), prolonged partial thromboplastin time (60 to 100 seconds), and decreased plasma fibrinogen levels.

Treatment

Malaria is treated with oral chloroquine in all but chloroquine-resistant *P. falciparum* infection.

Malaria caused by *P. falciparum*, which is resistant to chloroquine, requires treatment with oral quinine, given concurrently with pyrimethamine with sulfadoxine and a sulfonamide, such as sulfadiazine. Relapses require the same treatment, or quinine alone, followed by tetracycline. Mefloquine also may be used for chloroquine-resistant malaria.

The only drug effective against the hepatic stage of the disease that is available in the United States is primaquine phosphate, given daily for 14 days. This drug can

induce DIC from increased hemolysis of red blood cells (RBCs); consequently, it's contraindicated during an acute attack. (See [Nursing considerations for antimalarial drugs.](#))

For travelers spending less than 3 weeks in areas where malaria exists, weekly prophylaxis includes oral chloroquine, beginning 2 weeks before and ending 6 weeks after the trip. Chloroquine and pyrimethamine with sulfadoxine may be ordered for those staying longer than 3 weeks, although combination treatment can cause severe adverse reactions. If the traveler isn't sensitive to either component of pyrimethamine with sulfadoxine, he may be given a single dose to take if he has a febrile episode. (See [How to prevent malaria.](#))

Any traveler who develops an acute febrile illness should seek prompt medical attention, regardless of prophylaxis measures taken.

Nursing diagnoses

- u Activity intolerance
- u Decreased cardiac output
- u Fatigue
- u Fluid volume deficit
- u Hyperthermia
- u Impaired gas exchange
- u Impaired physical mobility
- u Impaired skin integrity
- u Pain
- u Risk for infection
- u Risk for injury

Key outcomes

- u The patient's vital signs will remain within normal range.
- u The patient's fluid volume will remain adequate.
- u The patient will remain afebrile.
- u The patient will have normal breath sounds.
- u The patient's arterial blood gas levels will return to normal.
- u The patient will acknowledge fears, feelings, and concerns about the current situation.

Nursing interventions

- u Assess the patient on admission and daily thereafter for fatigue, fever, orthostatic hypotension, disorientation, myalgia, and arthralgia. Enforce bed rest during periods of acute illness.

PREVENTION

How to prevent malaria

Follow these guidelines for preventing malaria, particularly if you practice or travel in mosquito-infested regions.

- u Drain, fill, and eliminate breeding areas of the *Anopheles* mosquito.
- u Install screens or mosquito netting in living and sleeping quarters in endemic areas. Use a residual insecticide on clothing and skin to discourage mosquito bites.
- u Seek treatment for known cases of malaria.
- u Question blood donors for a history of, or possible exposure to, malaria. They may give blood if they haven't taken any antimalarial drugs and are asymptomatic after 6 months outside an endemic area, if they were asymptomatic after treatment for malaria more than 3 years ago, or if they were asymptomatic after receiving malaria prophylaxis more than 3 years ago.
- u Seek prophylactic drug therapy before traveling to an endemic area.

- u Institute standard precautions. Protect the patient from secondary bacterial infection by following proper hand-washing and aseptic techniques. Double-bag all contaminated linens, and send them to the laundry as an isolation item.
- u To reduce fever, administer antipyretics as ordered. Document the onset and duration of fever as well as symptoms before, during, and after each episode. Administer analgesics as ordered.
- u Fluid balance is fragile, so keep a strict record of intake and output. Closely monitor I.V. fluids. Avoid fluid overload (especially in falciparum malaria) because it can lead to pulmonary edema and the aggravation of cerebral symptoms. Observe blood chemistry levels for hyponatremia and increased blood urea nitrogen, creatinine, and bilirubin levels. Monitor urine output hourly.
- u Slowly administer packed RBCs or whole blood while checking for crackles, tachycardia, and shortness of breath.
- u If humidified oxygen is ordered because of anemia, note the patient's response, particularly any changes in rate or character of respirations, or improvement in mucous membrane color.
- u Watch for and immediately report signs of internal bleeding, such as tachycardia, hypotension, and pallor.
- u Encourage frequent coughing and deep breathing, especially if the patient is on bed rest or has pulmonary complications. Record the amount and color of sputum.
- u Watch for adverse effects of drug therapy, and take measures to relieve them.
- u If the patient is comatose, change his position frequently and perform passive range-of-motion exercises every 3 to 4 hours. If the patient is unconscious or disoriented, provide proper supervision, use restraints only as needed, and keep an airway or padded tongue blade available.
- u Provide emotional support and reassurance, especially in critical illness.
- u Report all cases of malaria to local public health authorities.

Patient teaching

- u Explain the procedures and treatment to the patient and his family. Listen sympathetically, and answer questions clearly. Suggest that family members be tested for malaria. Emphasize the need for follow-up care to check the effectiveness of treatment and to manage residual problems.

PNEUMOCYSTIS CARINII PNEUMONIA

Because of its association with human immunodeficiency virus (HIV) infection, *Pneumocystis carini* pneumonia (PCP), a communicable, opportunistic infection, has increased in incidence since the 1980s. It occurs in the following hosts: premature or malnourished infants; children with primary immunodeficiency disease; patients receiving immunosuppressive therapy (particularly glucocorticoids) for cancer, organ transplantation, or other disorders; and people with acquired immunodeficiency syndrome (AIDS). The organism remains a leading cause of opportunistic infection and death among AIDS patients in industrialized countries.

Causes and pathophysiology

P. carinii, the cause of PCP, usually is classified as a protozoan, although some investigators consider it more closely related to fungi. The organism exists as a saprophyte in the lungs of humans and various animals. *P. carini* is part of the normal flora in most healthy people but becomes an aggressive pathogen in the immunocompromised patient. Impaired cell-mediated (T-cell) immunity is thought to be more important than impaired humoral (B-cell) immunity in predisposing the patient to PCP, but the immune defects involved are poorly understood.

The primary transmission route seems to be air, although the organism already resides in most people. The incubation period probably lasts for 4 to 8 weeks. Impaired cellular immunity is the major factor that predisposes a person to pneumocytosis. Defects in B-cell function also play a role.

The organism invades the lungs bilaterally and multiplies extracellularly. As the infestation grows, alveoli fill with organisms and exudate, impairing gas exchange. The alveoli hypertrophy and thicken progressively, eventually leading to extensive consolidation.

Complications

Typically, PCP can progress to pulmonary insufficiency and death if left untreated. Disseminated infection has occurred in both AIDS and non-AIDS patients.

Assessment findings

The patient typically has a history of an immunocompromising condition or procedure, such as HIV infection, leukemia, lymphoma, or organ transplantation.

PCP begins insidiously with increasing shortness of breath and a nonproductive cough. Anorexia, generalized fatigue, and weight loss may be reported. Although the patient may have hypoxemia and hypercapnea, he may not exhibit significant clinical symptoms. Throughout the illness, he may report a low-grade, intermittent fever.

Inspection may reveal tachypnea, dyspnea, and accessory muscle use when the patient breathes. With acute illness, he may appear cyanotic.

Late in the disease, when consolidation develops, chest percussion discloses dullness. Auscultation findings include crackles (in about one-third of patients) and decreased breath sounds (in patients with advanced pneumonia).

Diagnostic tests

Histologic studies can confirm *P. carini*. In many patients with HIV, initial examination of a first-morning sputum specimen (induced by inhaling an ultrasonically dispersed saline mist) may be sufficient. This technique usually is ineffective in patients without HIV.

In all patients, fiberoptic bronchoscopy remains the most commonly used diagnostic tool to confirm PCP. Invasive procedures, such as transbronchial biopsy and open lung biopsy, are less commonly used.

In addition, a chest X-ray may show slowly progressing, fluffy infiltrates and occasional nodular lesions or a spontaneous pneumothorax. These findings must be differentiated from findings in other types of pneumonia or adult respiratory distress syndrome.

A gallium scan may show increased uptake over the lungs even when the chest X-ray appears relatively normal.

In PCP, arterial blood gas (ABG) studies detect hypoxia and an increased A-a gradient.

Treatment

The drug of choice for all types of PCP is trimethoprim-sulfamethoxazole (TMP-SMZ) administered orally or I.V. Adverse reactions include fever, rash, neutropenia, thrombocytopenia, hepatitis, and hyperkalemia.

Pentamidine may be administered slowly I.V. in a single dose of 4 mg/kg/day; it is as effective as TMP-SMZ but is toxic for almost all recipients. Adverse effects include hypotension, cardiac arrhythmia, hyperglycemia or hypoglycemia, azotemia, electrolyte changes, and neutropenia. Other regimens are also prescribed for patients who don't tolerate either of these medications.

Supportive measures, such as oxygen therapy, mechanical ventilation, adequate nutrition, and fluid balance, are important adjunctive therapies. Oral morphine sulfate solution may reduce respiratory rate and anxiety, enhancing oxygenation.

Nursing diagnoses

u Activity intolerance u Altered nutrition: Less than body requirements u Fear u Fluid volume deficit u Hyperthermia u Impaired gas exchange u Impaired social interaction u Ineffective breathing pattern u Powerlessness

Key outcomes

- u The patient's vital signs will remain within normal range.
- u The patient's fluid volume will remain adequate.
- u The patient will remain afebrile.
- u The patient will have normal breath sounds.
- u The patient's ABG levels will return to normal.
- u The patient will use correct bronchial hygiene.
- u The patient will acknowledge fears, feelings, and concerns about the current situation.

Nursing interventions

- u Implement standard precautions.
- u Frequently assess the patient's respiratory status, and monitor ABG levels. Administer oxygen therapy as ordered.
- u Encourage ambulation, deep-breathing exercises, and incentive spirometry to facilitate effective gas exchange.
- u Administer antipyretics, as ordered, to relieve fever.
- u Monitor intake and output and daily weight to evaluate fluid balance. Replace fluids as ordered.
- u Monitor for adverse effects of antimicrobial drugs. If the patient is receiving co-trimoxazole, watch for nausea, vomiting, rash, bone marrow suppression, thrush, fever, hepatotoxicity, and anaphylaxis. If he's receiving pentamidine, watch for cardiac arrhythmias, hypotension, dizziness, azotemia, hypocalcemia, and hepatic disturbances.
- u Provide diversional activities and adequate rest periods.
- u Supply nutritional supplements as needed. Encourage the patient to eat a high-calorie, protein-rich diet. Offer small, frequent meals if the patient can't tolerate large amounts of food.
- u Give emotional support and help the patient identify and use meaningful support systems.

Patient teaching

- u Instruct the patient about the medication regimen, especially about the adverse effects.
- u Teach the patient energy conservation techniques.
- u If the patient requires oxygen therapy at home, explain that an oxygen concentrator may be most effective.
- u In high-risk populations, such as AIDS patients, TMP-SMZ may be prescribed prophylactically to prevent PCP.

TOXOPLASMOSIS

Depending on their environment and eating habits, up to 70% of people in the United States are infected with *Toxoplasma gondii*— making toxoplasmosis one of the most common infectious diseases. Occurring worldwide, it's less common in cold or hot, arid climates and at high elevations.

The disease usually causes localized infection. However, it may produce significant generalized infection, especially in immunodeficient patients, such as neonates, acquired immunodeficiency syndrome (AIDS) patients, patients who recently had an organ transplant, those with lymphoma, and those receiving immunosuppressant

therapy.

Ocular toxoplasmosis
<p>Ocular toxoplasmosis (active chorioretinitis) is characterized by focal necrotizing retinitis. It accounts for about 25% of all cases of granulomatous uveitis. Although usually the result of a congenital infection, it may not appear until adolescence or young adulthood, when infection is reactivated.</p> <p>Symptoms include blurred vision, scotoma, pain, photophobia, and impairment or loss of central vision. Vision improves as inflammation subsides but usually without recovery of lost visual acuity. Ocular toxoplasmosis may subside after treatment with prednisone.</p>

Once infected, the patient may carry the organism for life. Reactivation of the acute infection can occur. Congenital toxoplasmosis, characterized by lesions in the central nervous system (CNS), may result in stillbirth or serious birth defects.

Causes

Toxoplasmosis is caused by the protozoan *T. gondii*, which exists in trophozoite forms in the acute stages of infection and in cystic forms (tissue cysts and oocysts) in the latent stages. The infection is transmitted by ingestion of tissue cysts in raw or undercooked meat (heating, drying, or freezing destroys these cysts) or by fecal-oral contamination from infected cats. Toxoplasmosis also occurs in vegetarians who aren't exposed to cats, so some other means of transmission may exist.

Congenital toxoplasmosis follows transplacental transmission from a mother who acquires primary toxoplasmosis shortly before or during pregnancy. Congenital infection is more severe when acquired early in the pregnancy.

Complications

Toxoplasmosis may cause encephalitis, myocarditis, pneumonitis, hepatitis, or polymyositis. If the disease is acquired in the first trimester of pregnancy, it commonly results in stillbirth. About one-third of infants who survive have congenital toxoplasmosis with CNS involvement and chorioretinitis. (See [Ocular toxoplasmosis.](#))

Assessment findings

The patient's history may reveal an immunocompromised state, exposure to cat feces, or frequent ingestion of poorly cooked meat.

A patient with localized (mild, lymphatic) toxoplasmosis may complain of mononucleosis-like symptoms: malaise, myalgia, headache, fatigue, and sore throat. He'll also have a fever. A patient with generalized (fulminating, disseminated) infection may complain of headache, vomiting, cough, and dyspnea. His temperature may run as high as 106° F (41.1° C).

Inspection of the patient with generalized disease reveals delirium and seizures—signs of encephalitis. You also may note a diffuse maculopapular rash (except on the palms, soles, and scalp) and cyanosis.

Inspection of an infant with congenital toxoplasmosis may reveal hydrocephalus or microcephalus, seizures, jaundice, purpura, and rash. Other defects, which may not become apparent until months or years later, include strabismus, blindness, epilepsy, and mental retardation.

Palpation of the neonate reveals lymphadenopathy, splenomegaly, and hepatomegaly.

Auscultation of a patient with toxoplasmosis may reveal coarse crackles.

Diagnostic tests

Isolation of *T. gondii* in mice after their inoculation with specimens of body fluids, blood, and tissue, or *T. gondii* antibodies in such specimens, confirms toxoplasmosis.

Treatment

Most effective during the acute stage, treatment consists of drug therapy with sulfonamides and pyrimethamine for 4 to 6 weeks. The patient also may receive folinic acid to control pyrimethamine's adverse effects.

These drugs act synergistically against the trophozoites but don't eliminate already developed tissue cysts. For this reason, and because they don't alleviate the underlying immune system defect in AIDS, an AIDS patient needs toxoplasmosis treatment for life.

An AIDS patient who can't tolerate sulfonamides may receive clindamycin instead. This drug also is the primary treatment in ocular toxoplasmosis.

Nursing diagnoses

u Activity intolerance u Fatigue u Fluid volume deficit u Hyperthermia u Impaired skin integrity u Ineffective breathing pattern u Pain u Risk for injury

Key outcomes

- u The patient's vital signs will remain within normal range.
- u The patient will remain afebrile.
- u The patient's fluid volume will remain adequate.
- u The patient will verbally report having an increased energy level.
- u The patient won't develop complications.
- u The patient's respiratory rate will be maintained within 5 breaths of baseline.

Nursing interventions

- u Give antipyretics and, possibly, tepid sponge baths to decrease fever.
- u Make sure the patient with a high fever, vomiting, and sore throat receives sufficient fluid intake. Provide nutritionally adequate foods and, if needed, small, frequent feeding.
- u Promote bed rest during the acute stage. Later, help the patient gradually increase his level of activity.
- u Frequently assess respiratory status, especially in the immunocompromised patient. Provide chest physiotherapy and administer oxygen, as needed. Assist ventilation if needed.
- u Assess the patient for signs of neurologic involvement and increased intracranial pressure.
- u Don't palpate the patient's abdomen vigorously; this could lead to a ruptured spleen. For the same reason, discourage vigorous activity.
- u Modify the environment, as needed, to protect a patient with neurologic manifestations or chorioretinitis. Refer him for rehabilitation or counseling as needed.
- u Carefully monitor the patient's drug therapy.
- u Because sulfonamides cause blood dyscrasias and pyrimethamine depresses bone marrow, closely monitor the patient's hematologic values.
- u Report all cases of toxoplasmosis to the local public health department.

Patient teaching

- u Teach the patient about necessary medications, including the need for frequent blood tests.
- u Emphasize the importance of regularly scheduled follow-up care.
- u Advise all people to do the following to prevent the spread of toxoplasmosis: Wash their hands after working with soil because it may be contaminated with cat oocysts; cook meat thoroughly and freeze it promptly if it isn't for immediate use; change cat litter daily (cat oocysts don't become infective until 1 to 4 days after excretion); cover children's sand boxes; and keep flies away from food because flies transport oocysts.

TRICHOMONIASIS

Trichomoniasis is a protozoal infection of the lower genitourinary tract. It affects about 20% of sexually active women and 10% of sexually active men. The infection usually involves only the vagina or urethra.

The disease occurs worldwide. In women, the condition may be acute or chronic. The prognosis is good, especially if both sexual partners receive treatment concurrently; otherwise, the disease may recur. Symptoms may subside even if the disease isn't treated, although *Trichomonas vaginalis* infection persists, possibly resulting in abnormal cytologic cervical smears.

Causes

A tetraflagellated, motile protozoan, *T. vaginalis* causes trichomoniasis in women by infecting the vagina, the urethra and, possibly, the endocervix, Bartholin's glands, Skene's glands, and bladder. In men, it infects the lower urethra and, possibly, the prostate gland, seminal vesicles, and epididymis.

The organism grows best when the vaginal mucosa is more alkaline than normal (pH about 5.5 to 5.8). Factors that raise the vaginal pH—use of oral contraceptives, pregnancy, bacterial overgrowth, exudative cervical or vaginal lesions, and frequent douching, which disturbs lactobacilli that normally live in the vagina and maintain acidity—may predispose women to trichomoniasis.

Trichomoniasis usually is transmitted by intercourse; less often, it is transmitted by contaminated douche equipment and moist washcloths. An infected mother may transmit the infection to her newborn child through vaginal delivery.

Complications

Chronic trichomoniasis may lead to significant vaginal infection with mucosal irritation and erosion. Pelvic inflammatory disease also may occur.

Assessment findings

The patient's history may reveal unprotected sexual contact with an infected partner, a previous sexually transmitted disease, or a current sexually transmitted disease. About 70% of women, including those with chronic infections, and most men with trichomoniasis are asymptomatic.

A female patient with signs and symptoms may complain of vaginal discharge, severe itching, vulvovaginal irritation, dyspareunia, dysuria, urinary frequency and, occasionally, postcoital spotting, menorrhagia, and dysmenorrhea. These signs and symptoms may persist for a week to several months and may be more pronounced just after menstruation or during pregnancy. A male patient may complain of dysuria and urinary frequency.

In a female patient, your inspection may reveal vulvar and vaginal erythema and edema, frank excoriation, and a copious gray or greenish-yellow, malodorous, and possibly profuse and frothy discharge that usually can be seen in the posterior vaginal fornix.

Diagnostic tests

Direct microscopic examination of vaginal or seminal discharge confirms the diagnosis when it reveals *T. vaginalis*, a motile, pear-shaped organism. Examination of urine specimens also may reveal *T. vaginalis*.

Cervical examination by colposcopy may demonstrate punctate cervical hemorrhages, giving the cervix a strawberry appearance that is almost pathognomonic for this disorder. Visual inspection seldom reveals this sign.

Treatment

Oral metronidazole given simultaneously to both sexual partners effectively cures trichomoniasis. The recommended dosage is 250 mg of oral metronidazole given three times a day for 7 days or one 2-g oral dose.

Oral metronidazole hasn't been proven safe during the first trimester of pregnancy. A pregnant patient in the first trimester may insert a clotrimazole vaginal tablet at bedtime for 7 days for symptomatic relief. Sitz baths may help relieve symptoms.

Nursing diagnoses

- u Altered sexuality patterns u Altered urinary elimination u Anxiety u Impaired skin integrity u Pain u Sexual dysfunction

Key outcomes

- u The patient will maintain fluid balance; intake will equal output.
- u The patient will express a feeling of increased comfort.
- u The patient will express understanding of the treatment.
- u Complications will be minimized or prevented.
- u The patient will discuss the impact of the disorder on self and significant others.
- u The patient will acknowledge a problem or potential problem in sexual function.

Nursing interventions

- u Institute standard precautions when examining the patient or collecting specimens.
- u Administer sitz baths to relieve discomfort.
- u If the patient is pregnant, make sure she receives adequate treatment before delivery to prevent the neonate from contracting the infection.
- u Encourage the patient to notify sexual partners so that they can be checked for the disease.

Patient teaching

- u Instruct the patient not to douche before being examined for trichomoniasis.
- u To help prevent reinfection during treatment, urge abstinence from intercourse and encourage the use of condoms. Refer sexual partners for treatment even if they're asymptomatic.
- u If vaginal tablets are ordered, teach the patient the correct way to insert them.
- u Warn the patient to abstain from alcoholic beverages while taking metronidazole and for at least 3 days after he has finished taking it. Alcohol consumption may

- provoke a disulfiram-like reaction (confusion, headache, cramps, vomiting, and seizures). Also, tell the patient this drug may turn his urine dark brown.
- u Instruct the patient to notify the doctor if signs of candidal superinfection occur.
 - u Caution the patient to avoid douches and vaginal sprays because chronic use can alter vaginal pH.
 - u Tell the patient to scrub the bathtub with a disinfecting cleanser before and after sitz baths.
 - u Inform the patient that she can reduce the risk of genitourinary bacterial growth by wearing loose-fitting cotton underwear that allows ventilation. Bacteria flourish in a warm, dark, moist environment.

Helminths

Helminthic disorders result from infection with parasitic worms, such as the fluke, tapeworm, and roundworm. Examples of helminthic disorders range from ascariasis to trichinosis.

ASCARIASIS

Ascariasis (roundworm infection) is the most common helminthic infection. It occurs worldwide but is most common in tropical areas with poor sanitation and in areas where farmers use human stool as fertilizer. In the United States, it's more prevalent in the South, particularly among children younger than age 12.

Causes and pathophysiology

Ascariasis is caused by *Ascaris lumbricoides*, a large roundworm that resembles an earthworm. It's transmitted to humans by ingestion of soil contaminated with human stool that harbor *A. lumbricoides* ova. Ingestion may occur directly (by eating contaminated soil) or indirectly (by eating poorly washed raw vegetables grown in contaminated soil).

After ingestion, *A. lumbricoides* ova hatch and release larvae, which penetrate the intestinal wall and reach the lungs through the bloodstream. After about 10 days in pulmonary capillaries and alveoli, the larvae migrate to the bronchioles, bronchi, trachea, and epiglottis. There they are swallowed and returned to the intestine to mature into worms.

Complications

Ascariasis may lead to biliary or intestinal obstruction and pulmonary disease.

Assessment findings

The patient's history may reveal ingestion of poorly washed raw vegetables grown in contaminated soil. Most patients with ascariasis are asymptomatic. Some patients exhibit pulmonary symptoms, such as transitory coughing.

Mild intestinal infection may cause only vague stomach discomfort. The first clue may be vomiting a worm or passing a worm in the stool. Severe infection results in stomach pain, vomiting, restlessness, disturbed sleep and, in extreme cases, intestinal obstruction. Fever may occur when larvae are migrating through the lungs.

Inspection eventually may reveal weight loss and impaired growth. Bowel sounds may be hyperactive above the obstruction and diminished or absent below the obstruction. Auscultation of the chest may detect wheezing.

Palpation of the abdomen may reveal distention.

Diagnostic tests

The key to diagnosis is identifying ova in the stools, or adult worms, which may be passed rectally or by mouth.

Treatment

Anthelmintic therapy, the primary treatment, uses mebendazole or albendazole. These are contraindicated in pregnancy and in heavy infections, in which ectopic migration can occur. Pyrantel pamoate and piperazine are safe in pregnancy.

In intestinal obstruction, nasogastric (NG) suctioning controls vomiting. When suctioning can be discontinued, instill piperazine and clamp the nasogastric tube. If this is ineffective, surgery is probably needed. Endoscopic retrograde cholangiopancreatography and papillectomy may be required for helminth removal.

Nursing diagnoses

u Altered growth and development u Altered nutrition: Less than body requirements u Colonic constipation u Hyperthermia u Ineffective breathing pattern u Knowledge deficit u Pain u Risk for fluid volume deficit u Risk for infection

Key outcomes

- u The patient will remain afebrile.
- u The patient's elimination pattern will return to normal.
- u The patient will demonstrate appropriate skills and behaviors to the extent possible.
- u The patient will experience no further weight loss.
- u The patient's respiratory rate will be maintained within 5 breaths of baseline.
- u The patient's fluid volume will remain within acceptable range.

Nursing interventions

- u Although isolation is unnecessary, properly dispose of stool and soiled linen, and carefully wash your hands after patient contact.
- u If the patient is receiving NG suction, be sure to provide mouth care.
- u Maintain NG tube patency, and check for secretion returns every 4 hours.
- u Administer antipyretics and give tepid sponge baths to reduce fever.
- u Monitor respiratory status and administer oxygen or assist ventilation if pulmonary complications develop.
- u Question family members and other contacts about symptoms. Weigh the patient daily and monitor intake and output. Replace fluids as needed. Provide a nutritionally adequate diet and administer nutritional supplements, as prescribed. Administer anthelmintic drug therapy as ordered. Monitor NG tube aspirate to ensure drug absorption.

Patient teaching

- u Teach the patient to prevent reinfection by washing hands thoroughly, especially before eating and after defecating, and by bathing and changing underwear and bed linens daily.
- u Inform the patient of drug adverse effects. Tell him that piperazine may cause stomach upset, dizziness, and urticaria. Remember, piperazine is contraindicated in patients with seizure disorders. Pyrantel produces red stools and vomitus and may cause stomach upset, headache, dizziness, and rash; mebendazole may cause

abdominal pain and diarrhea.

ENTEROBIASIS

A benign intestinal disease, enterobiasis has several other names, including oxyuriasis and pinworm and seatworm infection. Found worldwide, this disease is common even in temperate regions with good sanitation. More than 40 million Americans are estimated to be infected; it's especially prominent among school children.

Infection and reinfection most often occurs in children between ages 5 and 14 and in certain institutionalized groups because of poor hygiene and frequent hand-to-mouth activity. Crowded living conditions commonly enhance its spread to several members of a family.

Causes

Enterobiasis is caused by the nematode *Enterobius vermicularis*. Adult pinworms live in the intestine until the female worms migrate to the perianal region to deposit their ova.

Direct transmission occurs when the patient's hands transfer infective eggs from the anus to the mouth. *Indirect transmission* occurs when the patient comes in contact with contaminated articles, such as linens and clothing.

Complications

Complications are uncommon but may include salpingitis, appendicitis, bowel ulceration, and pelvic granuloma.

Assessment findings

The patient's history may reveal contact with an infected person or infected articles.

Enterobiasis may be overlooked when it causes no symptoms. In symptomatic infection, the patient complains of intense perianal pruritus, especially at night, when the female worm crawls out of the anus to deposit ova. The pruritus causes the patient to wake up and scratch, disturbing his sleep and causing irritability. He usually doesn't have a fever.

Inspection may reveal perianal erythema and irritation.

Heavy infections can result in abdominal pain and weight loss.

Diagnostic tests

Identification of *Enterobius* ova recovered from the perianal area with a cellophane tape swab confirms the diagnosis. A stool sample usually is ova- and worm-free because these worms deposit the ova outside the intestine and die after migration to the anus.

Treatment

Drug therapy with pyrantel pamoate or mebendazole destroys these parasites. Effective eradication requires simultaneous treatment of family members and, in facilities, other patients.

Nursing diagnoses

u Impaired skin integrity u Pain u Risk for infection u Sleep pattern disturbance

Key outcomes

- u The patient will experience no skin breakdown.
- u The patient will achieve adequate food and fluid intake.
- u The patient will maintain adequate skin circulation.
- u The patient will express relief from pain.
- u The patient will show no physical signs that indicate sleep deprivation.

Nursing interventions

- u Obtain a specimen for evaluation. Place cellophane tape—sticky side out—on the base end of a test tube, and roll the tube around the perianal region. Make sure you collect the sample before the patient bathes and defecates in the morning. Then send the tape for examination under a microscope.
- u Administer drugs, as ordered, to combat infection and relieve distressing symptoms.
- u Before giving the tablet form of pyrantel, make sure the patient isn't sensitive to aspirin. The tablet has an aspirin coating.
- u As warranted, follow up on others who have come in contact with the patient.
- u Report all outbreaks of enterobiasis to school authorities.

Patient teaching

- u To help prevent the spread of this disease, tell parents to bathe their children daily (showers are preferable to tub baths) and to change underwear and bed linens daily.
- u Teach a child with the disease about proper personal hygiene, and stress the need for careful hand washing after defecation and before handling food. Discourage nail biting. If the child can't stop, suggest that he wear gloves until the infection clears.
- u If the patient receives pyrantel, tell him and his family that this drug colors the stool bright red and may cause vomiting; the vomitus also will be red.

HOOKWORM DISEASE

Hookworm disease (also called uncinariasis), a helminthic infection of the upper intestine, is chronic and debilitating. The disease's major sign is anemia. Sandy soil, high humidity, a warm climate, and failure to wear shoes all favor its transmission.

Hookworm disease is present in one-fourth of the world's population. Although it can cause cardiopulmonary complications, it's seldom fatal, except in debilitated people and in infants.

Causes

Hookworm disease is caused by *Ancylostoma duodenale* in southern Europe, North Africa, and northern Asia, and *Necator americanus* in the Western Hemisphere and equatorial Africa. Both forms of hookworm disease are transmitted to humans through direct skin penetration (usually in the foot) by hookworm larvae in soil contaminated with stool that contain hookworm ova. These ova develop into infectious larvae in 1 to 3 days.

Larvae travel through the lymphatic system to the pulmonary capillaries, where they penetrate alveoli and move up the bronchial tree to the trachea and epiglottis. There they are swallowed and enter the GI tract. When they reach the small intestine, they mature, attach to the jejunal mucosa, and suck blood, oxygen, and glucose from the intestinal wall. These mature worms then deposit ova, which are excreted in the stool, starting the cycle anew. Hookworm larvae mature in 5 to 6 weeks.

Complications

In severe and chronic infection, anemia from blood loss may lead to cardiomegaly (a result of increased oxygen demands), heart failure, and generalized, massive edema.

Assessment findings

The patient may report that he recently walked barefoot in an area with contaminated soil. He may have few symptoms, and the disease may be overlooked until the worms are passed in the stool. The earliest findings are irritation and pruritus at the entry site. Most patients are asymptomatic.

When the larvae reach the lungs, the patient may complain of sore throat and cough, possibly productive of bloody sputum. When intestinal infection occurs, he may report fatigue, nausea, weight loss, dizziness, uncontrolled diarrhea, and black, tarry stool. Fever occurs when larvae migrate through the lungs.

Inspection may reveal edema and an erythematous papulovesicular rash at the entry site. You also may observe irregular respirations during the migration of larvae through the lungs. Other possible signs include weight loss and growth retardation.

Auscultation of the chest may reveal crackles as larvae migrate through the lungs.

Diagnostic tests

Identification of hookworm ova in a stool smear confirms the diagnosis. Anemia suggests severe chronic infection. In an infected patient, blood studies show:

- u hemoglobin level of 5 to 9 g/dl (in a severe case)
- u white blood cell count as high as 47,000/mm³
- u eosinophil count of 500 to 700/mm³.

Treatment

Mebendazole or pyrantel pamoate is prescribed for hookworm infection. The patient also needs an iron-rich diet or iron supplements to prevent or correct anemia.

Nursing diagnoses

- u Altered growth and development
- u Altered nutrition: Less than body requirements
- u Diarrhea
- u Fatigue
- u Impaired gas exchange
- u Ineffective breathing pattern
- u Risk for infection

Key outcomes

- u The patient will demonstrate appropriate skills and behaviors to the extent possible.
- u The patient will experience no further weight loss.
- u The patient will avoid episodes of diarrhea.
- u The patient will verbally report having an increased energy level.
- u The patient will express a feeling of comfort with respirations.
- u The patient's respiratory rate will be maintained within 5 breaths of baseline.

Nursing interventions

- u If the patient has confirmed hookworm infestation, institute standard stool precautions, wear gloves, and wash your hands thoroughly after every patient contact. Promptly dispose of stool.
- u If the patient has severe anemia, administer humidified oxygen, if ordered, at a low to moderate flow. (Humidification helps the patient with upper airway irritation from the parasites.) Encourage coughing and deep breathing to stimulate removal of blood or secretions from involved lung areas and to prevent secondary infection.
- u Plan your care to allow frequent rest periods because the patient may tire easily. If anemia causes immobility, reposition him often to prevent skin breakdown.
- u Closely monitor the patient's intake and output. Note the quantity and frequency of diarrheal stools.
- u To help assess nutritional status, weigh the patient daily. To combat malnutrition, emphasize the importance of good nutrition, particularly foods high in iron and protein. If the patient receives iron supplements, explain that they'll darken his stools.
- u Administer anthelmintics on an empty stomach.
- u Interview the family and other close contacts to see if they have any symptoms.

Patient teaching

- u To help prevent reinfection, teach the patient proper hand-washing technique and sanitary disposal of stool. Tell him to wear shoes in endemic areas.

SCHISTOSOMIASIS

Schistosomiasis, also called bilharziasis, is a slowly progressive disease that is increasing in incidence worldwide. It is most prevalent in agricultural areas in Asia, Africa, and South America.

The degree of infection determines the intensity of illness. If untreated, significant morbidity and even mortality can result.

Causes and pathophysiology

Schistosomiasis is caused by blood flukes of the class *Trematoda*. Three major types of these parasites exist: *Schistosoma mansoni* and *S. japonicum* infect the intestinal tract; *S. haematobium* infects the urinary tract.

These cercariae penetrate the skin or mucous membranes and eventually work their way to the liver's venous portal circulation. There, they mature in 1 to 3 months. The adults then migrate to other parts of the body.

The female cercariae lay spiny eggs in blood vessels surrounding the large intestine or bladder. After penetrating the mucosa of these organs, the eggs are excreted in stool or urine. If the eggs hatch in fresh water, the first-stage larvae (miracidia) penetrate freshwater snails, which act as passive intermediate hosts. Cercariae produced in snails escape into water and begin a new life cycle.

The parasite is transmitted through bathing, swimming, wading, or working in water contaminated with *Schistosoma* larvae, which are known as cercariae during their infective stage.

Complications

Portal hypertension, hepatosplenomegaly, pulmonary hypertension, ascites, and hematemesis from ruptured esophageal varices can all result from schistosomiasis, as can heart and renal failure, which are possibly fatal complications.

Rarely, central nervous system complications occur. Granulomatous reactions to the eggs may lead to urinary obstruction or bladder irregularities. Hydronephrosis occurs late in the disease.

Assessment findings in schistosomiasis		
ORGANISM	INCIDENCE	ASSESSMENT FINDINGS
<i>Schistosoma japonicum</i>	Affects men more than women; particularly prevalent among farmers in Japan, China, and the Philippines	May cause acute infection, with sudden onset of fever, chills, headache, and cough. Palpation may reveal such complications as hepatosplenomegaly and lymphadenopathy.
<i>S. mansoni</i>	Prevalent in Western hemisphere, particularly Puerto Rico, Lesser Antilles, Brazil, and Venezuela; also occurs in the Nile delta, Sudan, and central Africa	May cause chronic infection, with irregular fever, fatigue related to anemia, abdominal pain, intermittent diarrhea, and weight loss. If liver involvement develops, palpation reveals hepatomegaly followed by splenomegaly. Inspection may reveal hematemesis related to esophageal varices.
<i>S. haematobium</i>	Prevalent in Africa, Cyprus, Greece, and India	Causes terminal hematuria, dysuria, and ureteral colic with secondary infection (symptoms include colicky pain, intermittent flank pain, and vague GI complaints); may culminate in total renal failure.

Assessment findings

The patient's history may reveal travel to an endemic area or swimming in contaminated water. Signs and symptoms of schistosomiasis depend on the specific causative parasite, the infection site, and the disease stage. (See [Assessment findings in schistosomiasis](#), and [Schistosomal dermatitis](#).)

Diagnostic tests

The presence of ova in the urine or stool or a mucosal lesion biopsy confirms the diagnosis. A white blood cell count shows eosinophilia.

Treatment

The treatment of choice for all types of schistosomiasis is the anthelmintic drug praziquantel. The patient needs to be examined again 3 to 6 months after treatment. If this checkup detects any living eggs, treatment may be resumed.

Nursing diagnoses

u Altered nutrition: Less than body requirements u Diarrhea u Fatigue u Fluid volume deficit u Hyperthermia u Pain

Key outcomes

- u The patient's fluid volume will remain within acceptable range.
- u The patient's elimination pattern will return to normal.
- u The patient will verbally report having an increased energy level.
- u The patient will experience no further weight loss.
- u The patient will remain afebrile.
- u The patient will express a feeling of comfort and relief from pain.

Nursing interventions

- u Plan your care to allow for sufficient rest periods. During the acute stage, the patient may need bed rest.
- u Monitor the frequency of the patient's bowel movements and the characteristics of his stools, his intake and output, and his daily weight. If his urinary tract is involved, monitor his frequency of urination and the color and amount of urine.
- u Replace fluids as needed, and provide adequate, nutritionally balanced meals. Administer nutritional supplements as needed.
- u Assess the patient for bleeding and anemia. Also check his blood work.
- u Administer anthelmintics, analgesics, and antipyretics as ordered.

Patient teaching

- u Explain the medication regimen to the patient.

Schistosomal dermatitis
Commonly called swimmers' itch or clam diggers' itch, schistosomal dermatitis affects those who bathe in and camp along freshwater lakes in the eastern and western United States. It's caused by schistosomal cercariae harbored by migratory birds.
The cercariae can penetrate the skin, causing a pruritic papular rash. Initially mild, the reaction grows more severe with repeated exposure. Treatment consists of 5% copper sulfate solution as an antipruritic and 2% methylene blue as an antibacterial agent.

- u Inform the patient about the need for follow-up testing. He should have stool specimens examined 1 to 2 months after therapy ends.
- u To help prevent the spread of schistosomiasis, teach the patient to avoid contaminated water.
- u If the patient lives in an endemic area, explain the importance of working toward getting the local water supply purified. If he must enter this water, tell him to wear protective clothing and to dry himself afterward.

STRONGYLOIDIASIS

Strongyloidiasis (threadworm infection) is a parasitic intestinal infection that occurs worldwide. It's endemic in the tropics and subtropics as well as areas associated with poor hygiene. Outbreaks also occur in facilities. Its incidence in the United States is low.

Susceptibility to strongyloidiasis is universal; infection doesn't confer immunity. Because the reproductive cycle of the threadworm may continue in the untreated host for as long as 45 years after the initial infection, autoinfection is highly probable.

Most patients with strongyloidiasis recover completely, but debilitation from protein loss occasionally is fatal. Massive autoinfection, especially in immunocompromised patients, also can be fatal.

Causes and pathophysiology

Strongyloidiasis is caused by the helminth *Strongyloides stercoralis*. Transmission to humans usually occurs through contact with soil that contains infective *S. stercoralis* filariform larvae. Such larvae develop from noninfective rhabditoid (rod-shaped) larvae in human stool. The filariform larvae penetrate the human skin, usually at the feet, and then migrate by way of the lymphatic system to the bloodstream and the lungs.

After they enter the pulmonary circulation, the filariform larvae break through the alveoli and migrate upward to the pharynx, where they are swallowed. Then they lodge in the small intestine, where they deposit eggs that mature into noninfective rhabditoid larvae. Next, these larvae migrate into the large intestine and are excreted in stool, starting the cycle again. The threadworm life cycle, which begins with penetration of the skin and ends with excretion of rhabditoid larvae, takes 17 days.

In autoinfection, rhabditoid larvae mature in the intestine to become infective filariform larvae.

Complications

If the infection is severe, malnutrition from substantial fat and protein loss, anemia, and lesions resembling ulcerative colitis may result in a secondary bacterial infection. Ulcerated intestinal mucosa may lead to perforation.

Possibly fatal septicemia and massive invasion of organs can occur. These effects of autoinfection are most likely to develop in immunocompromised patients. (See [Signs of disseminated strongyloidiasis.](#))

Assessment findings

The patient's history may reveal an immunocompromised state or institutionalization. The patient may report walking in contaminated soil without shoes.

The patient may be asymptomatic, or he may complain of a cough during the stage of larval migration through the lungs. After that, he may complain of such intestinal symptoms as colicky abdominal pain and diarrhea. He also may develop fatigue, weakness, and weight loss. During the pulmonary stage, he may have a fever.

During inspection, you may note an erythematous, pruritic, papular rash at the entrance site, particularly the feet. The rash may become generalized.

Auscultation may reveal normal or hyperactive bowel sounds. You also may hear crackles during the pulmonary stage.

Diagnostic tests

Observation of *S. stercoralis* larvae in a fresh stool specimen allows diagnosis (2 hours after excretion, rhabditoid larvae look like hookworm larvae). Repeated testing may be needed. During the pulmonary phase, sputum may show many eosinophils and larvae.

Treatment

Because of the potential for autoinfection, the patient needs treatment with thiabendazole for 2 to 3 days. The total dose shouldn't exceed 3 g. He also may need protein replacement, blood transfusions, and I.V. fluids.

Treatment is necessary if *S. stercoralis* remains in stools after therapy. Corticosteroids are contraindicated because they increase the risk of autoinfection and dissemination and also predispose the patient to GI ulceration.

Nursing diagnoses

- u Altered nutrition: Less than body requirements
- u Diarrhea
- u Ineffective breathing pattern
- u Pain
- u Risk for fluid volume deficit
- u Risk for infection

Key outcomes

- u The patient's elimination pattern will return to normal.
- u The patient will experience no further weight loss.
- u The patient's respiratory rate will be maintained within 5 breaths of baseline.
- u The patient's arterial blood gas levels will return to normal.
- u The patient will express a feeling of comfort and relief from pain.
- u The patient's fluid volume will remain within normal range.

Nursing interventions

- u Monitor the patient's intake and output and daily weight, especially if treatment includes blood transfusions and I.V fluids. Ask the dietary department to provide a high-protein diet. The patient may need nutritional supplements or tube feeding to increase his caloric intake.
- u Assess the frequency of the patient's bowel movements and the characteristics of his stools.
- u Monitor serum protein levels.
- u Wear gloves when handling bedpans or giving perineal care, and promptly dispose of stool.
- u Because direct person-to-person transmission doesn't occur, the patient doesn't need isolation. However, label all stool specimens for the laboratory as contaminated.
- u Check the patient's family and close contacts for signs of infection.
- u If the patient has pulmonary infection, reposition him frequently; encourage incentive spirometry, coughing, and deep breathing; and administer oxygen as ordered.
- u Administer anthelmintic therapy as ordered.

WARNING

Signs of disseminated strongyloidiasis

Disseminated strongyloidiasis is a potentially fatal disease that occurs in immunocompromised patients, such as those with lymphoma, leukemia, lepromatous leprosy, or human immunodeficiency virus infection, and those taking corticosteroids.

If your patient is at risk for this disorder, be alert for severe generalized abdominal pain, diffuse pulmonary infiltrates, pericarditis, myocarditis, hepatic granulomas, cholecystitis, ileus, shock, and signs of meningitis or sepsis from gram-negative bacilli. (Diagnostic tests may not show eosinophilia.)

Patient teaching

- u Teach the patient about anthelmintic drug therapy.
- u Emphasize the need for follow-up stool examination, continuing several weeks after treatment.
- u Warn the patient that thiabendazole may cause mild nausea, vomiting, drowsiness, and giddiness.
- u To prevent reinfection, teach the patient proper hand-washing technique. Stress the importance of washing his hands before eating and after defecating, and of wearing shoes when in endemic areas.

TAENIASIS

Also called cestodiasis and commonly called tapeworm, taeniasis is a parasitic infection that can result from several types of parasites. The incidence of tapeworm infestation varies with the type.

Tapeworm usually is a chronic but benign intestinal disease. However, infestation with *Taenia solium* may cause dangerous systemic and central nervous system (CNS) symptoms if larvae invade the brain and striated muscle of vital organs. Tapeworm seldom is fatal unless it isn't treated.

Causes

Taeniasis is caused by *Taenia saginata* (beef tapeworm), *T. solium* (pork tapeworm), *Diphyllobothrium latum* (fish tapeworm), or *Hymenolepis nana* (dwarf tapeworm).

T. saginata, *T. solium*, and *D. latum* are transmitted to humans by ingestion of uncooked or undercooked beef, pork, or fish (such as pike, trout, salmon, and turbot) that contains tapeworm cysts. Gastric acids break down these cysts in the stomach, freeing them to mature. The mature tapeworms then fasten to the intestinal wall and produce ova that pass from the body in stool.

H. nana is transmitted directly from person to person and requires no intermediate host. It completes its life cycle in the intestine. Inadequate hand washing facilitates its spread.

Complications

Severe tapeworm infection can lead to dehydration and malnutrition.

Assessment findings

Signs and symptoms vary with the type of infestation. A patient with beef tapeworm may complain of a crawling sensation in the perianal area (caused by worm segments that have been passed rectally) and intestinal obstruction (the result of long worm segments that have twisted in the intestinal lumen).

Pork tapeworm can cause seizures, headache, and personality changes. A patient with fish tapeworm may experience signs and symptoms of anemia (his hemoglobin may drop as low as 6 to 8 g/dl).

The signs and symptoms of a patient with dwarf tapeworm depend on his nutritional status and the number of parasites. A patient with a mild infestation commonly has no symptoms. If the infestation is severe, he may complain of anorexia, diarrhea, restlessness, dizziness, and apathy.

Diagnostic tests

Observation of tapeworm ova or body segments in stool allows diagnosis of a tapeworm infestation. Because ova aren't excreted continuously, confirmation may require multiple specimens.

Treatment

Administration of praziquantel cures up to 95% of patients. In beef, pork, and fish tapeworm infestation, the patient receives the drug once; in severe dwarf tapeworm infestation, twice (5 to 7 days each, spaced 2 weeks apart).

After drug treatment, all types of tapeworm infestation require follow-up stool specimens during the next 3 to 5 weeks to check for remaining ova or worm segments. Persistent infestation requires a second course of medication.

Nursing diagnoses

- u Altered nutrition: Less than body requirements u Altered tissue perfusion (GI) u Diarrhea u Risk for fluid volume deficit u Risk for infection

Key outcomes

- u The patient's elimination pattern will return to normal.
- u The patient will experience no further weight loss.
- u The patient's fluid volume will remain within acceptable range.
- u The patient's intake and output will remain within normal limits.
- u Nausea and vomiting will be eliminated.
- u The patient's vital signs will remain stable.

Nursing interventions

- u Carefully dispose of the patient's excretions. Wear gloves when providing personal care and handling excretions, bedpans, and bed linens. Afterward, wash your hands thoroughly and make sure the patient does the same.
- u Ask the patient for a list of people he has had contact with. If possible, advise them to seek medical attention to determine if they're infected.
- u Document the patient's level of consciousness, and report any changes immediately. If he develops CNS symptoms, keep an artificial airway or padded tongue blade close at hand, raise side rails, keep the bed low, and help him with walking, as needed.
- u Monitor intake and output and nutritional status. Replace fluids as needed. Offer a nutritionally adequate diet and administer supplements, as prescribed.

Patient teaching

- u To prevent reinfection, teach the patient proper hand-washing technique and the need to cook meat and fish thoroughly. Stress the need for follow-up evaluations to monitor the success of therapy and to detect possible reinfection.

TRICHINOSIS

Also called trichiniasis and trichinelliasis, trichinosis is a chronic infection that occurs worldwide. It's especially common in populations that eat pork or bear meat.

Trichinosis may produce multiple symptoms; respiratory, central nervous system (CNS), and cardiovascular complications; and, rarely, death. In the United States

trichinosis usually is mild.

Causes

Trichinosis is caused by larvae of the intestinal roundworm *Trichinella spiralis*. Transmission occurs through ingestion of uncooked or undercooked meat that contains *T. spiralis* cysts. Such cysts are found primarily in swine and less often in dogs, cats, bears, horses, wild boars, foxes, wolves, and marine animals. These cysts result from the animals' ingestion of similarly contaminated flesh. In swine, eating table scraps or raw garbage causes such infection. Human-to-human transmission doesn't occur.

After the *T. spiralis* cyst enters the body, gastric juices free the worm from the cyst capsule. It reaches sexual maturity in a few days. Then the female roundworm burrows into the intestinal mucosa and reproduces. The larvae are transported through the lymphatic system and the bloodstream. They become embedded as cysts in striated muscle, especially in the diaphragm, chest, arms, and legs.

Complications

Trichinosis can cause such complications as encephalitis, myocarditis, pneumonia, and respiratory failure.

Assessment findings

The patient's history may reveal ingestion of uncooked or undercooked meat, especially pork. Most patients are asymptomatic. Even when symptoms do occur, their frequency and severity vary.

During the first week, the patient may complain of intestinal symptoms, most commonly diarrhea. He also may report other symptoms, such as abdominal discomfort and vomiting.

During the second week, the patient may complain of systemic symptoms, most prominently muscle pain. He also may experience headache, weakness, fatigue, cough, shortness of breath, and dysphagia. His temperature usually is elevated, ranging from 102° to 104° F (38.9° to 40° C).

With the appearance of systemic symptoms, inspection may reveal periorbital edema, possibly related to subconjunctival hemorrhages, and chemosis. You'll occasionally observe retinal hemorrhage. You may note a rash, along with edema in affected muscles (including the eye, masseter, neck, and lumbrical muscles as well as limb flexors).

Diagnostic tests

Infection may be difficult to prove. The patient's history is important to the diagnosis, particularly regarding the ingestion of pork or wild animal meats (and identifying individuals who consumed meat from the same source). Symptoms from a presumptive diagnosis and an increase of parasite-specific antibodies (assayed by bentonite flocculation test) confirm the diagnosis. Skeletal muscle biopsies can show encysted larvae 10 days after ingestion. If a sample of the contaminated meat is available, analysis also shows larvae.

Elevated acute and convalescent antibody titers (determined by flocculation tests 3 to 4 weeks after infection) confirm the diagnosis.

Blood eosinophilia occurs in 90% of symptomatic patients. Other abnormal test results include elevated serum alanine aminotransferase, aspartate aminotransferase, creatine kinase, and lactate dehydrogenase levels and an elevated eosinophil count (up to 15,000/mm ³) during the acute stages. A normal or increased lymphocyte level (up to 300/mm³) and increased protein levels in cerebrospinal fluid indicate CNS involvement.

Treatment

Current anthelmintic drugs are ineffective against trichinella larvae in muscle. Mebendazole is active against the enteric stages of the parasite. Glucocorticoids are beneficial in severe myosites and myocarditis. This disease usually is self-limiting, and complete recovery occurs within a few months.

Supportive therapy, such as bed rest, administration of salicylates, and physical therapy to maintain and enhance muscle function, usually proves effective.

If symptoms persist for several years, the patient may need mebendazole therapy. He'll need corticosteroids only if he has a fever, allergic symptoms, leukocytosis, and eosinophilia.

Nursing diagnoses

- u Activity intolerance
- u Diarrhea
- u Hyperthermia
- u Impaired physical mobility
- u Impaired skin integrity
- u Impaired swallowing
- u Ineffective breathing pattern
- u Pain
- u Risk for fluid volume deficit
- u Sensory or perceptual alterations (visual)

Key outcomes

- u The patient's elimination pattern will return to normal.
- u The patient will express a feeling of comfort and relief from pain.
- u The patient will avoid skin breakdown or infection.
- u The patient's fluid volume will remain within acceptable range.

PREVENTION

Preventing trichinosis

To help prevent trichinosis, teach patients about correct cooking and storing methods, not only for pork and pork products, but also for meat from carnivores. To kill trichinae, internal meat temperatures should reach 150° F (66° C), and meat color should change from pink to gray (unless the meat has been cured or frozen for at least 10 days at low temperatures).

Warn travelers to other countries or to poor areas in the United States to avoid eating pork. Swine in these areas often are fed raw garbage.

- u The patient will verbally report having an increased energy level.
- u The patient will maintain muscle strength and joint range-of-motion.

Nursing interventions

- u Reduce the patient's fever with tepid baths, cooling blankets, or antipyretics. Relieve muscle pain with analgesics, bed rest, and proper body alignment.
- u If the patient has a fever, vomiting, and diarrhea, monitor his intake and output and daily weight. Replace fluids as needed.
- u Provide skin care after bowel movements to prevent excoriation.

- u To prevent pressure sores, frequently reposition the patient and gently massage bony prominences.
- u Assess the patient's respiratory status. Administer oxygen and assist respiration as needed.
- u Encourage the patient to exercise to maintain muscle strength and function.
- u Provide safety measures for the visually impaired patient, and assist with mobility during convalescence.
- u Report all cases of trichinosis to local public health authorities.

Patient teaching

- u Explain the importance of bed rest. Sudden death from cardiac involvement may occur in a patient with moderate to severe infection who has resumed activity too soon. Warn the patient to continue bed rest into the convalescent stage to avoid a serious relapse and, possibly, death. (See [Preventing trichinosis.](#))

Miscellaneous infections

This category includes chlamydial infections, chronic fatigue and immune dysfunction syndrome, and vancomycin-resistant enterococcus.

CHLAMYDIAL INFECTIONS

Urethritis in men, cervicitis in women, and—much less commonly in the United States—lymphogranuloma venereum in both sexes all result from chlamydial infections. And all are linked to one organism: *Chlamydia trachomatis*. These infections are the most common sexually transmitted diseases in the United States. (See [Chlamydia trachomatis.](#))

Children born of infected mothers may contract associated otitis media, pneumonia, and trachoma inclusion conjunctivitis during passage through the birth canal. Although trachoma inclusion conjunctivitis seldom occurs in the United States, it's a leading cause of blindness in Third World countries.

Causes

Transmission of *C. trachomatis*, an intracellular obligate bacterium, primarily follows vaginal or rectal intercourse or oral-genital contact with an infected person. Because signs and symptoms of chlamydial infections commonly appear late in the course of the disease, sexual transmission of the organism occurs unknowingly.

Complications

Untreated, chlamydial infections can lead to acute epididymitis, salpingitis, pelvic inflammatory disease (PID) and, eventually, sterility. In pregnant women, chlamydial infections are associated with spontaneous abortion, premature rupture of membranes, premature delivery, and neonatal death, although a direct link with *C. trachomatis* hasn't been established.

Complications of lymphogranuloma venereum include urethral and rectal strictures, perirectal abscesses, and rectovesical-rectovaginal and ischiorectal fistulas. Elephantiasis with enlargement of the penis or vulva occasionally occurs.

Assessment findings

The patient may have a history of unprotected sexual contact with an infected person, an unknown partner, or multiple sex partners. He also may have another sexually transmitted disease or had one in the past.

Symptoms vary with the specific type of chlamydial infection; many patients have no symptoms. If the patient has cervicitis, she may complain of pelvic pain and dyspareunia. If PID develops, she may report severe abdominal pain, nausea, vomiting, fever, chills, breakthrough bleeding, and bleeding after intercourse. A woman with urethral syndrome may experience dysuria and urinary frequency.

A male patient with urethritis may complain of dysuria, urinary frequency, and pruritus. If epididymitis develops, he may complain of severe scrotal pain. Prostatitis may cause lower back pain, urinary frequency, dysuria, nocturia, and painful ejaculation.

If the infection involves the rectum, the patient may complain of diarrhea, tenesmus, and pruritus.

A patient with lymphogranuloma venereum may have such systemic signs and symptoms as myalgia, headache, weight loss, backache, fever, and chills.

Inspection by speculum of the patient with cervicitis may reveal cervical erosion and mucopurulent discharge.

Inspection of a male patient with urethritis may disclose urethral discharge, which may be copious and purulent, and meatal erythema. If he develops epididymitis, you'll note scrotal swelling and urethral discharge.

In a patient with proctitis, you may note mucopurulent discharge and diffuse or discrete ulceration in the rectosigmoid colon. Inspection of a patient with lymphogranuloma venereum may reveal a primary lesion—a painless vesicle or nonindurated ulcer. Such an ulcer usually is 2 to 3 mm in diameter and occurs on the glans or shaft of the penis; on the labia, vagina, or cervix; or in the rectum. It commonly goes unnoticed.

If a female patient with cervicitis develops PID, palpation reveals tenderness over the lower quadrant, abdominal distention and, sometimes, rigidity.

Palpation of a patient with lymphogranuloma venereum may reveal enlarged inguinal lymph nodes, especially in a male patient. These nodes may become fluctuant, tender masses. Regional nodes draining the initial lesion may enlarge and appear as a series of bilateral buboes. Untreated buboes may rupture and form sinus tracts that discharge a thick, yellow, granular secretion. The patient eventually may develop a scar or an indurated inguinal mass.

Chlamydia trachomatis

In chlamydial infections, microscopic examination reveals *Chlamydia trachomatis*, a unicellular parasite with a rigid cell wall.

Diagnostic tests

Laboratory tests provide definitive diagnosis of chlamydial infection. A swab culture from the infection site (urethra, cervix, or rectum) usually establishes urethritis, cervicitis, salpingitis, endometritis, and proctitis. Culture of aspirated blood, pus, or cerebrospinal fluid establishes epididymitis, prostatitis, and lymphogranuloma venereum.

If the infection site is accessible, the doctor may first attempt direct visualization of cell scrapings or exudate with Giemsa stain or fluorescein-conjugated monoclonal antibodies. However, tissue cell cultures are more sensitive and specific.

Serologic studies to determine previous exposure to *C. trachomatis* include complement fixation tests and immunofluorescence microscopy. The enzyme-linked immunosorbent assay detects the *C. trachomatis* antibody as effectively as the immunofluorescence microscopy test and is useful as a screening test.

Treatment

The recommended treatment for chlamydial infection consists of doxycycline or tetracycline. The patient can receive ofloxacin or azithromycin.

A patient with lymphogranuloma venereum needs extended treatment.

Nursing diagnoses

u Altered sexuality patterns u Altered urinary elimination u Impaired skin integrity u Pain u Risk for infection u Sexual dysfunction

Key outcomes

- u The patient will voice feelings about potential or actual changes in sexuality.
- u The patient will express concern about self-concept, esteem, and body image.
- u The patient will maintain fluid balance; intake will equal output.
- u The patient will exhibit improved or healed lesions or wounds.
- u The patient will express relief from pain.

Nursing interventions

- u Use standard precautions when examining the patient, giving patient care, and handling contaminated material. Properly dispose of all soiled dressings and contaminated instruments.
- u Monitor the patient for complications.
- u Examine and test the patient's sexual contacts for chlamydial infection.
- u Check the newborn infant of an infected mother for signs of infection. Take specimens for culture from the infant's eyes, nasopharynx, and rectum. Positive rectal cultures will peak by 5 to 6 weeks postpartum.
- u If required in your state, report all cases of chlamydial infection to local public health authorities for follow-up on sexual contacts. (The doctor or laboratory personnel may have done this already.)

Patient teaching

- u Teach the patient the dosage requirements of his prescribed medication. Stress the importance of taking all of his medication, even after symptoms subside.
- u Teach the patient to follow proper hygiene measures.
- u To prevent eye contamination, tell the patient not to touch any discharge and to wash his hands before touching his eyes.
- u To prevent reinfection during treatment, recommend that the patient abstain from intercourse, or encourage him to use condoms.
- u Urge the patient to inform sexual partners of his infection so that they can seek treatment also. Explain that they should receive treatment regardless of their test results.
- u Suggest that the patient and his sexual partners receive testing for the human immunodeficiency virus.
- u Tell the patient to return for follow-up testing.

CHRONIC FATIGUE AND IMMUNE DYSFUNCTION SYNDROME

Also called chronic fatigue syndrome, chronic Epstein-Barr virus, myalgic encephalomyelitis, and Yuppie flu, this syndrome is characterized by incapacitating fatigue. The patient's symptoms may wax and wane, but they're often severely debilitating and can last for months or years.

Although most prevalent among professionals in their 20s and 30s, the syndrome affects people of all ages, occupations, and income levels. The diagnosis is more common in women than in men or children, especially women under age 45. Sporadic incidence and epidemic clusters have been observed.

Causes

The precise cause of chronic fatigue syndrome isn't known. Although the cause originally was attributed to the Epstein-Barr virus, that hypothesis has since been rejected on the basis of serologic and epidemiologic observation.

Several other causative viruses have been proposed and investigated, including cytomegalovirus, herpes simplex virus types 1 and 2, human herpesvirus 6, Inoue-Melnick virus, human adenovirus 2, enteroviruses, measles virus, and a retrovirus that resembles human T-cell lymphotropic virus type II. The onset in some patients suggests a viral illness, but whether the syndrome results from a new or a reactivated infection isn't known.

Another theory holds that some symptoms may result from an overactive immune system. In addition, genetic predisposition, age, hormonal balance, neuropsychiatric

factors, sex, previous illness, environment, and stress appear to have a role in the syndrome.

Complications

Chronic fatigue syndrome causes few complications, but its debilitating nature greatly affects the patient's sense of well-being.

Assessment findings

The patient characteristically complains of prolonged, overwhelming fatigue, along with other signs and symptoms, including sore throat, myalgia, and cognitive dysfunction. The Centers for Disease Control and Prevention uses a working case definition to group symptoms and severity. (See [Diagnostic criteria in chronic fatigue syndrome.](#))

Diagnostic tests

No definitive test exists for this disorder. Diagnostic testing should include tests to rule out other illnesses, such as Epstein-Barr virus, leukemia, and lymphoma.

Some patients with chronic fatigue syndrome have reduced natural killer cell cytotoxicity, abnormal CD4:CD8 T-cell ratios, decreases in immunoglobulin subclasses, mild lymphocytosis, circulating immune complexes, and increased levels of antimicrosomal antibodies. But because these findings vary from patient to patient, they're of uncertain clinical significance.

A psychiatric screening may aid diagnosis because many patients have an underlying psychiatric disorder. Also, they commonly experience depression and anxiety after the syndrome's onset.

Treatment

Treatment focuses on supportive care. The patient with myalgia or arthralgia can benefit from non-steroidal anti-inflammatory drugs. A patient who sleeps excessively can receive an antidepressant such as fluoxetine. A patient who has trouble sleeping or who experiences pain may benefit from amitriptyline.

Nonsteroidal anti-inflammatory drugs may relieve headache, diffuse pain, and fever. Antihistamines can also help relieve symptoms. Psychiatric evaluation may be helpful. Unproved treatments should be avoided. Behavior therapy may be helpful.

Nursing diagnoses

- Activity intolerance
- Altered role performance
- Fatigue
- Pain
- Powerlessness
- Self-esteem disturbance
- Sleep pattern disturbance

Key outcomes

- The patient will verbally report having an increased energy level.
- The patient will express feelings about diminished capacity to perform usual roles.
- The patient will recognize limitations imposed by illness and express feelings about these limitations.
- The patient will make decisions regarding the course of treatment and management of the illness.
- The patient will voice feelings related to self-esteem.
- The patient will join in self-care and the decision-making process.
- The patient will report decreased pain.

Diagnostic criteria in chronic fatigue syndrome

Chronic fatigue is defined by the presence of:

- new or onset relapsing fatigue that isn't the result of ongoing exertion, alleviated by rest, and results in reduced occupational, educational, social, or personal activities or efforts.
- four or more of the following symptoms that occur for 6 months or more:
 - self-reported impairment in short-term memory or concentration
 - sore throat
 - tender cervical or axillary nodes
 - muscle pain
 - multiple joint pain without redness or swelling
 - headaches of a new pattern or severity
 - nonrefreshing sleep
 - postexertional malaise lasting 24 hours or longer.

Nursing interventions

- Give the patient emotional support through the often long period of diagnostic testing and the protracted, often debilitating course of illness.
- Refer the patient for counseling as needed and to a local support group, if available. Make sure that the group advocates helping the patient lead as normal a life as possible. If necessary, refer him to a mental health center or a career counselor.

Patient teaching

- Suggest that the patient decrease activities when his fatigue is greatest. But advise him to avoid bed rest, which has no proven therapeutic value. A graded exercise program, although often difficult for the patient to accept, may help him feel better. Stress the importance of starting with a short exercise period and slowly increasing exercise time.
- If the patient needs medication, explain the medication regimen. If the doctor prescribes an antidepressant, explain how the medication can help relieve other signs and symptoms, such as sleep pattern disturbances and appetite changes.
- Help the patient return to a normal lifestyle. Begin by helping him plan a gradual return to work.

VANCOMYCIN-RESISTANT ENTEROCOCCUS

Vancomycin-resistant enterococcus (VRE) is a mutation of a very common bacterium that is spread easily from person to person by direct contact. Facilities in more than 40 states have reported VRE, with rates as high as 14% in oncology units of large teaching facilities.

Patients most at risk for VRE include immunosuppressed patients and those with severe underlying disease; patients with a history of taking vancomycin, third-generation cephalosporins, or antibiotics targeted at anaerobic bacteria (such as *Clostridium difficile*); patients with indwelling urinary or central venous catheters; elderly patients, especially those with prolonged or repeated hospital admissions; patients with malignancies or chronic renal failure; patients undergoing cardiothoracic or intra-abdominal surgery or organ transplants; patients with wounds with an opening to the pelvic or intra-abdominal area, including surgical wounds, burns, and pressure ulcers; patients with enterococcal bacteremia, often associated with endocarditis; and patients exposed to contaminated equipment or to a

VRE-positive patient.

Causes

VRE enters a health care facility by way of an infected or colonized patient or colonized health care worker. VRE is spread through direct contact between the patient and caregiver or patient-to-patient. It can also be spread through patient contact with contaminated surfaces, such as an over-bed table. The organism is able to live for weeks on surfaces and has been detected on patients' gowns, bed linens, and handrails.

Complications

VRE can result in sepsis, multisystem dysfunction, and death in immunocompromised patients.

Assessment findings

There are no specific signs and symptoms of VRE. The causative agent may be found incidentally when culture results disclose the organism.

Diagnostic tests

Someone with no signs or symptoms of infection is considered colonized if VRE can be isolated from a stool sample or rectal swab. If colonized, a patient is more than 10 times more likely to become infected with VRE, such as through a breach in the immune system.

Treatment

There is no specific treatment at this time for eradicating VRE. Recently, the Centers for Disease Control and Prevention and the Hospital Infection Control Practices Advisory Committee proposed a two-level system of precautions to simplify isolation. The first level calls for standard precautions, which incorporate standard blood and body fluid precautions and body substance isolation precautions to be used for all patient care. The second level calls for transmission-based precautions, implemented when a particular infection is suspected.

To prevent the spread of VRE, some facilities perform weekly surveillance cultures on at-risk patients in intensive care units or oncology units and those who were transferred from long-term care facilities. Any colonized patient is then placed in contact isolation until cultures are negative or the patient is discharged. Colonization can last indefinitely, and no protocol is established for the length of time a patient should remain in isolation.

Because no single antibiotic currently available can eradicate VRE, the doctor may opt not to treat an infection at all in some cases. Instead, the doctor may stop all antibiotics and simply wait for normal bacteria to repopulate and replace the VRE strain. Combinations of various drugs may also be used, depending on the source of the infection.

Nursing diagnoses

u Altered tissue perfusion (cardiopulmonary) u Fluid volume deficit u Hyperthermia u Impaired tissue integrity u Pain

Key outcomes

- u The patient's collateral circulation will be maintained.
- u Hemodynamic stability will be maintained.
- u The patient's cardiac output will remain adequate.
- u The patient will remain afebrile.
- u The patient's fluid volume will remain adequate.

Nursing interventions

- u Consider grouping infected patients together and having the same nursing staff care for them.
- u Use contact isolation precautions when in contact with the patient. A private room and dedicated equipment should be used and the environment should be disinfected.
- u Wash hands before and after care of the patient. Good hand washing is the most effective way to prevent VRE from spreading. Use an antiseptic soap such as chlorhexidine because bacteria have been cultured from worker's hands after washing with milder soap.
- u Change gloves when contaminated or when moving from a soiled area of the body to a clean one.
- u Don't touch potentially contaminated surfaces, such as a bed or bed stand, after removing gown and gloves.
- u Equipment used on the patient shouldn't be laid on the bed or bed stand and should be wiped with appropriate disinfectant before leaving the room.
- u Be especially cautious in caring for a patient with an ileostomy, colostomy, or draining wound that isn't contained by a dressing.
- u Ensure judicious and careful use of antibiotics. Encourage physicians to limit the use of antibiotics.

Patient teaching

- u Provide teaching and emotional support to the patient and family members.
- u Instruct family and friends to wear protective garb when they visit the patient and show them how to dispose of it.
- u Instruct the patient to take antibiotics for the full prescription period, even if he begins to feel better.

INTRODUCTION

Trauma is the third leading cause of death in the United States, surpassed only by cardiovascular disease and cancer. In people under age 35, it's the leading cause of death.

There are three types of trauma:

- u *blunt trauma*, which leaves the body surface intact
- u *penetrating trauma*, which disrupts the body surface
- u *perforating trauma*, which leaves entrance and exit wounds as an object passes through the body.

The basic elements of trauma care include triage; assessing and maintaining the patient's airway, breathing, and circulation; protecting the cervical spine; assessing the patient's level of consciousness (LOC); and preparing the patient for transport and surgery *as necessary*.

Triage: First things first

Triage involves setting emergency care priorities by making sound, rapid assessments. Your assessments and subsequent interventions are based on the severity and number of injuries and on the availability of immediate and long-term resources, such as personnel to provide care and facilities to save the patient's life.

In triage, patients are classified according to the urgency of their needs and their likelihood of survival if treated. For instance, if mass casualties occur, some patients with massive injuries may not receive immediate care because the available personnel and facilities make survival unlikely.

The need for triage commonly arises at the scene of injury and continues in the emergency department. Following facility protocol, you may decide which patient to treat first, which of his injuries to treat first, how best to use other members of the medical team, and how to control patient and staff traffic.

Victims are usually assigned to one of the following categories:

- u *Emergent*. A patient in this category has a life-threatening injury that requires treatment within a few minutes to prevent death or further injury. The category covers patients with respiratory distress or cardiopulmonary arrest and severe hemorrhage or shock.
- u *Urgent*. A patient with a serious but not immediately life-threatening injury—a stable head, chest, or abdominal injury or a long-bone fracture—is included in this category. This patient should receive treatment within 1 hour.
- u *Delayed*. Included in this category is a patient who has a minor injury, such as a laceration or an abrasion, and can wait 4 to 6 hours for treatment.
- u *Indefinite*. A patient in this category can wait indefinitely for treatment or be referred to a clinic. In a disaster or military situation, this category also applies to any patient with massive injuries who has a marginal chance for recovery even with immediate, vigorous care.
- u *Deceased*.

When caring for a trauma victim, talk to him while giving care. Explain what you're going to do before you touch him. Also, try to handle difficult situations diplomatically and intelligently, recognize your limitations, and ask for help when you need it.

Keep in mind that trauma care takes its toll on you, too. In many cases, you must deal with patients and families who are emotionally upset, angry, belligerent, intoxicated, or frightened; some may speak only a foreign language. Remember to work calmly and rationally.

Begin with the ABCs

Always begin your care of an injured patient with a brief assessment of the ABCs: airway, breathing, and circulation. Obtain a brief history from the patient, family, friends, or medical personnel who saw the patient before he entered the facility.

To assess airway patency, check for respiratory distress or signs of obstruction, such as stridor, choking, and cyanosis. Be especially alert for respiratory distress in a patient who inhaled chemicals or was in a fire, particularly if he has upper body burns. If his airway is obstructed, first check the cervical alignment: He should have a secure and correctly sized cervical collar or cervical immobilization device (such as towel rolls on both sides of his head and tape across his forehead). Then remove the obstruction, such as vomitus, dentures, blood clots, or foreign bodies, from his mouth.

To open the airway, use a jaw-thrust maneuver. (Don't use the head-tilt maneuver for a trauma patient. Suspect cervical spine injury until X-rays rule it out.) Then insert an oropharyngeal or nasopharyngeal airway (except in a patient with massive facial trauma or possible basal skull fracture). As necessary, assist with endotracheal tube insertion or cricothyroidotomy. If rescue personnel inserted an esophageal obturator airway, leave it in place until the patient is intubated. This prevents the patient from aspirating if he vomits.

Next, make sure the patient's breathing is adequate. Look, listen, and feel for respirations: See if the patient's chest is rising and falling symmetrically, and check breath sounds. Note the rate and depth of respirations, use of accessory and abdominal muscles for breathing, and tracheal position. Observe for circumoral cyanosis. Also look for jugular vein distention and any open wounds. If the patient isn't breathing, call for help immediately and begin mouth-to-mouth, bag, valve, or mask resuscitation. Also administer supplemental oxygen.

To assess circulation, check for carotid and peripheral pulses. If the patient has neck injuries, palpate the femoral pulse instead. If circulation has stopped, start cardiopulmonary resuscitation at once.

If you see an external hemorrhage, apply direct pressure to the bleeding site; if the wound is on an extremity, elevate it above heart level, if possible. If this measure doesn't control the bleeding, apply direct pressure to the pressure point proximal to the site.

ALERT Apply a tourniquet only if the hemorrhage is life-threatening. Because a tourniquet halts distal circulation, its use could cause the patient to lose an arm or a leg.

If the patient's head and neck aren't already immobilized, use an immobilization device, sandbags, a backboard, or tape to do so. Then obtain cervical spine X-rays to rule out spinal cord injury before moving the patient again.

Assess vital signs

Monitor the patient's vital signs, even if he appears stable, because changes can occur rapidly. Document the patient's baseline vital sign readings and obtain new readings every 5 to 15 minutes until his condition stabilizes. Place the patient on a cardiac monitor and pulse oximeter for continuous monitoring.

Check the patient's pupillary and motor responses to assess neurologic status. Report his LOC, using a stimulus-response method rather than categorizing; don't use words like “semiconscious” or “stuporous.” Report decorticate (flexor) or decerebrate (extensor) postures immediately.

Remember, a patient without a head injury also can have an abnormal neurologic response. Any injury that impairs ventilation or perfusion can cause cerebral edema and raise intracranial pressure. If the patient has neurologic symptoms and is hypotensive, look for an extracranial cause because intracranial bleeding usually isn't the cause of hypotension.

Next, perform a secondary survey of the patient by systematically assessing the entire body. Carefully logroll the patient over and assess for multiple injuries.

Give the patient oxygen and monitor oxygenation response. Draw samples for arterial blood gas measurement, and calculate the effects of the supplemental oxygen. This lets you establish a baseline for oxygen and acid-base therapy. A patient with multiple injuries always needs supplemental oxygen because of blood loss and overwhelming physiologic stress. If he's conscious, he should show compensatory hyperventilation. If he doesn't, suspect neurologic involvement or chest injury.

Draw blood for typing and cross matching, a complete blood count, prothrombin time, partial thromboplastin time, platelet levels, and routine blood studies, including amylase, electrolyte, and glucose levels. Then begin at least two I.V. lines with 14G or 16G catheters for fluid resuscitation with normal saline or lactated Ringer's solution.

If the wound is tetanus-prone, ask the patient or a family member when he had his last tetanus immunization. Administer tetanus prophylaxis, as ordered. (See [Managing tetanus prophylaxis.](#))

CULTURAL TIP Members of some cultures such as Jehovah's Witnesses are opposed to vaccines and may refuse such treatment. Members of many cultures don't immunize their children. It's important to determine the child's (or adult's) current immunization status as they may be at increased risk for developing complications.

As indicated, insert an indwelling urinary catheter, unless you see blood at the meatus or in the scrotum, if you suspect an anterior pelvic fracture or if the patient has a displaced prostate gland.

Insert a nasogastric tube or, if the patient has facial fractures, an orogastric tube. During tube insertion, maintain cervical spine immobilization. Next, administer prophylactic antibiotics. As ordered, arrange for appropriate diagnostic studies, such as computed tomography scans, X-rays, peritoneal lavage, or excretory urography, and notify appropriate medical or surgical specialists.

Combat shock

Because severe injuries commonly lead to shock, inspect the patient's skin for color and note skin temperature and moisture. Make sure he's receiving I.V. fluids (lactated Ringer's or normal saline solution), followed by blood or blood products, if warranted.

CULTURAL TIP Members of some religious groups, such as Jehovah's Witnesses, are opposed to the administration of blood and blood products. Some may be persuaded in emergencies to receive these products, but a court order may be needed if the situation is life-threatening and the patient (or parent of an injured child) still refuses.

Managing tetanus prophylaxis				
HISTORY OF TETANUS IMMUNIZATIONM (NUMBER OF DOSES)	TETANUS-PRONE WOUNDS		NON-TETANUS-PRONE WOUNDS	
	Td*	TIG**	Td	TIG
Uncertain	Yes	Yes	Yes	No
0 to 1	Yes	Yes	Yes	No
2	Yes	No (yesif more than 24 hours since wound was inflicted)	Yes	No
3 or more	No (Yes if more than 5 years since last dose)	No	No (yes if more than 10 years since last dose) [†]	No
* Td = Tetanus and diphtheria toxoids absorbed (for adult use), 0.5 ml				
** TIG = Tetanus immune globulin (human), 250 units				
† When Td and TIG are given concurrently, separate syringes and separate sites should be used.				
<i>Note:</i> For children under age 7, tetanus and diphtheria toxoids and pertussis vaccine, absorbed (DPT) are preferred over tetanus toxoid alone. If the pertussis vaccine is contraindicated, administer tetanus and diphtheria toxoids, absorbed (DT).				

In all cases of massive external or suspected internal bleeding, watch for hypovolemia and estimate the amount of blood lost. Remember that a blood loss of 500 to 1,000 ml might not change systolic blood pressure, but it might elevate the patient's pulse rate.

Stay alert for signs of occult bleeding, common in the chest, abdomen, and thigh. Assess for occult bleeding by taking serial girth measurements at these sites. Use a tape measure and mark where you placed it on the body with a marking pen so that you measure in exactly the same place each time. This way you can accurately detect any enlargement. Increased diameter of the abdomen, chest, or thigh typically means leakage of blood into these tissues. Such blood loss will induce classic signs of hypovolemic shock (tachycardia, tachypnea, hypotension, restlessness, decreased urine output, delayed capillary refill, and cold, clammy skin).

Observe for faint, irregularly formed hemorrhagic patches on the skin around the umbilicus (Cullen's sign), which may signal retroperitoneal hematoma. Retroperitoneal bleeding may not cause abdominal tenderness.

If the patient shows clinical signs of hypovolemia, begin I.V. therapy immediately with two or more large-bore catheters, and regulate fluids according to the severity of hypovolemia. Assist with the insertion of a central venous pressure or pulmonary artery catheter to monitor circulating blood volume.

Splinting for transport

Look for limb fractures and dislocations, and check the patient's circulation and neurovascular status distal to the injury. Do this by palpating pulses distal to the injury and looking for the classic signs and symptoms of arterial insufficiency: decreased or absent pulse, pallor, paresthesia, pain, and paralysis. Splint the injury and apply traction, as needed.

Next, prepare the victim for transport. Use special care in suspected cervical spine injury. Splint the areas above and below the injury site to prevent further soft-tissue and neurovascular damage and to minimize pain. For instance, if the forearm is injured, splint the wrist and elbow, too. (See [Types of splints.](#))

In addition, ensure that family members or significant others are informed or updated about the patient's condition, permission forms are obtained as necessary, and emotional support is provided to the patient's family either by staff or clergy.

Types of splints

Types of splints include:

- u **soft splint**—a nonrigid splint, such as a pillow or towels
- u **hard splint**—a rigid splint with a firm surface, such as a long or short board, an aluminum ladder splint, and a cardboard splint
- u **air splint**—an inflatable splint
- u **traction splint**—a splint that uses traction to decrease angulation and reduce pain, such as a Hare or Thomas splint.

Tips for applying a splint

When splinting a patient's injury, keep in mind the following guidelines:

- u Splint most injuries “as they lie,” except when neurovascular status is compromised.
- u Have one person support the injured part while another applies padding and the splint.
- u Secure the splint with straps or gauze—not with an elastic bandage.
- u To apply an air splint, slide the splint backward over your arm and grasp the distal portion of the injured extremity. Then slip the splint from your arm onto the patient's extremity and inflate the splint.

Head injuries

Injuries to the head range from minor concussions to life-threatening hematomas and herniation. They also include injuries to structures of the head such as the jaw.

CEREBRAL CONTUSION

More serious than a concussion, a cerebral contusion is an ecchymosis of brain tissue that results from a severe blow to the head. A contusion disrupts normal nerve functions in the bruised area and may cause loss of consciousness, hemorrhage, edema, and even death.

Causes and pathophysiology

A cerebral contusion results from acceleration-deceleration or coup-contrecoup injuries. It is also seen in child, spouse, and elder abuse.

A cerebral contusion can occur directly beneath the site of impact (coup) when the brain rebounds against the skull from the force of a blow (a beating with a blunt instrument, for example), when the force of the blow drives the brain against the opposite side of the skull (contrecoup), or when the head is hurled forward and stopped abruptly (as in a motor vehicle crash when the driver's head strikes the windshield). The brain continues moving and slaps against the skull (acceleration) and then rebounds (deceleration).

Complications

When injuries cause the brain to strike against bony prominences inside the skull (especially to the sphenoidal ridges), intracranial hemorrhage or hematoma can occur. The patient also may suffer tentorial herniation. (See [Understanding intracranial hemorrhage, hematoma, and tentorial herniation.](#))

Residual headache and vertigo may complicate recovery. Secondary effects, such as brain swelling, may accompany serious contusions, resulting in increased intracranial pressure (ICP) and herniation.

Assessment findings

The patient's history (obtained from family, friends, and emergency personnel, if necessary) reveals a severe traumatic impact to the head, commonly against a blunt surface such as a car dashboard.

Signs and symptoms vary, depending on the location of the contusion and the extent of damage. A period of unconsciousness, possibly lasting 6 hours or more, may follow the trauma. An unconscious patient may appear pale and motionless, whereas a conscious patient may appear drowsy or easily disturbed by any form of stimulation, such as noise or light. A conscious patient may become agitated or violent.

Assessment of an unconscious patient may reveal below-normal blood pressure and temperature. His pulse rate may be within normal levels but feeble, and his respirations may be shallow. In a conscious patient, temperature, pulse rate, and respiratory status vary, depending on his physical and emotional status.

ASSESSMENT TIP A severe increase in blood pressure and increased ICP can cause brain stem herniation.

Inspection may reveal severe scalp wounds, labored respirations and, possibly, involuntary evacuation of the bowels and bladder. Palpation may disclose less obvious head injuries such as hematoma. On palpation, the unconscious patient's skin will feel cold.

ADVANCED PRACTICE

Understanding intracranial hemorrhage, hematoma, and tentorial herniation

Left untreated, intracranial hemorrhage, hematoma, and tentorial herniation can be life-threatening. These conditions are among the most serious consequences of head injury.

Causes

A rapid accumulation of blood between the skull and the dura mater is an epidural hemorrhage or hematoma. A subdural hemorrhage or hematoma is a slow accumulation of blood between the dura mater and the subarachnoid membrane. An intracerebral hemorrhage or hematoma occurs within the cerebrum itself. Tentorial herniation results from injured brain tissue that swells and forces itself through the tentorial notch, constricting the brain stem.

Signs and symptoms

An epidural hemorrhage or hematoma can cause immediate loss of consciousness, followed by a lucid interval that lasts from minutes to hours. This eventually gives way to a rapidly progressive decrease in level of consciousness. Other effects include contralateral hemiparesis, progressively severe headache, ipsilateral pupillary dilation, and signs of increased intracranial pressure (ICP). These disorders also cause a decrease in pulse and respiratory rates and an increase in systolic blood pressure.

With a subacute or chronic subdural hemorrhage or hematoma, blood accumulates slowly, so symptoms may not occur until days after the injury. In an acute subdural hematoma, symptoms appear earlier because blood accumulates within 24 hours of the injury. Loss of consciousness occurs, typically with weakness or paralysis.

An intracerebral hemorrhage or hematoma usually causes nuchal rigidity, photophobia, nausea, vomiting, dizziness, seizures, decreased respiratory rate, and progressive obtundation.

Signs and symptoms of tentorial herniation include drowsiness, confusion, dilation of one or both pupils, hyperventilation, nuchal rigidity, bradycardia, and decorticate or decerebrate posturing. Irreversible brain damage or death can occur rapidly.

Treatment

An intracranial hemorrhage may require a craniotomy to locate and control bleeding and to aspirate blood. Epidural and subdural hematomas usually are drained by aspiration through burr holes in the skull. Increased ICP—which can occur in hemorrhage, hematoma, and tentorial herniation — may be controlled with mannitol I.V., steroids, or diuretics, but emergency surgery is usually required.

Neurologic findings may include hemiparesis, decorticate or decerebrate posturing, and unequal pupillary response. With effort, you may be able to rouse an unconscious patient temporarily. If you're performing a neurologic examination after the acute stage of the injury, you may find that the patient has returned to a relatively alert state, perhaps with temporary aphasia, slight hemiparesis, or unilateral numbness.

Diagnostic tests

Cerebral angiography outlines vasculature, and a computed tomography (CT) scan shows ischemic or necrotic tissue, cerebral edema, areas of petechial hemorrhage, and subdural, epidural, and intracerebral hematomas. A CT scan also may reveal a shift in brain tissue.

Treatment

Immediate treatment may include establishing a patent airway and, if necessary, tracheotomy or endotracheal intubation. Treatment also may consist of careful administration of I.V. fluids (lactated Ringer's or normal saline solution), I.V. mannitol to reduce ICP, and restricted fluid intake to decrease intracerebral edema. Dexamethasone may be given I.M. or I.V. for several days to control cerebral edema.

The patient's ICP may be reduced by maintaining his partial pressure of arterial carbon dioxide (Pa CO₂) between 30 and 35 mm Hg. Accomplish this by adjusting the ventilator settings for an intubated patient. A decreased Pa CO₂ constricts cerebral blood vessels and reduces cerebral blood flow, thus reducing ICP. Serial arterial blood gas studies allow monitoring of oxygenation.

If necessary, additional treatments may include blood transfusion and craniotomy to control bleeding and aspirate blood.

Nursing diagnoses

u Altered thought processes u Anxiety u Impaired verbal communication u Pain u Risk for fluid volume deficit u Risk for infection u Risk for injury u Risk for posttrauma syndrome u Sensory or perceptual alterations

Key outcomes

- u The patient will use support systems to assist with coping.
- u The patient will maintain a stable neurologic state.
- u The patient and family members will state the cause of acute confusion.
- u The patient will express a feeling of comfort and pain relief.
- u The patient's fluid volume will remain adequate.
- u The patient will remain free from signs and symptoms of infection.

Nursing interventions

- u Maintain a patent airway. Suction as indicated and assist with endotracheal intubation or tracheotomy as necessary.
- u Monitor serial arterial blood gases; report changes in trends.
- u Perform neurological examinations; focus on level of consciousness (LOC), motor responses, and ICP.
- u Monitor vital signs and respirations regularly (usually every 15 minutes). Abnormal respirations could indicate a breakdown in the patient's respiratory center in the brain stem and possibly an impending tentorial herniation, which is a neurologic emergency.
- u Frequently check the patient's neurologic status, including his LOC. Assess him for restlessness, orientation, and pupillary response.
- u Administer medications, as ordered.
- u Protect the patient from injury according to his condition. Use side rails, assist the unsteady patient when walking, stay with the patient while he uses the bathroom, and place the confused patient where he can be easily observed.
- u To decrease the patient's anxiety, speak calmly to him and explain your actions, even if he's unconscious.
- u Insert an indwelling urinary catheter, as ordered. Monitor intake and output.
- u If the patient is unconscious, insert a nasogastric tube to prevent aspiration, but only after a basilar skull fracture has been ruled out. Otherwise, the tube may be inserted into the cranial vault.
- u Carefully observe the patient for leakage of cerebrospinal fluid (CSF). Check the bed sheets for a blood-tinged spot surrounded by a lighter ring (halo sign). If CSF

leakage develops and spinal injury is ruled out, raise the head of the bed 30 degrees. If you detect CSF leakage from the nose, place a gauze pad under the nostrils. If CSF leaks from the ear, position the patient so that his ear drains naturally; don't pack the ear or nose.

ALERT To prevent central nervous system (CNS) infection, avoid cleaning or suctioning the ears or nose of a patient with a head injury. Doing so could introduce microorganisms into the CNS.

- u If the patient is unconscious and spinal injury is ruled out, elevate the head of the bed and maintain the patient's head in the midline position to decrease ICP. If his head is turned to the side, he may have poor jugular venous return, which can increase ICP.
- u Restrict total fluid intake to reduce volume and intracerebral swelling.
- u After the patient is stabilized, clean and dress any superficial scalp wounds. (If the skin has been broken, the patient may need tetanus prophylaxis.) Assist with suturing if needed.
- u If the patient develops temporary aphasia, provide an alternative means of communication.

Patient teaching

- u Tell the patient not to cough, sneeze, or blow his nose because these activities can increase ICP.
- u Instruct the patient to observe for CSF drainage and to be alert for signs of infection.
- u Teach the patient and family members how to observe for mental status changes. Tell them to return to the facility or to call the doctor if such changes occur.

CONCUSSION

By far the most common head injury, a concussion results from an acceleration-deceleration injury or a blow to the head hard enough to jostle the brain and make it strike the skull, causing temporary neural dysfunction, but not hard enough to cause a cerebral contusion. Most concussion victims recover within 48 hours. Repeated concussions, however, exact a cumulative toll on the brain.

Causes

The blow that causes a concussion is usually sudden and forceful—a fall to the ground, a punch to the head, a motor vehicle crash. Sometimes such a blow results from child, spouse, or elder abuse.

Complications

A concussion usually causes no significant anatomic brain injury. Seizures, persistent vomiting, or both may occur. Rarely, a concussion leads to intracranial hemorrhage.

Assessment findings

The patient's history may reveal a short-term loss of consciousness, vomiting, and anterograde and retrograde amnesia: He can't recall what happened immediately after the injury and has difficulty recalling the events that led up to it. Typically, he repeats the same questions. The presence of anterograde amnesia and the duration of retrograde amnesia reliably correlate with the injury's severity.

A family member or friend may report that the patient is behaving out of character. The patient usually complains of dizziness, nausea, and severe headache.

During inspection, you may note that an adult patient behaves irritably or lethargically. Skull palpation may reveal tenderness or hematomas caused by the injury. Neurologic assessment findings usually are normal.

Although these assessment findings can occur with a concussion, they also may result from a more serious head injury. Medical evaluation is necessary to rule out serious injury to the brain.

Diagnostic tests

Computed tomography scanning and magnetic resonance imaging help rule out fractures and more serious injuries.

Treatment

Most patients require no treatment except bed rest, observation, and nonnarcotic analgesics for headache.

Nursing diagnoses

- u Anxiety u Ineffective individual coping u Pain u Risk for fluid volume deficit u Risk for injury u Risk for posttrauma syndrome

Key outcomes

- u The patient will state and carry out appropriate interactions for pain relief.
- u The patient's vital signs will remain stable.
- u The patient's fluid volume will remain adequate.
- u The patient will identify factors that increase the potential for injury.
- u The patient will recover or be rehabilitated from physical injuries to the greatest extent possible.

HOME CARE

What your patient needs to know after a concussion

Before the patient's discharge, follow these teaching guidelines: Instruct the caregiver to awaken the patient every 2 hours through the night and to ask his name and whether he can identify the caregiver.

Advise the caregiver to return the patient to the facility immediately if he is difficult to arouse, is disoriented, has seizures, or experiences a persistent or worsening headache, forceful or constant vomiting, blurred vision, any change in personality, abnormal eye movements, a staggering gait, or twitching. If the patient is a child, explain to the parents that some children have no apparent ill effects immediately after a concussion but may grow lethargic or somnolent a few hours later. Teach the patient the signs of postconcussion syndrome — headache, vertigo, anxiety, personality changes, memory loss, and fatigue. Explain that these signs may persist for several weeks.

Nursing interventions

- u Initially, monitor vital signs continuously and check for additional injuries.

- u Check vital signs, level of consciousness, and pupil size every 15 minutes. If the patient's condition worsens or fluctuates, he should be admitted for neurosurgical consultation. If he remains stable after 4 or more hours of observation, he may be discharged (with a head injury instruction sheet) in the care of a responsible adult.
- u Observe the patient for headache, dizziness, irritability, and anxiety. If his condition worsens, perform a complete neurologic evaluation and notify the doctor.
- u Observe seizure precautions if seizures have occurred.
- u Monitor fluid and electrolyte levels and replace them as necessary.

Patient teaching

- u Explain to the patient who is discharged from the emergency department that a responsible adult, such as a family member or friend, should continue to observe his condition at home. (See [What your patient needs to know after a concussion.](#)) If this isn't possible, the patient may be hospitalized for a brief time.
- u Tell him not to take anything stronger than nonnarcotic analgesics for a headache. Warn him not to take aspirin because it may heighten the risk of bleeding.
- u If vomiting occurs, instruct the patient to eat small, light meals until it stops. (Occasional vomiting is normal after sustaining a concussion.)

DISLOCATED OR FRACTURED JAW

Displacement of the temporomandibular joint results in a dislocated jaw. A break in one or both of the two maxillae (upper jawbones) or the mandible (lower jawbone) constitutes a fractured jaw. Treatment usually restores jaw alignment and function.

Causes

Simple dislocations or fractures are usually caused by a manual blow along the jawline as may occur in cases of child, spouse, or elder abuse; more serious compound fractures frequently result from motor vehicle crashes.

Complications

Infection can be a serious complication of a fractured jaw. A fracture can cause a large sublingual hematoma, which may compromise the airway. Injury can also traumatize the nerves that innervate the jaw and face.

Assessment findings

The patient's history reveals an injury to the jaw, and the patient reports mandibular pain beginning right after the injury.

Inspection reveals malocclusion (the most obvious sign of dislocation or fracture), swelling, ecchymosis, loss of function, and asymmetry.

Palpation of the injured area reveals pain and swelling. During palpation, note whether the patient experiences any altered sensation. A mandibular fracture that damages the alveolar nerve produces paresthesia or anesthesia of the chin and lower lip.

Diagnostic tests

X-rays confirm the diagnosis; for a more accurate diagnosis, panorex views are usually required. The patient may be required to sit upright for the test unless this is contraindicated by the condition, such as a possible cervical spine fracture.

Treatment

As in all traumatic injuries, treatment involves first checking for a patent airway, adequate breathing, and circulation. After that, treatment focuses on controlling hemorrhage and caring for any other injuries. The patient may need an oropharyngeal airway, nasotracheal intubation, or a tracheotomy to help maintain an adequate airway.

Treatment also includes:

- u medications to relieve pain and anxiety and to prevent infection before and after surgery, if indicated
- u in dislocated jaw, manual reduction under anesthesia
- u in fractured jaw, surgical reduction and fixation by wiring to restore mandibular and maxillary alignment (wiring usually is removed after 6 to 8 weeks)
- u in maxillary fracture, reconstruction and repair of soft-tissue injuries as necessary
- u reimplantation of any lost teeth within 6 hours, if possible, while they're still viable (teeth and bone fragments aren't removed during surgery unless they have to be).

Nursing diagnoses

u Altered nutrition: Less than body requirements u Anxiety u Body image disturbance u Impaired verbal communication u Ineffective airway clearance u Pain u Risk for aspiration u Risk for fluid volume deficit u Risk for infection u Risk for posttrauma syndrome u Sensory or perceptual alterations

Key outcomes

- u The patient will express a feeling of comfort and pain relief.
- u The patient will state feelings and fears related to the traumatic event.
- u The patient will avoid aspiration.
- u The patient's fluid volume will remain adequate.
- u The patient will have no further weight loss.

Nursing interventions

- u Before and after surgery, administer medications for pain and anxiety as needed.
- u Before surgery, maintain the patient's airway and monitor vital signs. For a patient with a mandibular fracture and soft-tissue injuries, administer tetanus prophylaxis as ordered.
- u After surgery, position the patient on his side with his head slightly elevated. A nasogastric tube usually is in place, with low suction to remove gastric contents and prevent nausea, vomiting, and aspiration of vomitus. As necessary, suction the nasopharynx through the nose or by pulling the cheek away from the teeth and inserting a small suction catheter through any natural gap between the teeth.
- u As soon as the patient awakens after surgery, remind him that he can't open his mouth if he has a fixation device in place.
- u If the patient isn't intubated, provide nourishment through a straw. If a natural gap exists between his teeth, insert the straw there; if not, one or two teeth may have to be extracted. Such extraction should be avoided when possible. Start with clear liquids. After the patient can tolerate fluids, offer milk shakes, eggnog, broth, juices, pureed foods, and commercially prepared nutritional supplements. If possible, give soft foods with a straw. Give water after each liquid feeding, followed by mouthwash.
- u If the patient can't tolerate oral fluids, administer I.V. fluids to maintain hydration.
- u Record the patient's baseline weight, and perform a nutrition and hydration assessment.
- u Administer antiemetics, as ordered, to minimize the patient's nausea and prevent aspiration of vomitus (a very real danger in a patient who has a wired jaw). Keep a pair of wire cutters at the patient's bedside to snip the wires if the patient vomits or has difficulty breathing due to an occluded airway.

ALERT Make sure you're able to gain access to the patient's airway at all times. If the patient's jaw is wired, keep a pair of wire clippers at the bedside to cut the wires in an emergency—for instance, to prevent aspiration if the patient vomits. When the patient becomes ambulatory, have him keep wire clippers available at all times,

and make sure he knows which wires to cut if an emergency should occur.

- u An oral irrigating device such as a dental water pulsator may be used for mouth care while the wires are intact. Brush teeth and gums and provide oral hygiene at least every 4 hours. Oral hygiene enhances comfort, aids healing of oral wounds, and prevents severe infections. You also can apply paraffin wax to wire ends to protect buccal surfaces.
- u Because the patient will have difficulty talking while his jaw is wired, provide him with a magic slate or a pencil and paper. Also suggest appropriate diversions.

Patient teaching

- u Instruct family members to obtain help immediately if the patient appears to have trouble breathing.
- u Explain to the patient and family members the importance of high-calorie food supplements, and teach them how to puree foods.
- u Advise the patient to avoid alcohol. Explain that it may cause nausea, interact with medications, and dull reflexes necessary for airway clearance.
- u Tell the patient to avoid carbonated beverages because the foaming action may cause airway problems.
- u Teach the patient how to perform adequate mouth care. Stress the importance of oral hygiene, and suggest that he use a soft, child-sized toothbrush. Tell him to brush his teeth after each meal and at bedtime.
- u Encourage the patient to keep follow-up appointments so that the doctor can make sure his fixation device is functioning properly.
- u Tell the patient to avoid swimming and other water activities until the jaw wiring is removed; if he should accidentally get water in his lungs or start to drown, it would be difficult to clear the airway rapidly with the jaw wired shut.
- u Instruct the patient and family members to carry wire cutters at all times in case of an emergency.

FRACTURED NOSE

A fractured nose is the most common facial fracture. It usually results from blunt injury and is commonly associated with other facial fractures. The severity of the fracture depends on the direction, force, and type of the blow. A severe comminuted fracture may cause extreme swelling or bleeding that may jeopardize the airway and require a tracheotomy during early treatment.

Causes

Fractures of the nasal bones usually result from direct trauma. The causative injury can be relatively minor such as a fall, or more severe such as a motor vehicle accident.

Complications

Nasal fractures can cause septal deviation and bone displacement, resulting in an airway obstruction. These complications can be permanent if treatment is inadequate or delayed. The patient may also develop septal hematoma, leading to abscess formation and avascular and septic necrosis. Other possible complications include cerebrospinal fluid (CSF) leakage and intracranial air penetration, which may lead to meningitis.

Assessment findings

The patient's history reveals a direct blow to the nose. He usually reports the immediate onset of pain, a nosebleed (ranging from minimal trickling to hemorrhage), and soft-tissue swelling. If his nasal passages are obstructed, he may breathe noisily.

If you perform inspection soon after the injury, you may note a swollen nose with bleeding and deformity or displacement of the nose from the midline. A fracture may not be obvious, however, because swelling can obscure the break.

Inspection performed several hours after the injury may reveal periorbital ecchymoses (raccoon's eyes), nasal displacement, and deformity.

You may be able to identify the fracture on palpation.

Diagnostic tests

X-rays help to confirm the diagnosis and determine the extent of injury.

Treatment

The patient may not need treatment unless he has suffered bone displacement, septal deviation, or a cosmetic deformity.

When necessary, prompt treatment restores normal facial appearance and reestablishes bilateral nasal passages after swelling subsides. Reduction of the fracture (restoring the displaced bone fragments to their normal positions) corrects alignment; immobilization (intranasal packing and an external splint shaped to the nose and taped) maintains it.

Nasal fractures should be reduced within the first 24 hours if possible, using local anesthesia for an adult and general anesthesia for a child. Severe swelling may delay treatment for several days to per week, making reduction more difficult. In this case, the patient may need general anesthesia.

If CSF leakage occurs, the patient needs close observation and antibiotic therapy. Septal hematoma requires incision and drainage to prevent necrosis.

Nursing diagnoses

- u Body image disturbance u Impaired tissue integrity u Ineffective airway clearance u Pain u Risk for infection u Risk for posttrauma syndrome

Key outcomes

- u The patient will express a feeling of comfort and pain relief.
- u The patient will state feelings and fears related to the traumatic event.
- u The patient will acknowledge change in body image.
- u The patient will report symptoms that indicate need for medical treatment.
- u The patient's vital signs, temperature, and laboratory values will remain within normal limits.

Nursing interventions

- u Start treatment immediately to reduce swelling, control bleeding, and relieve pain.
- u While waiting for X-rays, apply ice packs to the nose to minimize swelling. Wrap the ice packs in a light towel to prevent the ice from directly contacting the skin. To control anterior bleeding, gently apply local pressure. Posterior bleeding is rare and requires an internal tamponade.
- u After packing and splinting, apply ice in a plastic bag.
- u Administer ordered pain medications as required.
- u Elevate the patient's head to reduce swelling unless it's contraindicated (suspected cervical spine fracture).

Patient teaching

- u The patient will find breathing more difficult as the swelling increases, so instruct him to breathe slowly through his mouth. To warm the inhaled air during cold weather, tell him to cover his mouth with a handkerchief or scarf. To prevent subcutaneous emphysema or intracranial air penetration (and potential meningitis), warn him not to blow his nose.
- u Tell the patient to open his mouth when sneezing. Explain that this helps prevent infection and movement of bony fragments. Also advise him to avoid decongestant sprays, which can decrease the nasal blood supply needed for healing.
- u Instruct the patient to keep his head elevated on pillows while sleeping during the first 24 hours to reduce swelling and promote comfort.

PERFORATED EARDRUM

A perforated eardrum, which results from a rupture of the tympanic membrane, may cause hearing loss.

Causes

The usual cause of a perforated eardrum is trauma: the deliberate or accidental insertion of a sharp object (such as a hair pin) or a sudden excessive change in pressure (from an explosion, a blow to the head, flying, or diving). The injury may also result from untreated otitis media and, in children, from acute otitis media.

Complications

Especially if untreated, a perforated eardrum can result in infection, such as mastoiditis and meningitis, and permanent hearing loss.

Assessment findings

The patient's history usually reveals some type of mild or severe trauma to the ear. The patient may report introducing a foreign object into the ear, or he may have a middle ear infection.

The patient may complain of the sudden onset of a severe earache and bleeding from the ear, usually the first indications of a perforated eardrum. He may also report hearing loss, tinnitus, and vertigo.

During your assessment, you may observe signs of hearing loss such as the patient turning his unaffected ear toward you when you speak. If inspection of the outer ear reveals drainage, note its color and odor: Purulent otorrhea within 24 to 48 hours of injury signals infection.

An otoscopic examination reveals the perforated tympanic membrane and confirms the diagnosis.

A neurologic examination of the facial nerves should reveal normal voluntary facial movements if no facial nerve damage occurred from the injury.

Diagnostic tests

Audiometric testing allows evaluation of middle ear function.

Culture of the drainage can identify a causative organism, if infection caused the rupture. X-rays of the temporal lobe and skull are used to determine if there is an associated fracture, especially when a bad fall causes the perforation.

Treatment

Most eardrum perforations heal spontaneously in a few weeks. If any crust remains on the tympanic membrane after 2 weeks, an ear specialist removes it under magnification to see if healing is complete. If necessary, treatment includes local and systemic antibiotic therapy and analgesics for pain.

A large perforation with uncontrolled bleeding may require immediate surgery to approximate the ruptured edges. If the patient needs surgical closure, he may undergo a myringoplasty or tympanoplasty.

Nursing diagnoses

- u Anxiety
- u Knowledge deficit
- u Pain
- u Risk for infection
- u Risk for injury
- u Sensory or perceptual alterations (auditory)

Key outcomes

- u The patient will cope with the condition without demonstrating severe signs of anxiety.
- u The patient and family members will express an understanding of hearing changes that may occur.
- u The patient will state and carry out appropriate interventions for pain relief.
- u The patient and family members will express understanding of potential causes of injury.
- u The patient will remain free from signs and symptoms of infection.

Nursing interventions

- u If the patient is bleeding from the ear, use a sterile, cotton-tipped applicator to absorb the blood, and check for purulent drainage or evidence of cerebrospinal fluid leakage (clear fluid).
- u Apply a sterile dressing over the outer ear.
- u Administer prescribed analgesics as necessary.
- u Administer prescribed antibiotics.
- u If the patient has difficulty hearing, face him, speak distinctly and slowly, and try to provide a quiet environment.

Patient teaching

- u Make sure the patient understands the ordered treatment. If he needs surgery, reinforce the doctor's explanation and answer any questions the patient has.
- u Warn against irrigating the ear.
- u Caution the patient not to clean the middle ear canal with a cotton-tipped applicator. Explain that this may further injure the eardrum.
- u Advise the patient and family members to exercise care when washing the patient's hair. Water may enter the middle ear and cause infection.
- u Tell the patient to avoid swimming unless the doctor gives him permission, and then to use earplugs to prevent water from entering the ears.
- u Stress the importance of completing the course of antibiotic therapy as prescribed.
- u Teach the patient and family members about proper safety equipment in the workplace and at home to prevent injuries to the ear.

SKULL FRACTURES

The first concern in a skull fracture is possible damage to the brain rather than the fracture itself; therefore, the injury is considered a neurosurgical condition. Signs and symptoms reflect the severity and extent of the head injury.

Skull fractures may be simple (closed) or compound (open) and may displace bone fragments. They're also described as linear, comminuted, or depressed. A linear,

or hairline, fracture doesn't displace structures and seldom requires treatment. A comminuted fracture splinters or crushes the bone into several fragments. A depressed fracture pushes the bone toward the brain; it's considered serious only if it compresses or lacerates underlying structures. A child's thin, elastic skull allows a depression without a fracture.

Skull fractures also are classified according to location, such as cranial vault or basilar. A basilar fracture occurs at the base of the skull and involves the cribriform plate and the frontal sinuses. Because of the danger of cranial nerve complications, dural tears, and meningitis, basilar fractures usually are far more serious than vault fractures.

Causes

Like concussions and cerebral contusions or lacerations, skull fractures invariably result from a traumatic blow to the head. Motor vehicle crashes, bad falls, and severe beatings (especially in children and elderly people) top the list of causes.

Complications

Skull fractures can lead to infection, intracerebral hemorrhage and hematoma, brain abscess, and increased intracranial pressure (ICP) from edema. A linear fracture across a suture line in an infant increases the possibility of epidural hematoma.

Recovery from the injury can be complicated by the residual effects of the injury, such as seizure disorders, hydrocephalus, and organic brain syndrome.

Assessment findings

The patient's history—obtained from the patient, family members, eyewitnesses, or emergency personnel—reveals a traumatic injury to the skull. The patient may have lost consciousness and developed other neurologic changes. If conscious, he may complain of a persistent, localized headache.

Your assessment may reveal decreased pulse and respiratory rates as well as labored respirations. On inspection, a conscious patient with a linear fracture and a concussion may appear dazed. If he has another type of skull fracture, he may appear anxious and, depending on his neurologic status, may have normal responses or appear agitated and irritable.

Because scalp wounds commonly accompany skull fractures, inspection of the scalp may reveal abrasions, contusions, lacerations, or avulsions. If the scalp was lacerated or torn away, you may note profuse bleeding. The patient, however, may be in shock from other injuries or from medullary failure if the head injury is severe. You'll also note swelling and ecchymosis in the area of the injury, a sign that a fracture has occurred.

Other findings on inspection may include bleeding in the nose, pharynx, or ears; under the conjunctivae; under the periorbital skin (raccoon's eyes); and behind the eardrum. You may also observe Battle's sign (postauricular ecchymosis).

Inspection of the ears and nose may reveal cerebrospinal fluid (CSF) and brain tissue leakage. The halo sign—a blood-tinged spot surrounded by a lighter ring caused by leakage of CSF—may also appear on the patient's pillowcase or bed linens.

Palpation of the head may reveal palpable fractures, areas of swelling and, possibly, hematoma. A vault fracture commonly causes soft-tissue swelling near the site, which makes the fracture difficult to detect without X-rays.

During your neurologic assessment, you may observe altered level of consciousness (LOC) along with other classic signs and symptoms of brain injury. These include agitation and irritability, abnormal deep tendon reflexes, altered pupillary and motor responses, hemiparesis, dizziness, seizures, and projectile vomiting. Loss of consciousness may last for hours, days, weeks, or indefinitely. Keep in mind that linear fractures associated only with concussion don't produce loss of consciousness.

Your neurologic assessment also may reveal vision loss in a patient with a sphenoidal fracture, and unilateral hearing loss or facial paralysis in a patient with a temporal fracture. (See [Additional findings with skull fractures.](#))

Diagnostic tests

A computed tomography (CT) scan may locate the fracture. (Cranial vault fractures aren't visible or palpable.) Reagent strips reveal the presence or absence of CSF in nasal or ear drainage. (*Note:* A positive result is also obtained if the patient is hyperglycemic.)

Cerebral angiography locates vascular disruptions from internal pressure or injury. Magnetic resonance imaging, a CT scan, and a radioisotope scan disclose intracranial hemorrhage from ruptured blood vessels.

Treatment

Although a simple linear skull fracture can tear an underlying blood vessel or cause a CSF leak, most linear fractures require only supportive treatment. Such treatment includes mild analgesics (acetaminophen) as well as cleaning, debriding, and suturing the wound after injection of a local anesthetic. Be sure to note the patient's coagulation time if he's taking anticoagulants at home. An increased International Normalized Ratio (INR) may necessitate treatment with fresh frozen plasma.

If the patient hasn't lost consciousness, he should be observed in the emergency department for at least 4 hours. After this period, a patient with stable vital signs can be discharged. He should receive an instruction sheet for 24 to 48 hours of observation at home.

More severe vault fractures, especially depressed fractures, usually require a craniotomy to elevate or remove fragments that have been driven into the brain and to extract foreign bodies and necrotic tissue. This reduces the risk of infection and further brain damage. Cranioplasty follows the use of tantalum mesh or acrylic plates to replace the removed skull section. The patient commonly requires antibiotics, tetanus prophylaxis, and (in profound hemorrhage) blood transfusions. The patient may require sedating medication, such as Ativan (lorazepam) to help reduce seizures, or an anticonvulsant may be required.

For status epilepticus, the patient may receive an anticonvulsant, usually 10 to 15 mg/kg of I.V. phenytoin sodium administered at a rate of not more than 50 mg/minute. A maintenance dose should then be ordered to prevent the recurrence of seizures.

A basilar fracture calls for immediate prophylactic antibiotics to prevent meningitis from CSF leaks. The patient also needs close observation for secondary hematomas and hemorrhages; surgery may be necessary. Also, a patient with either a basilar or a vault fracture requires I.V. or I.M. dexamethasone to reduce cerebral edema and minimize brain tissue damage.

Nursing diagnoses

u Altered nutrition: Less than body requirements u Altered thought processes u Anxiety u Impaired skin integrity u Ineffective breathing pattern u Ineffective family coping: Compromised u Pain u Risk for infection u Risk for injury u Risk for posttrauma syndrome u Sensory or perceptual alterations

ADVANCED PRACTICE

Additional findings with skull fractures

When jagged bone fragments pierce the dura mater of the cerebral cortex, skull fractures can cause subdural, epidural, or intracerebral hemorrhage or hematoma. Clinical findings due to the resulting lesions may include hemiparesis, unequal pupils, dizziness, seizures, projectile vomiting, increased pulse and respiratory rates, and progressive unresponsiveness.

A sphenoidal fracture can damage the optic nerve, causing blindness. A temporal fracture may cause unilateral deafness or facial paralysis. A basilar skull fracture commonly produces hemorrhage from the nose, pharynx, or ears; blood under the periorbital skin (raccoon's eyes) and under the conjunctiva; and Battle's sign (supermastoid ecchymosis), sometimes with bleeding behind the eardrum. Basilar skull fractures can cause cerebrospinal fluid or brain tissue to leak from the nose or ears.

Elderly patients may have cortical brain atrophy, which leaves more space for brain swelling under the cranium. Such patients consequently may not show signs of increased intracranial pressure until the pressure is very high.

Key outcomes

- u The patient will express a feeling of comfort and pain relief.
- u The patient will maintain a stable neurologic state.
- u The patient will state feelings and fears related to the traumatic event.
- u The patient will report breathing comfort, either verbally or through behavior.
- u Family members will express their concerns about coping with the patient's illness.

Nursing interventions

- u Establish and maintain a patent airway; the patient may need intubation. Suction him through the mouth, not the nose, to avoid introducing bacteria into CSF if the patient has a CSF leak.
- u If the patient's nose is draining CSF, wipe it—don't let him blow it. If an ear is draining, cover it lightly with sterile gauze—don't pack it or use a cotton-tipped applicator.
- u Assess LOC, pupillary checks, and reflexes as well as vital signs every 15 minutes until stable. Report changes immediately to the doctor or neurosurgeon.
- u Position a patient with a head injury so that secretions can drain properly. If he has a CSF leak, elevate the head of the bed 30 degrees; if he doesn't, leave the head of the bed flat, but position him on his side or abdomen. Remember that such a patient is at risk for jugular compression, leading to increased ICP, when he isn't positioned on his back. So be sure to keep his head properly aligned.

ALERT If your patient has a head injury, don't place him in the low (Trendelenburg) position. Such a position increases ICP and produces cerebral venous stasis. The pressure of the abdomen on the diaphragm also causes respiratory distress. In addition, tilting the patient's head to either side can result in an increase of ICP, and it's preferable to keep the patient's head in alignment.

- u Carefully cover scalp wounds with a sterile dressing; control any bleeding as necessary.
- u Monitor laboratory studies and replace electrolytes as necessary. Monitor INR if the patient had been taking anticoagulants, and monitor his response to treatment with fresh frozen plasma (FFP).
- u Institute seizure precautions, but don't restrain the patient. Agitated behavior may be due to hypoxia or increased ICP, so be alert for these. Carefully monitor an elderly patient. He may have brain atrophy and therefore more space for cerebral edema under the cranium. He may have increased ICP but no signs. Speak in a calm, reassuring voice, and touch the patient gently. Don't make any sudden, unexpected moves.
- u To help relieve the patient's anxiety, explain all procedures to him and tell him what to expect before performing the procedure.
- u Avoid administering narcotics or sedatives because they may depress respirations, increase carbon dioxide levels, and lead to increased ICP. They also can mask changes in neurologic status. Give acetaminophen for pain, as ordered.
- u If the patient needs surgery for the skull fracture, obtain consent, as needed, to shave his head. Explain that you're doing this to provide a clean area for surgery. Then type and crossmatch his blood. Monitor baseline laboratory studies, such as a complete blood count, prothrombin time, partial thromboplastin time, electrolyte levels, and urinalysis.
- u After surgery, monitor the patient's vital signs and neurologic status often (usually every 5 minutes until he's stable and then every 15 minutes for 1 hour). Report any changes in LOC. Because skull fractures and brain injuries heal slowly, don't expect dramatic postoperative improvement.
- u During the patient's recovery from surgery, frequently monitor intake and output and maintain indwelling urinary catheter patency. Ensure adequate fluid intake. Avoid hypotonic fluids (even dextrose 5% in water) because they can increase cerebral edema; give them only as ordered.
- u If the patient is unconscious, provide parenteral nutrition, as ordered, or use a nasogastric tube. The patient may regurgitate and aspirate food if you use a nasogastric tube.
- u If the patient's fracture doesn't require surgery, wear sterile gloves and gently clean lacerations and the surrounding area. Assist with suturing if necessary. Cover the lacerations with sterile gauze.
- u Provide emotional support for the patient and family members. Explain the need for procedures to reduce the risk of brain injury.

Patient teaching

- u Before discharge, instruct the patient's family to watch closely for changes in mental status, LOC, and respirations. Tell them to return the patient to the facility immediately if LOC decreases, if headache persists after several doses of acetaminophen, if he vomits more than once, or if weakness develops in his arms or legs.
- u Instruct the patient to take acetaminophen for his headache.
- u Teach the patient and family members how to care for his scalp wound. Emphasize the need to return for suture removal and follow-up evaluation.

Neck and spinal injuries

Because of the risk of paralysis, neck and spinal injuries call for especially careful treatment.

ACCELERATION-DECELERATION INJURIES

Also known as whiplash, acceleration-deceleration cervical injuries result from sharp hyperextension and flexion of the neck that damages muscles, ligaments, disks, and nerve tissue. The prognosis is excellent: Symptoms usually subside with symptomatic treatment.

Causes

Any injury that forcibly causes hyperextension and flexion of the neck can result in whiplash. Common causes include motor vehicle crashes, sports accidents, and falls. For example, in a motor vehicle crash, a rear-end collision propels the patient's trunk forward on the pelvis, throwing the head into hyperextension and stretching the anterior structure of the neck; a head-on impact initially produces acute flexion and subsequently a reflex hyperextension.

Complications

Although rare, a possible complication of acceleration-deceleration injuries is nerve damage that results in numbness, tingling, or weakness.

Assessment findings

The patient's history reveals an acceleration-deceleration injury. He usually reports that symptoms first appeared 12 to 24 hours after the injury. If the injury is mild, symptoms may not appear until another 12 to 24 hours pass.

The patient typically complains of moderate to severe pain in the anterior and posterior neck. Within several days, the anterior pain diminishes but posterior pain persists or even intensifies. (You may not see the patient until he has reached this point because many patients don't seek medical attention at first.) He also may report dizziness, headache, and vomiting.

During inspection of the neck, you may note neck muscle asymmetry. Neurologic examination may reveal gait disturbances, rigidity or numbness in the arms, and spatial instability that affects balance. Palpation reveals pain at the exact location of the injury.

Diagnostic tests

Full cervical spine X-rays rule out cervical fracture.

Treatment

Until X-rays rule out cervical fracture, treatment focuses on protecting the cervical spine. Initial treatment includes bed rest, the use of a soft cervical collar, and application of ice packs. Oral analgesics provide pain relief, and oral corticosteroids help reduce inflammation and relieve chronic discomfort. To restore flexibility, physical therapy, including mobilization exercises, is started at 72 hours after the injury. It's combined with application of moist heat and a gradually decreased use of the soft cervical collar.

If the patient experiences persistent ligamentous or articular pain, he may benefit from cervical traction and diathermy treatment.

Nursing diagnoses

u Altered role performance u Anxiety u Impaired physical mobility u Knowledge deficit u Pain u Risk of posttrauma syndrome

Key outcomes

- u The patient will articulate factors that intensify pain and modify behavior accordingly.
- u The patient will develop effective coping mechanisms.
- u The patient will express a desire to overcome lack of knowledge.
- u The patient will attain the highest degree of mobility possible within the confines of injury.
- u The patient will state feelings and fears related to the traumatic event.

Nursing interventions

- u As in all suspected spinal injuries, assume that the patient has an injured spine until proven otherwise. If you're at the scene of the accident, make sure a patient with suspected whiplash or other injuries keeps their neck and head immobile. If necessary, immobilize the patient's neck by holding the head stable and in alignment until emergency personnel are able to immobilize the patient's neck with tape and a hard cervical collar or sandbags.
- u Until an X-ray rules out cervical fracture, move the patient as little as possible. Before X-rays are taken, carefully remove any neck jewelry the patient is wearing. Warn him against movements that could injure the spine.
- u Administer medications for pain as ordered.
- u Apply a soft cervical collar as directed.

Patient teaching

- u The patient with whiplash is likely to be discharged immediately. To help decrease his anxiety, reassure him that uncomplicated whiplash has an excellent prognosis. Be sure he fully understands the treatment and why he must restrict his activity.
- u Stress the importance of limiting activity during the first 72 hours after the injury. Tell the patient to rest for a few days and not to lift heavy objects.
- u If the patient needs a soft cervical collar, teach him how to put it on.
- u If a narcotic has been prescribed for pain relief, emphasize the need for safety in the home. Tell the patient not to drive and to avoid the use of alcohol while taking the medication.
- u Warn the patient to return to the facility or to call the doctor immediately if he develops persistent pain or numbness, tingling, or weakness of the extremities.

SPINAL INJURIES

Usually the result of trauma to the head or neck, spinal injuries (other than spinal cord damage) include fractures, contusions, and compressions of the vertebral column. Spinal injuries most commonly occur in the twelfth thoracic, first lumbar, and fifth, sixth, and seventh cervical areas. The real danger from such injuries is associated damage to the spinal cord.

Causes

Most serious spinal injuries result from motor vehicle crashes, falls, diving into shallow water, and gunshot and related wounds. Less serious spinal injuries typically are caused by improper lifting of heavy objects and by minor falls. Spinal dysfunction may also result from hyperparathyroidism and neoplastic lesions.

Complications

Spinal injuries can be complicated by spinal cord damage, resulting in paralysis and even death. The extent of cord damage depends on the level of injury to the spinal column. Autonomic dysreflexia, spinal shock, and neurogenic shock are complications of spinal injuries.

Assessment findings

The patient's history may reveal trauma, a neoplastic lesion, an infection that could produce a spinal abscess, or an endocrine disorder. The patient typically complains of muscle spasms and back or neck pain that worsens with movement. In cervical fractures, point tenderness may be present; in dorsal and lumbar fractures, pain may radiate to other body areas, such as the legs.

Physical assessment (including a neurologic assessment) helps locate the level of injury and detect any spinal cord damage.

General observation of the patient reveals that he limits movement and activities that cause pain. Inspection reveals any surface wounds that occurred with the spinal injury. Palpation can identify pain location, loss of sensation, deformity, and the presence of areflexia.

If the injury damages the spinal cord, note that clinical effects range from mild paresthesia to quadriplegia and shock. (See [Spinal shock, neurogenic shock,](#)

Diagnostic tests

Spinal X-rays, myelography, and computed tomography scans and magnetic resonance imaging are used to locate the fracture and site of the compression.

Treatment

The primary treatment after spinal injury is immediate immobilization to stabilize the spine and prevent cord damage; other treatment is supportive.

Cervical injuries require immobilization by application of a hard cervical collar, sandbags on both sides of the patient's head, or skeletal traction with skull tongs or a halo device. When a patient shows clinical evidence of spinal cord injury, high doses of I.V. methylprednisolone are started.

Treatment of stable lumbar and dorsal fractures consists of bed rest on a firm surface (such as a bed board), analgesics, and muscle relaxants until the fracture stabilizes (usually in 10 to 12 weeks). Later treatment includes exercises to strengthen the back muscles and a back brace or corset to provide support while walking.

An unstable dorsal or lumbar fracture requires a plaster cast, a turning frame and, in severe fracture, laminectomy and spinal fusion.

When the damage results in compression of the spinal column, neurosurgery may relieve the pressure. If the cause of compression is a neoplastic lesion, chemotherapy and radiation may relieve the compression by shrinking the lesion. Surface wounds that accompany the spinal injury require wound care and tetanus prophylaxis unless the patient was recently immunized.

Nursing diagnoses

- u Anxiety u Body image disturbance u Diversional activity deficit u Fluid volume deficit u Hopelessness u Impaired physical mobility u Ineffective airway clearance u Ineffective breathing pattern u Ineffective individual coping u Knowledge deficit u Pain u Risk for aspiration u Risk for disuse syndrome u Risk for impaired skin integrity u Risk for infection u Risk for posttrauma syndrome u Risk for spiritual distress u Sensory or perceptual alterations

Key outcomes

- u The patient will express a feeling of comfort and pain relief.
- u The patient will develop effective coping mechanisms.
- u The patient will attain the highest degree of mobility possible within the confines of injury.
- u The patient will state feelings and fears related to the traumatic event.
- u The patient's airway will remain patent.
- u The patient's ventilation will remain adequate.
- u The patient will show no sign of aspiration.
- u The patient will maintain muscle strength and joint range of motion.

Nursing interventions

- u As with all spinal injuries, suspect cord damage until proved otherwise. Apply a properly sized cervical collar if cervical injury is suspected.
- u During the initial assessment and X-rays, immobilize the patient on a firm surface.

ALERT Tell the patient not to move. Avoid moving him because hyperflexion can damage the spinal cord. If you must move the patient, get at least two other members of the staff to help you logroll him so that you don't disturb his body alignment.

- u Offer comfort and reassurance to the patient, talking to him quietly and calmly. Remember, the fear of possible paralysis will be overwhelming. Allow a family member who isn't too distraught to stay with him.
- u If the injury necessitates surgery, administer prophylactic antibiotics as ordered. Catheterize the patient, as ordered, to avoid urine retention, and monitor defecation patterns to avoid impaction.
- u If the patient has a halo or skull tong traction device, clean the pin sites daily and provide analgesics for headaches. During traction, turn the patient often to prevent pneumonia, embolism, and skin breakdown. Perform passive range-of-motion exercises to maintain muscle tone. If available, use a rotating bed to facilitate turning and avoid spinal cord injury.
- u Position the patient properly according to injuries to avoid aspiration.
- u If necessary, insert a nasogastric tube to prevent gastric distention.
- u Suggest appropriate diversionary activities to fill the hours of immobility. Offer prism glasses for reading.
- u Watch closely for neurologic changes. Immediately report changes in skin sensation and loss of muscle strength. Either could point to pressure on the spinal cord, possibly as a result of edema or shifting bone fragments.
- u Help the patient walk as soon as the doctor allows, most likely with a back brace.

ADVANCED PRACTICE

Spinal shock, neurogenic shock, dysreflexia, and hyperreflexia

Spinal Shock

Spinal shock is the loss of autonomic, reflex, motor, and sensory activity below the level of the cord lesion. Signs include flaccid paralysis, loss of deep tendon and perianal reflexes, and loss of motor and sensory function. Until resolution (1 to 6 weeks after the injury is sustained), the extent of cord damage can't be assessed. The return of reflex activity heralds the resolution of spinal shock.

Neurogenic shock

Neurogenic shock is the loss of autonomic function below the level of injury, producing orthostatic hypotension, bradycardia, and loss of the ability to sweat below the level of the lesion. This abnormal vasomotor response occurs secondary to the disruption of sympathetic impulses from the brain stem to the thoracolumbar area. It's seen most frequently in cervical cord injury.

Autonomic dysreflexia or hyperreflexia

Autonomic dysreflexia (or autonomic hyperreflexia) is a serious condition that occurs after spinal shock with lesions at +6 or above. Symptoms include cold or goose-fleshed skin below the lesion level, bradycardia, hypertension, and severe pounding headache. The cause may be a noxious stimulus, such as a distended bladder or skin lesion. Rapid identification and removal of the stimulus may eliminate the need for pharmacologic treatment for headache and hypertension.

Patient teaching

- u Explain traction methods to the patient and family members, and reassure them that halo or skull tong traction devices don't penetrate the brain.
- u Tell the patient about the prescribed regimen for home care.
- u Teach the patient exercises to maintain physical mobility.
- u Instruct the patient about his medications, including adverse effects and the duration of treatment.

- u Stress the importance of follow-up examinations.

Thoracic and abdominal injuries

Blunt and penetrating abdominal and chest injuries are commonly life-threatening and require immediate treatment.

BLUNT AND PENETRATING ABDOMINAL INJURIES

Blunt and penetrating abdominal injuries may damage major blood vessels and internal organs. Such injuries are potentially fatal; the prognosis depends on the extent of injury and the organs damaged but is improved by prompt diagnosis and surgical repair.

Causes

Blunt (nonpenetrating) abdominal injuries usually result from motor vehicle crashes, fights, falls from heights, and sports accidents. Penetrating abdominal injuries usually result from stabbings and gunshots.

Complications

Immediate life-threatening complications include hemorrhage and hypovolemic shock. Later complications include infection and dysfunction of major organs, such as the liver, spleen, pancreas, and kidneys.

Assessment findings

The patient's history reveals an accidental or forcibly inflicted abdominal injury. Symptoms vary with the degree of injury and the organs damaged. The patient with a blunt or penetrating abdominal injury typically is in obvious discomfort or pain.

A patient with a blunt abdominal injury may report severe pain radiating beyond the abdomen to the shoulders, as well as nausea and vomiting.

CULTURAL TIP Members of some cultures may be more expressive regarding pain and, at times, it may seem out of proportion with the injury sustained. Regardless, all complaints of pain should be evaluated to determine its nature and causation.

A penetrating abdominal wound may be obvious, especially if the patient is bleeding in the abdominal area. (If you observe the wound in the upper abdominal area, consider it a thoracoabdominal injury until proven otherwise.)

Inspection pinpoints the type of abdominal injury and helps determine its severity. Depending on the severity of the injury, the patient may be pale, cyanotic, or dyspneic. Inspection of the patient with a blunt abdominal injury may also reveal bruises, abrasions, contusions and, possibly, distention. (See [Effects of blunt abdominal trauma](#).)

For a patient with a penetrating abdominal injury, inspection reveals the type of wound and associated blood loss. Internal bleeding due to this type of trauma may be further determined by diagnostic tests, such as a computed tomography scan, serial hemoglobin and hematocrit studies, or exploratory surgery. Gunshots usually produce both entrance and exit wounds, with variable blood loss, pain, and tenderness. The patient also may exhibit pallor, cyanosis, tachycardia, shortness of breath, and hypotension.

Palpation may reveal the extent of pain and tenderness and, in blunt abdominal injuries, abdominal splinting or rigidity. Rib fractures commonly accompany blunt abdominal injuries. Auscultation may disclose tachycardia, decreased breath sounds, absent or decreased bowel sounds, or bowel sounds in the chest.

Diagnostic tests

Specific tests vary with the patient's condition but usually include abdominal X-rays and examination of the stools and stomach contents for blood. Chest X-rays, preferably done with the patient upright, may show free air from suspect ruptured organs.

Several blood studies usually are performed. Decreased hematocrit and hemoglobin levels point to blood loss. Coagulation studies are used to evaluate clotting ability. White blood cell count normally is elevated but doesn't necessarily point to infection. Typing and cross matching precede blood transfusion.

Arterial blood gas analysis evaluates respiratory status. A pancreatic injury typically results in elevated serum amylase levels. Also, levels of aspartate aminotransferase and alanine aminotransferase increase with tissue injury and cell death.

Excretory urography and cystourethrography show renal and urinary tract damage. Radioisotope scanning and ultrasound examination detect liver, kidney, and spleen injuries. Angiography discloses specific injuries, especially to the kidneys.

Peritoneal lavage is performed to check for blood, amylase, bile, food, fiber, and stool. Computed tomography scanning helps detect the extent of the injury and other injuries that may have occurred. Exploratory laparotomy reveals specific injuries when other clinical evidence is incomplete.

Treatment

The patient needs an immediate infusion of I.V. fluids and blood components to control hemorrhage and prevent hypovolemic shock.

The patient also may require intubation and mechanical ventilation or supplemental oxygen, as well as insertion of a nasogastric (NG) tube and an indwelling urinary catheter.

ALERT When administering emergency care to a patient with a penetrating abdominal injury, *don't* remove the penetrating object. Not only could that cause further damage, but it could also make determining the nature of the injury more difficult. Instead, secure the penetrating object and leave it in place until the surgical team is ready to remove it.

After stabilization, abdominal injuries may require surgical repair. Analgesics, withheld until after a definitive diagnosis, increase the patient's comfort. Antibiotics prevent infection.

The patient may require hospitalization, depending on the extent of injury; an asymptomatic patient may require observation for only 6 to 24 hours.

Nursing diagnoses

u Altered tissue perfusion u Anxiety u Decreased cardiac output u Fluid volume deficit u Impaired gas exchange u Impaired skin integrity u Nutritional alteration: Less than body requirements u Pain u Risk for infection u Risk for posttrauma syndrome

Key outcomes

- u The patient will maintain adequate ventilation.
- u The patient's fluid volume will remain within acceptable range.

- u The patient will express a feeling of comfort and pain relief.
- u The patient and family members will express understanding of special dietary needs.
- u The patient will develop effective coping mechanisms.
- u The patient will regain skin integrity.
- u Wounds and incisions will appear clean, pink, and free of purulent drainage.

Effects of blunt abdominal trauma

When a blunt object strikes a person's abdomen, it increases the intra-abdominal pressure. Depending on the force of the blow, the trauma can lacerate the liver and spleen, rupture the stomach, bruise the duodenum, and even damage the kidneys.

Nursing interventions

- u Provide emergency care as needed to support the patient's vital functions.
- u To maintain airway and breathing, intubate the patient and provide mechanical ventilation as necessary. Otherwise, provide supplemental oxygen.
- u When possible, explain each procedure to the patient before performing it to alleviate anxiety.
- u Using large-bore needles, start two I.V. lines for monitoring and rapid fluid infusion, using lactated Ringer's solution. Draw a blood sample for laboratory studies. Also, insert an NG tube and, if necessary, an indwelling urinary catheter; monitor stomach aspirate and urine for blood.
- u Obtain vital signs for baseline data. Continue monitoring them every 15 minutes until the patient's condition stabilizes.
- u Apply a sterile dressing to any open wounds. Splint a suspected pelvic injury on arrival by tying the patient's legs together with a pillow between them. Move the patient as little as possible.
- u If evisceration has occurred, minimize unnecessary movement of the patient. Apply a wet saline dressing to exposed abdominal contents.
- u Administer analgesics as ordered. Narcotics usually aren't recommended, but if the patient has severe pain, they may be administered in small, titrated I.V. doses as ordered.
- u Give tetanus prophylaxis and prophylactic I.V. antibiotics as ordered.
- u Stabilize impaled objects and leave the wound uncleaned and intact for forensic evaluation.
- u Prepare the patient for surgery. Obtain a consent form signed by the patient or a responsible relative. A consent form is necessary unless surgery must be performed immediately to save the patient's life.
- u If the injury was caused by a motor vehicle crash, find out if the police were notified; if they weren't, notify them. If the patient suffered a gunshot or stab wound, also notify the police, place all his clothes in a bag, and retain them for the police. Document the number and sites of the wounds.

Patient teaching

- u A patient with a blunt abdominal injury may be assessed and discharged from the emergency department. But some injuries, such as delayed rupture of the spleen, may not become apparent for several hours or days. Tell the patient to notify the doctor if he experiences any of the following: increased abdominal pain; shoulder pain that isn't the result of shoulder trauma (Kehr's sign); malaise, lethargy, or dizziness (signs of slow blood loss); unexplained fever; nausea or vomiting, particularly if it's persistent; hematemesis or melena; or lightheadedness, restlessness, diaphoresis, or hemoptysis.

BLUNT CHEST INJURIES

Types of blunt chest injuries include myocardial and pulmonary contusions and rib and sternal fractures. Such fractures can be simple, multiple, displaced, or jagged. Chest injuries account for one-fourth of all trauma deaths in the United States.

Causes

Most blunt chest injuries result from motor vehicle crashes. Other causes include sports, fights, and blast injuries.

Complications

Potentially fatal complications, such as hemothorax, hemorrhagic shock, pneumothorax and tension pneumothorax, flail chest, and diaphragmatic rupture, can result from rib and sternal fractures that commonly occur with blunt chest trauma. Liver laceration also may occur due to rib fracture.

Hemothorax occurs when a rib lacerates lung tissue or an intercostal artery, causing blood to collect in the pleural cavity. This compresses the lung, limiting respiratory capacity.

Pneumothorax occurs when a fractured rib tears the pleura and punctures a lung, allowing air to fill the pleural cavity and possibly leading to tension pneumothorax. Multiple rib fractures can cause flail chest: A portion of the chest wall "caves in," resulting in a loss of chest wall integrity and inadequate lung inflation.

Diaphragmatic rupture (usually on the left side) causes severe respiratory distress. Unless treated early, abdominal viscera may herniate through the rupture into the thorax (with resulting bowel sounds in the chest); both circulation and the lungs' vital capacity may be compromised. The diaphragmatic nerve may be injured by severing or edema and can result in loss of diaphragmatic excursion and respiratory distress.

Other complications of blunt chest trauma include rupture of the aorta, which is almost always immediately fatal; myocardial tears; cardiac tamponade; pulmonary artery tears; ventricular rupture; and bronchial, tracheal, or esophageal tears or rupture.

Assessment findings

The patient's history reveals a recent blunt injury to the chest, and the patient may complain of dyspnea and chest pain. Other clinical features vary with the

complications caused by the chest injury.

A patient with a sternal fracture—usually a transverse fracture located in the middle or upper sternum—may complain of persistent chest pain, even at rest. A patient with a rib fracture may complain of tenderness over the fracture site and pain that worsens with deep breathing and movement. Inspection reveals shallow, splinted respirations (a result of the painful breathing). Palpation reveals slight edema over the fracture site. You may note hypoventilation on auscultation.

If the patient develops a hemothorax, he'll report chest pain after the injury along with some form of respiratory distress. Depending on the seriousness of the hemothorax, inspection may disclose no obvious respiratory distress, mild respiratory distress, or severe dyspnea with restlessness and pallor or cyanosis. The patient may have asymmetrical chest movements and flat neck veins. In a massive hemothorax, you may observe bloody sputum or hemoptysis.

Palpation of a hemothorax may reveal unilateral decreased fremitus and decreased chest expansion on inspiration. If the hemothorax is small, percussion won't detect any changes. If the hemothorax is moderate or massive, percussion reveals dullness over the area of fluid collection. Auscultation may reveal unilateral diminished breath sounds or, in a more severe hemothorax, unilateral absent breath sounds. The patient with moderate or massive hemothorax also has hypotension and tachycardia.

If the patient develops a pneumothorax, he'll usually complain of acute, sharp chest pain and shortness of breath. Inspection of this patient may disclose an obviously increased respiratory rate, cyanosis, agitation, and, possibly, asymmetrical chest expansion.

Percussion reveals unilateral hyperresonance. On auscultation, breath sounds are diminished or absent on the affected side. You'll also note a crunching sound that occurs with each heartbeat—Hamman's sign, which indicates mediastinal air accumulation.

If a tension pneumothorax develops, the patient may complain of acute chest pain. On inspection, you may observe cyanosis, increasing dyspnea, tracheal deviation, distended neck veins, and asymmetrical or paradoxical neck movement. Palpation confirms the tracheal deviation and may disclose subcutaneous crepitus in the neck and upper chest area. Percussion usually reveals unilateral hyperresonance. On auscultation, you'll note unilateral absent breath sounds, muffled heart sounds, and hypotension.

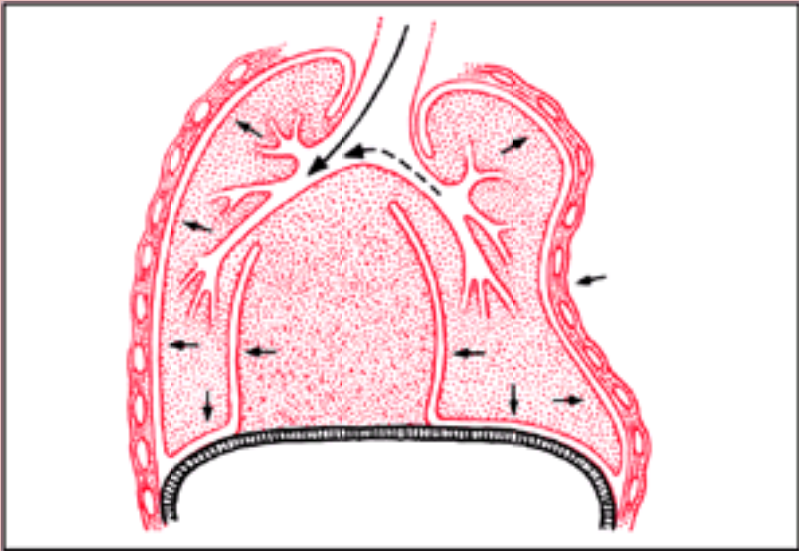

A patient who develops flail chest may report severe pain (from the rib fractures) and extreme shortness of breath. On inspection, you may note that he appears restless. You also may see bruising and disfigurement in the chest area; rapid, shallow respirations; cyanosis; and paradoxical chest movements. (See [Paradoxical breathing in flail chest.](#))

Paradoxical breathing in flail chest

Flail chest causes a distinctive breathing pattern.

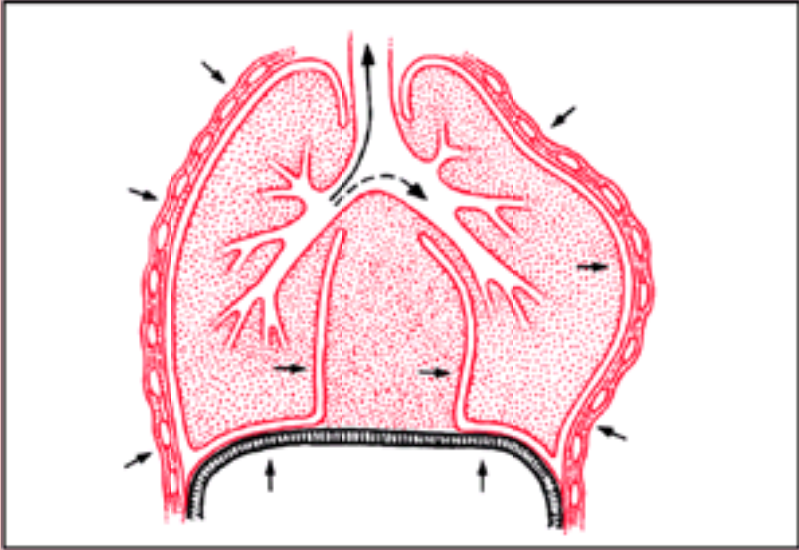

Inspiration

The chest wall normally expands during inspiration, drawing air into the lungs. But in flail chest, the injured freefloating section retracts as the patient inhales. Atelectasis can occur because lung tissue beneath the injury can't expand.

Expiration

During expiration, the flail section moves contrary to the rest of the chest wall, bulging outward. As a result, the patient can't expel air effectively.

Palpation may reveal tachycardia, bony crepitus at the fracture site, and subcutaneous crepitus. Auscultation may disclose hypotension and diminished breath sounds.

In a patient with pulmonary contusions, assessment findings include hemoptysis, pallor or cyanosis, dyspnea and, possibly, signs of airway obstruction. Myocardial contusions may produce tachycardia, ecchymosis, chest pain, and electrocardiogram (ECG) abnormalities. Diaphragmatic rupture causes severe respiratory distress. If the patient doesn't receive immediate treatment, assessment reveals a decrease in the vital capacity and serious circulatory changes—the result of herniation of the abdominal contents into the thorax.

Diagnostic tests

Chest X-rays may confirm rib and sternal fractures, pneumothorax, flail chest, pulmonary contusions, lacerated or ruptured aorta, tension pneumothorax (mediastinal shift), diaphragmatic rupture, lung compression, or atelectasis with hemothorax.

With cardiac damage, an ECG may show right bundle-branch block. In myocardial contusions, arrhythmias, conduction abnormalities, and STT wave changes may

occur.

Serum levels of aspartate aminotransferase, alanine aminotransferase, lactate dehydrogenase, creatine kinase (CK), and the isoenzyme CK-MB are elevated.

Angiography reveals aortic laceration or rupture.

Contrast studies and liver and spleen scans detect diaphragmatic rupture.

Echocardiography, computed tomography scans, and nuclear heart and lung scans show the extent of injury.

Treatment

Blunt chest injuries call for controlling bleeding and maintaining a patent airway, adequate ventilation, and fluid and electrolyte balance. Further treatment depends on the specific injury and complications:

- u Single fractured ribs are managed conservatively with mild analgesics and follow-up examinations to check for indications of a pneumothorax or hemothorax. To prevent atelectasis, the patient should perform incentive spirometry, deep breathing, and coughing for lung expansion. Intercostal nerve blocks may help with more severe fractures.
- u Treatment for a pneumothorax involves inserting a spinal, 14G, or 16G needle into the second intercostal space at the midclavicular line to release pressure. Then the doctor inserts a chest tube in the affected side to normalize pressure and reexpand the lung. The patient also receives oxygen and I.V. fluids. The patient may require intubation and mechanical ventilation.
- u Shock related to hemothorax calls for I.V. infusion of lactated Ringer's or normal saline solution. If the patient loses more than 1,500 ml of blood or more than 30% of circulating blood volume, he'll also need a transfusion of packed red blood cells or an autotransfusion. He may also require intubation, mechanical ventilation, and possible thoracotomy. Chest tubes are inserted into the fifth or sixth intercostal space at the midaxillary line to remove blood.
- u Treatment of flail chest may include endotracheal intubation and mechanical ventilation with positive pressure. The patient also may receive I.V. muscle relaxants. If the patient requires controlled ventilation, he'll receive a neuromuscular blocking agent. If an air leak occurs, the patient may need operative fixation of the flail chest.
- u Pulmonary contusions are managed with colloids to replace volume and maintain oncotic pressure. (Steroid use is controversial.) The patient may also need endotracheal intubation and mechanical ventilation as well as antibiotics, diuretics, and analgesics.
- u Myocardial contusions call for monitoring to detect arrhythmias and prevent cardiogenic shock. Drug therapy depends on the type of arrhythmia. Treatment is similar to that for myocardial infarction.
- u For myocardial rupture, septal perforation, and other cardiac lacerations, immediate surgical repair is mandatory. Less severe ventricular wounds require use of a digital or balloon catheter. Atrial wounds require a clamp or balloon catheter.
- u The patient with an aortic rupture or laceration who reaches the hospital alive needs immediate surgery, using synthetic grafts or anastomosis to repair the damage. He requires a large volume of I.V. fluids (usually lactated Ringer's solution) and whole blood along with oxygen at a very high rate. A pneumatic antishock garment is applied, and the patient is promptly transported to the operating room.
- u For a patient with a diaphragmatic rupture, a nasogastric tube is inserted to temporarily decompress the stomach, and the patient is prepared for surgical repair.

Nursing diagnoses

u Altered body image u Anxiety u Decreased cardiac output u Fluid volume deficit u Impaired gas exchange u Impaired physical mobility u Ineffective airway clearance u Ineffective breathing pattern u Pain u Risk for impaired skin integrity u Risk for infection u Risk for posttrauma syndrome

Key outcomes

- u The patient will express a feeling of comfort and pain relief.
- u The patient will attain the highest degree of mobility possible within the confines of injury.
- u The patient will state feelings and fears related to the traumatic event.
- u The patient will report feeling comfortable when breathing.
- u The patient will show no sign of aspiration.
- u The patient will carry out activities of daily living without weakness or fatigue.
- u The patient will maintain adequate ventilation.

Nursing interventions

- u Continuously monitor any patient with a blunt chest injury.
- u Frequently check pulses (including peripheral pulses) and level of consciousness. Also evaluate the color and temperature of skin, depth of respiration, use of accessory muscles, and length of inhalation compared with exhalation.
- u Look for tracheal deviation, a sign of tension pneumothorax. Also look for distended jugular veins and paradoxical chest motion. Listen to the patient's heart and breath sounds carefully, and palpate for subcutaneous emphysema and fractured ribs.
- u For simple rib fractures, administer mild analgesics, encourage bed rest, and apply heat. Don't strap or tape the chest.
- u Anticipate the possible need to insert chest tubes, especially if bleeding is prolonged. To prevent atelectasis, frequently turn the patient and encourage him to perform coughing and deep breathing.
- u For more severe fractures, assist with administration of intercostal nerve blocks. (Obtain X-rays before and after this treatment to rule out pneumothorax.)
- u For pneumothorax, assist during placement of the chest tube. Administer oxygen and I.V. fluids as ordered.
- u For flail chest, place the patient in semi-Fowler's position. Oxygenate the patient and anticipate intubation and controlled mechanical ventilation after emergency chest tube insertion. Observe for signs of tension pneumothorax. Suction the patient as needed. Start I.V. therapy, and observe closely for signs of excessive or insufficient fluid resuscitation and of acid-base imbalance. If paralytic agents are necessary while the patient is mechanically ventilated, be sure to administer analgesics and sedation to control pain and anxiety.
- u For hemothorax, assist with chest tube insertion, observe the volume and consistency of chest drainage, and administer oxygen. Begin autotransfusion, if indicated. Monitor and document vital signs and blood loss. Immediately report falling blood pressure, rising pulse rate, and uncontrolled hemorrhage, all of which require a thoracotomy to stop bleeding.
- u For pulmonary contusions, monitor blood gas levels to ensure adequate ventilation. Provide oxygen therapy, mechanical ventilation, chest tube care, and I.V. therapy as needed. Administer ordered colloids, analgesics, and corticosteroids.
- u For suspected cardiac damage, care is essentially the same as for a patient with a myocardial infarction. Cardiac monitoring or telemetry detects arrhythmias, and the patient should be carefully monitored for signs of cardiogenic shock. Impose bed rest in semi-Fowler's position (unless contraindicated). Administer oxygen, analgesics, and supportive drugs such as a digitalis glycoside, as ordered, to control heart failure or supraventricular arrhythmia. Watch for cardiac tamponade, which calls for pericardiocentesis.
- u If the patient has decreased mobility, reposition him at least every 2 hours to maintain skin integrity. Inspect his skin and keep it clean and dry.

Patient teaching

- u Reinforce the doctor's explanation of the patient's condition and treatment plan. Make sure the patient and family members understand the care that is required.
- u Teach the patient about the type of respiratory therapy he needs to have, such as incentive spirometry or postural drainage.
- u Teach the patient breathing exercises to maintain effective pulmonary function. Explain the need for turning, coughing, and deep breathing.
- u Discuss the medications prescribed for pain, including their adverse effects.
- u Teach splinting techniques for turning, deep breathing, and ambulation.
- u Encourage the patient not to smoke. Explain that smoking increases tracheobronchial secretions and decreases blood oxygen saturation.
- u Teach the patient with rib or sternal fractures that pain will persist for several weeks. Tell him to take analgesics as prescribed.
- u Advise the patient to notify the doctor if pain worsens or is accompanied by fever, a productive cough, and shortness of breath. These may indicate infection.
- u Tell the patient to avoid contact sports until the pain is resolved and the doctor permits him to resume such activities.

PENETRATING CHEST WOUNDS

Depending on its size, a penetrating chest wound may cause varying degrees of damage to bones, soft tissue, blood vessels, and nerves.

The risk of death and disease from a chest wound depends on the size and severity of the wound. Gunshot wounds are usually more serious than stab wounds because they cause more severe lacerations and rapid blood loss and because ricochet commonly damages large areas and multiple organs. With prompt, aggressive treatment, up to 90% of patients with penetrating chest wounds recover.

Causes

Stab wounds from a knife or an ice pick and gunshot wounds are the most common penetrating chest wounds. Explosions or firearms fired at close range are the usual source of large, gaping wounds.

Complications

Penetrating chest wounds may lead to arrhythmias; cardiac tamponade; mediastinitis; subcutaneous emphysema; bronchopleural fistula; myocardial rupture; shock, tears, and lacerations of the tracheobronchial tree; pneumothorax; hemothorax, and rib and sternal fractures.

Assessment findings

The patient's history reveals the cause of the chest wound. The chest wound may be obvious, possibly accompanied by a sucking sound as the diaphragm contracts and air enters the chest cavity through the opening in the chest wall.

The patient's level of consciousness depends on the extent of the injury. If he's awake and alert, he may be in severe pain. This will cause him to splint his respirations, reducing his vital capacity.

Inspection reveals the location and type of chest wound. (If you observe the wound in the lower thoracic area, consider it a thoracoabdominal injury until proved otherwise.) If hemopneumothorax is present, the patient will appear dyspneic, tachypneic, anxious, and cyanotic. He may try to sit up to catch his breath. You may note tracheal deviation, depending on the severity.

On palpation, you'll note a weak, thready pulse, the result of massive blood loss and hypovolemic shock. Percussion reveals flatness over areas of blood collection in the pleural or pericardial sac. Auscultation reveals decreased blood pressure and tachycardia from anxiety and blood loss. It also reveals diminished breath sounds over the area of lung collapse in hemopneumothorax. (See [How severe is the wound?](#))

How severe is the wound?

Examine the wound site to help determine the severity of a penetrating wound. To assess the severity of a stab wound, you also need to determine the type and size of the weapon used to inflict the wound and the location and angle of entry. For a gunshot wound, you need to determine the following:

- u weapon and missile type
- u missile velocity
- u victim's distance from the weapon
- u location of entrance and exit wounds.

Diagnostic tests

Chest X-rays allow evaluation of the injury and confirm chest tube placement. Arterial blood gas analysis helps evaluate the patient's respiratory status. A complete blood count may show low hemoglobin and hematocrit, reflecting severe blood loss. Additional tests may include arteriography, aortography, bronchoscopy, computed tomography scanning, echocardiography, and esophagoscopy.

Treatment

In a penetrating chest wound, treatment involves maintaining a patent airway and providing ventilatory support as needed. Chest tube insertion allows the reestablishment of intrathoracic pressure and drainage of blood from a hemothorax.

The patient's wound needs surgical repair. The patient also may need analgesics, antibiotics, tetanus prophylaxis, and infusion of blood products and I.V. fluids.

Nursing diagnoses

u Altered tissue perfusion u Anxiety u Decreased cardiac output u Fluid volume deficit u Impaired gas exchange u Impaired skin integrity u Ineffective breathing pattern u Pain u Risk for infection u Risk for posttrauma syndrome

Key outcomes

- u The patient will maintain adequate ventilation.
- u The patient will maintain adequate cardiac output.
- u The patient's fluid volume will remain within normal limits.
- u The patient will develop effective coping mechanisms.
- u The patient will express a feeling of comfort and pain relief.

Nursing interventions

- u Immediately evaluate the patient's airway, breathing, and circulation. Establish a patent airway, and provide ventilatory support as needed. Monitor pulses frequently for rate and quality.
- u Don't remove an impaled object, but stabilize it as necessary. Only a surgeon in a controlled environment should remove an impaled object.
- u Look for entrance and exit wounds, leaving them undisturbed for forensic evaluation.
- u Retain all clothing and objects for forensic evaluation.
- u Apply wound dressings as needed, always using sterile technique.
- u Place an occlusive dressing (for example, petroleum gauze) over a sucking wound. Monitor the patient for signs of tension pneumothorax. If such signs develop, temporarily remove the occlusive dressing to create a simple pneumothorax.
- u Assist with insertion of central lines for monitoring and fluid replacement, if indicated.
- u Monitor for signs of hemorrhagic shock.
- u Ensure adequate I.V. access with at least two large-bore peripheral catheters.
- u Obtain blood samples for type and cross matching.
- u Estimate blood loss (remember to look *under* the patient to estimate loss) and control bleeding. Replace blood and fluids as necessary.
- u If warranted, obtain and set up equipment for autotransfusion, particularly when the patient has massive blood loss.
- u Assist with chest X-ray and placement of chest tubes (using waterseal drainage) to reestablish intrathoracic pressure and to drain blood in a hemothorax. A second X-ray will evaluate the position of tubes and their function.

- u After chest tubes are in place, be sure to watch for bleeding and substantial air leakage through chest tubes, a sign of lung lacerations. Also monitor closely for a blood loss of more than 200 ml/hour through chest tubes, the result of severe vascular injury. Report such findings to the doctor immediately.
- u Provide ordered analgesics to relieve pain.

CULTURAL TIP Pain relief through medication administration also facilitates breathing and expansion of the lungs, thus preventing complications. However, some people are very stoic and may refuse to admit they're in pain. The purpose and intended effect of the treatment should be explained to the patient. Alternatives, such as splinting and visual imagery, may also be used.

- u Throughout treatment, monitor central venous pressure and vital signs to detect hypovolemia.
- u Monitor pulse oximetry.

Patient teaching

- u Reassure the patient, especially if he's the victim of a violent crime. Report the incident to the police in accordance with local laws. Help contact the patient's family, and offer them reassurance as well.
- u Reinforce the doctor's explanation of the patient's condition and treatment plan. Make sure the patient and family members understand the care required.
- u Teach the patient about the type of respiratory therapy he needs. Also teach him breathing exercises to maintain effective pulmonary function. Explain the need for turning, coughing, and deep breathing.
- u Discuss the medications prescribed for pain, including adverse effects.
- u Encourage the patient not to smoke. Explain that smoking increases tracheobronchial secretions and decreases blood oxygen saturation.
- u Advise the patient to notify the doctor if pain worsens or is accompanied by fever, a productive cough, and shortness of breath. These may indicate infection.
- u Tell the patient to avoid contact sports until the pain is resolved and the doctor lets him resume such activities.

Injuries of the extremities

These injuries can range from mild sprains or strains to traumatic amputation.

ARM AND LEG FRACTURES

An arm or a leg fracture is a break in the continuity of the bone, usually caused by major trauma. A fracture can result in substantial muscle, nerve, and other soft-tissue damage. The prognosis varies with the extent of disability or deformity, the amount of tissue and vascular damage, the adequacy of reduction and immobilization, and the patient's age, health, and nutritional status. Children's bones usually heal rapidly and without deformity; the bones of adults in poor health or those with osteoporosis or impaired circulation may never heal properly.

Causes

Most arm and leg fractures result from major trauma, such as a fall on an outstretched arm, a skiing or motor vehicle crash, and child, spouse, or elder abuse (shown by multiple or repeated episodes of fractures). However, in a person with a pathologic bone-weakening condition, such as osteoporosis, bone tumor, or metabolic disease, a mere cough or sneeze can cause a fracture. Prolonged standing, walking, or running can cause stress fractures of the foot and ankle—usually in nurses, postal workers, soldiers, and joggers.

Complications

Possible complications of fractures include arterial damage, nonunion, fat embolism, infection, shock, avascular necrosis, and peripheral nerve damage. (See [Identifying peripheral nerve injuries.](#))

Identifying peripheral nerve injuries		
The chart below lists signs and symptoms that can help you pinpoint where a patient has nerve damage. Keep in mind that you won't be able to rely on these signs and symptoms in a patient with severed extension tendons or severe muscle damage.		
NERVE	ASSOCIATED INJURY	SIGN OR SYMPTOM
<i>Radial</i>	Fracture of the humerus (especially the middle and distal thirds)	The patient can't extend his thumb.
<i>Ulnar</i>	Fracture of the medial humeral epicondyle	The patient can't perceive pain in the tip of his little finger.
<i>Median</i>	Elbow dislocation or wrist or forearm injury	The patient can't perceive pain in the tip of his index finger.
<i>Peroneal</i>	Tibia or fibula fracture or dislocation of knee	The patient can't extend his foot (this also may indicate sciatic nerve injury).
<i>Sciatic and tibial</i>	Rare with fractures or dislocations	The patient can't perceive pain in his sole.

Severe fractures, especially of the femoral shaft, may cause substantial blood loss and life-threatening hypovolemic shock.

Assessment findings

The patient's history usually reveals what caused the fracture. The patient typically reports pain that increases with movement and an inability to intentionally move the part of the arm or leg distal to the injury. The severity of the pain depends on the fracture type. The patient also may complain of a tingling sensation distal to the injury, possibly indicating nerve and vessel damage. (See [Classifying fractures.](#))

ASSESSMENT TIP: Arm and leg fractures may produce any or all of the “5 P's”: Pain and joint tenderness, pallor, pulse loss, paresthesia, and paralysis. The last three are distal to the fracture site.

Inspection may disclose soft-tissue edema, an obvious deformity or shortening of the injured limb, and discoloration over the fracture site. Open fractures produce an obvious skin wound and bleeding. Gentle palpation usually reveals warmth, crepitus, and, possibly, dislocation. Numbness distal to the injury and cool skin at the end of the extremity may indicate nerve and vessel damage.

Auscultation may reveal loss of pulses distal to the injury, an indication of possible arterial compromise or nerve damage.

Diagnostic tests

Anteroposterior and lateral X-rays of the suspected fracture, as well as X-rays of the joints above and below it, confirm the diagnosis. Angiography can help assess concurrent vascular injury.

Treatment

The primary goals of treatment are to return the injured limb to maximal function, to prevent complications, and to obtain the best possible cosmetic results.

Emergency treatment consists of splinting the limb above and below the suspected fracture where it lies, applying a cold pack, and elevating the limb, all of which reduce edema and pain. A severe fracture that causes blood loss calls for direct pressure to control bleeding. The patient with a severe fracture also may need fluid replacement (including blood products) to prevent or treat hypovolemic shock.

After a fracture is confirmed, treatment begins with reduction (restoring displaced bone segments to their normal position). This is followed by immobilization with a splint, a cast, or traction.

In closed reduction (manual manipulation), a local anesthetic such as lidocaine and an analgesic such as morphine I.M. minimize pain; a muscle relaxant such as diazepam I.V. or a sedative such as Midazolam facilitates the muscle stretching necessary to realign the bone. (An X-ray confirms reduction and proper bone alignment.) General anesthesia may be needed for closed reduction.

When closed reduction is impossible, open reduction during surgery reduces and immobilizes the fracture by means of rods, plates, or screws. Afterward, the patient usually must wear a plaster cast.

When a splint or cast fails to maintain the reduction, immobilization requires skin or skeletal traction, using a series of weights and pulleys. In skin traction, elastic bandages and moleskin coverings are used to attach the traction devices to the patient's skin. In skeletal traction, a pin or wire inserted through the bone distal to the fracture and attached to a weight allows more prolonged traction.

Treatment for an open fracture also requires careful wound cleaning, tetanus prophylaxis, prophylactic antibiotics and, possibly, additional surgery to repair soft-tissue damage.

Nursing diagnoses

u Altered role performance u Altered tissue perfusion u Anxiety u Diversional activity deficit u Fear u Impaired physical mobility u Impaired skin integrity u Ineffective individual coping u Pain u Risk for disuse syndrome u Risk for fluid volume deficit u Risk for infection u Risk for injury u Self-care deficit

Key outcomes

- u The patient will articulate factors that intensify pain and modify behavior accordingly.
- u The patient will identify factors that increase the potential for injury.
- u The patient will maintain muscle strength and tone and joint range of motion.
- u The patient will identify factors that increase the potential for injury.
- u The patient will attain the highest degree of mobility possible within the confines of injury.
- u The patient will express feelings about his present condition.

Nursing interventions

- u Reassure the patient with a fracture, who will probably be frightened and in pain. Ease pain with analgesics as needed.
- u If the patient has a severe open fracture of a large bone, such as the femur, watch for signs of shock. Monitor his vital signs; a rapid pulse, decreased blood pressure, pallor, and cool, clammy skin may indicate shock. Administer I.V. fluids and blood products, as ordered.
- u If the fracture requires long-term immobilization with traction, reposition the patient often to increase comfort and prevent pressure ulcers. Assist with active range-of-motion exercises to prevent muscle atrophy. Encourage deep breathing and coughing to avoid hypostatic pneumonia.
- u In long-term immobilization, urge adequate fluid intake to prevent urinary stasis and constipation. Watch for signs of renal calculi (flank pain, nausea, and vomiting).
- u Provide for diversional activity. Allow the patient to express his concerns over lengthy immobilization and the problems it creates.
- u Provide good cast care. While the cast is wet, support it with pillows. Observe for skin irritation near cast edges, and check for foul odors or discharge, particularly after open reduction, compound fracture, or skin lacerations and wounds on the affected limb.
- u Encourage the patient to start moving around as soon as he can, and help him with walking. (Remember, the patient who's been bedridden for some time may be dizzy at first.)
- u After cast removal, refer the patient for physical therapy to restore limb mobility.

Patient teaching

- u Help the patient set realistic goals for recovery.
- u Show the patient how to use his crutches properly.
- u Tell the patient with a cast to report signs of impaired circulation (skin coldness, numbness, tingling, or discoloration) immediately. Warn him against getting the cast wet, and instruct him not to insert foreign objects under the cast.
- u Teach the patient to exercise joints above and below the cast as ordered.
- u Tell the patient not to walk on a leg cast or foot cast without the doctor's permission. If the patient has a fiberglass cast, he may be able to walk immediately. Plaster casts require 48 hours to dry and harden.
- u Emphasize the importance of returning for follow-up care.

PATHOPHYSIOLOGY

Classifying fractures

One of the best-known systems for classifying fractures uses a combination of general terms to describe the fracture (for example, a simple, nondisplaced, oblique fracture).

Below are definitions of the classifications and terms used to describe fractures along with illustrations of fragment positions and fracture lines.

General classification of fractures

- Simple (closed):** Both fragments don't penetrate the skin.
- Compound (open):** Bone fragments penetrate the skin.
- Incomplete (partial):** Continuity isn't completely interrupted.
- Complete:** Bone continuity is completely interrupted.

Classification of fragment position

comminuted: Bone breaks into separate small pieces.

Angulated: Fragments lie at an angle to each other.

Impacted: One bone fragment is forced into another.

Displaced:Fracture fragments separate and are deformed.

Nondisplaced: The two sections of bone maintain essentially normal alignment.

Segmental: Fractures occur in two adjacent areas with an isolated central segment.

Overriding: Fragments overlap, shortening the total bone length.

Avulsed: Fragments are pulled from normal position by muscle contractions or ligament resistance.

Classification of fracture line

Linear: The fracture line runs parallel to the bone's axis

Longitudinal: The fracture line extends in a longitudinal (but not parallel) direction along the bone's axis.

Oblique: The fracture line crosses the bone at roughly a 45-degree angle to the bone's axis.

Spiral: The fracture line crosses the bone at an oblique angle creating a spiral pattern.

Transverse: The fracture line forms a right angle with the bone's axis.

DISLOCATIONS AND SUBLUXATIONS

Commonly causing extreme pain, dislocations are displacements of joint bones so that their articulating surfaces totally lose contact; subluxations are partial displacements of the articulating surfaces. Dislocations and subluxations occur at the joints of the shoulders, elbows, wrists, digits, hips, knees, ankles, and feet.

These injuries may accompany fractures of these joints or result in deposition of fracture fragments between joint surfaces. Even without a concomitant fracture, a displaced bone may damage surrounding muscles, ligaments, nerves, and blood vessels, especially if reduction is delayed.

Causes

A dislocation or subluxation may be caused by a congenital problem (such as congenital dislocation of the hip), or it may follow trauma or disease of surrounding joint

tissues (for example, Paget's disease of the bone).

Complications

Nerve injury and vascular impairment, such as avascular necrosis, may complicate a dislocation or subluxation. Bone necrosis also may occur.

Assessment findings

The patient's history may reveal the direct cause of the injury. If trauma caused the injury, it may be accompanied by joint surface fractures. The patient may complain of extreme pain.

Inspection may reveal a deformity around the joint and a change in the length of the involved extremity. Palpation may detect impaired joint mobility and point tenderness.

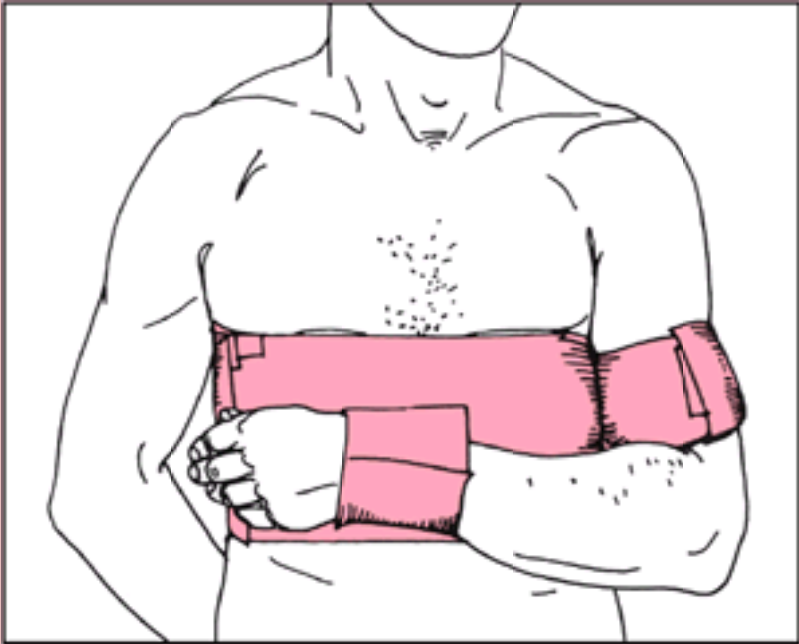

Diagnostic tests

X-rays are used to confirm the diagnosis and identify any associated fractures.

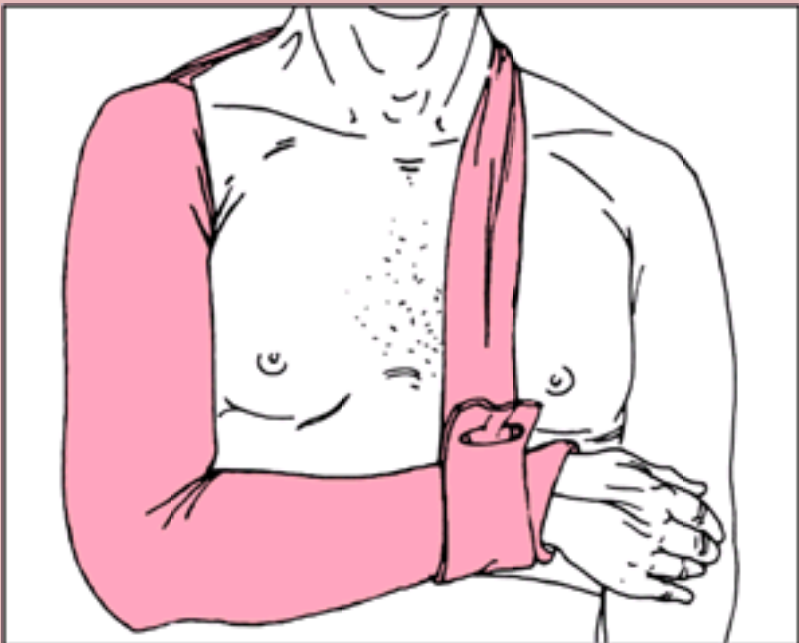

Immobilizing a shoulder dislocation

When a shoulder dislocation has been reduced, an external immobilization device, such as the elastic shoulder immobilizer or the stockinette Velpeau splint, can maintain the position until healing takes place. The device should remain on for about 3 weeks.

Elastic shoulder immobilizer

Stockinette Velpeau splint

Treatment

Immediate reduction and immobilization can prevent additional tissue damage and vascular impairment. Closed reduction consists of manual traction under general anesthesia or local anesthesia and sedatives. During reduction, morphine I.V. controls pain; midazolam I.V. controls muscle spasm and facilitates muscle stretching during traction. Some injuries require open reduction under regional block or general anesthesia. Such surgery may include wire fixation of the joint, skeletal traction, and ligament repair.

After reduction, a splint, a cast, traction, or another device immobilizes the joint. In most cases, immobilizing the digits for 2 weeks, hips for 6 to 8 weeks, and other dislocated joints for 3 to 6 weeks allows surrounding ligaments to heal. (See [Immobilizing a shoulder dislocation.](#))

Nursing diagnoses

u Altered tissue perfusion (peripheral) u Body image disturbance u Impaired physical mobility u Impaired skin integrity u Knowledge deficit u Pain u Risk for disuse syndrome u Self-care deficit

Key outcomes

- u The patient will articulate factors that intensify pain and modify behavior accordingly.
- u The patient will identify factors that increase the potential for injury.
- u The patient will maintain muscle strength and tone.
- u The patient will maintain joint range of motion.

Nursing interventions

- u Assess vascular condition to establish a baseline; reassess intermittently to detect vascular compromise.
- u Immediately report signs of severe vascular compromise, such as pallor, pain, loss of pulse, paralysis, and paresthesia. If such signs develop, the patient needs an immediate orthopedic examination and emergency reduction.
- u Until reduction immobilizes the dislocated joint, don't attempt manipulation. Apply ice to ease pain and edema. Splint the extremity “as it lies,” even if the angle is awkward.
- u When a patient receives I.V. drugs to relieve pain and to relax him, he may develop respiratory depression or even respiratory arrest. Therefore, keep an airway and a handheld resuscitation bag nearby during and after reduction, and monitor pulse oximetry readings and vital signs.
- u To avoid skin damage, watch for signs of pressure injury inside and outside the dressing.
- u Encourage prescribed active range-of-motion exercises for adjacent nonimmobilized joints.
- u After removal of the cast or splint, inform the patient that he may gradually return to normal joint activity.
- u After reduction of a dislocated hip (required immediately), stress the importance of follow-up visits to detect septic femoral head necrosis from vascular damage.

Patient teaching

- u To avoid injury from a dressing that is too tight, instruct the patient to report numbness, pain, cyanosis, and coldness of the extremity below the cast or splint.
- u Explain prescribed medications for pain relief.
- u Teach the patient and family members to evaluate skin integrity and neurovascular status while the joint is immobilized.
- u Show the patient how to use assistive devices, such as crutches or a sling, as needed.
- u As appropriate, explain that the patient may need help with self-care until the joint can be used again.
- u Stress the importance of gradually exercising the joint after splint removal.
- u At discharge, emphasize the need for follow-up visits.

SPRAINS AND STRAINS

A sprain—usually a relatively minor injury—is a complete or incomplete tear in the supporting ligaments surrounding a joint. (A sprained ankle is a common joint injury.) A strain, which can be acute or chronic, is an injury to a muscle or tendinous attachment. Both injuries usually heal without surgical repair. (See [Classifying sprains and strains.](#))

Causes

A sprain usually follows a sharp twisting motion of the affected joint. An acute strain usually results from vigorous muscle overuse, overstress, or over-stretching of a single muscle or muscle group.

Complications

A sprain can result in an avulsion fracture, which occurs when a bone fragment is pulled out of place by a ligament. A chronic strain results from the accumulated effects of repeated muscle overuse.

Assessment findings

The patient's history reveals how the sprain or strain occurred.

If the patient has a sprain, his history also reveals whether he's physically active (which may have caused the injury) or sedentary (which puts him at increased risk for musculoskeletal injury) and if he's had similar injuries or a systemic disease that could cause musculoskeletal problems (for example, foot neuropathy in a diabetic patient could cause a sprain). He may report local pain that worsens during joint movement and loss of mobility. This loss of mobility may not occur until several hours after the injury.

ADVANCED PRACTICE

Classifying sprains and strains

The guide below will help you classify the severity of sprains and strains.

Sprains

- u *Grade 1 (mild):* minor or partial ligament tear with normal joint stability and function
- u *Grade 2 (moderate):* partial tear with mild joint laxity and some function loss
- u *Grade 3 (severe):* complete tear or incomplete separation of ligament from bone, causing total joint laxity and function loss

Strains

- u *Grade 1 (mild):* microscopic muscle or tendon tear (or both) with no loss of strength
- u *Grade 2 (moderate):* incomplete tear with bleeding into muscle tissue and some loss of strength
- u *Grade 3 (severe):* complete rupture, usually resulting from separation of muscle from muscle, muscle from tendon, or tendon from bone (this type of strain usually stems from sudden, violent movement or direct injury)

The patient with an acute strain may report sharp, transient pain and rapid swelling. When the severe pain has subsided, he may complain of muscle tenderness. He may tell you he heard a snapping or popping noise at the time of the injury. The patient with a chronic strain reports stiffness, soreness, and generalized tenderness.

Inspection of a sprain reveals ecchymosis from blood extravasating into surrounding tissues and swelling, a key sign of a sprain. Palpation may reveal point tenderness in a moderate or severe sprain.

Inspection of a strain reveals swelling over the injury site and, if the injury is several days old, ecchymosis. Palpation reveals the degree of swelling and defines the area of tenderness.

Diagnostic tests

X-rays rule out fractures and confirm damage to ligaments. (See [Sprains and strains: An inside view.](#))

PATHOPHYSIOLOGY

Sprains and strains: An inside view

Except for possible swelling and discoloration, you can't see a sprain or a strain. But the patient can surely feel one. In a sprain, he feels the stretching or tearing of a ligament—the fibrous tissue that binds joints together.

He'll feel a partial muscle tear in an acute or chronic strain. A strain also may affect tendons the fibrous tissue that connects muscle to bone. Here is what each type of injury looks like.

KNEE SPRAIN

CALF STRAIN

Treatment

Ice should be applied to the injury site as soon as possible to control swelling. After 24 to 48 hours, treatment should switch to heat to encourage reabsorption of blood and to promote healing and comfort.

The patient may need the injury splinted or immobilized to promote comfort and aid healing. The patient may need surgery if the muscle, tendon, or ligament ruptured or if the ligaments torn by the sprain don't heal properly, causing recurrent dislocation. Some athletes may request immediate surgical repair to hasten healing. A rehabilitation or exercise program may help ensure a gradual progression of activity.

Nursing diagnoses

u Impaired physical mobility u Knowledge deficit u Pain u Risk for injury

Key outcomes

- u The patient will attain the highest level of mobility possible within the confines of the injury.
- u The patient will express a feeling of comfort and pain relief.
- u The patient will identify factors that increase the potential for injury.

Nursing interventions

- u Immediately after the injury, control swelling by elevating the joint above the level of the patient's heart and by intermittently applying ice, as ordered, during the first 12 to 48 hours. To prevent a cold injury, place a towel between the ice pack and the skin.
- u Immobilize a sprain with an elastic bandage or an air cast. If the sprain is severe, use a soft cast. For a sprained ankle, apply the elastic bandage from the toes to mid-calf.
- u Depending on the severity of the injury, the patient may need codeine or another analgesic. If he has a sprained ankle, he may need crutches.
- u Perform range-of-motion exercises, progressing from passive to active, to prevent joint contractures and muscle atrophy.

Patient teaching

- u Make sure you provide comprehensive teaching because a patient with a sprain or strain seldom requires hospitalization.
- u Instruct the patient to elevate the joint for 48 to 72 hours after the injury. (Explain that he can use pillows to elevate the joint while he's sleeping.) Also teach him to apply ice intermittently for the first 12 to 48 hours. Advise him to switch to intermittent applications of heat after that.
- u If the joint has been wrapped in an elastic bandage, teach the patient how to reapply it by wrapping from below to above the injury, forming a figure eight. Tell him to remove the bandage before going to sleep and to loosen it if the leg becomes pale, numb, or painful.
- u Stress the need for movement to alleviate the effects of immobility. Teach the patient how to perform range-of-motion exercises.
- u Tell the patient to use aspirin, acetaminophen, or other prescribed analgesics for discomfort. Make sure he understands the purpose of the prescribed medication and any adverse reactions that could occur.
- u Provide crutch-gait training for the patient with a sprained ankle.
- u Instruct the patient to call the doctor if the pain worsens or persists. If so, an additional X-ray may detect a fracture that initially was missed.
- u Warn the patient that he may further injure the joint if he overstresses it before healing is complete. This is especially true if he has an ankle or a knee injury.
- u Athletes may tape wrists and ankles before sports activities to support those areas, possibly preventing injury.

TRAUMATIC AMPUTATION

Traumatic amputation—the accidental loss of a body part—usually involves a finger, a toe, an arm, or a leg. In complete amputation, the member is totally severed; in partial amputation, some soft-tissue connection remains.

The prognosis has improved because of early, improved emergency and critical care management, new surgical techniques, early rehabilitation, prosthesis fitting, and new prosthesis designs. New limb reimplantation techniques have been moderately successful, but incomplete nerve regeneration remains a major limiting factor.

Causes

A traumatic amputation may result from a cutting, tearing, or crushing insult involving the use of factory, farm, or power tools, or from a motor vehicle crash.

Complications

Hypovolemic shock and sepsis are possible complications in traumatic amputation. If reimplantation is attempted, residual paralysis may occur.

Assessment findings

The patient history reveals the type of accident that caused the amputation. Inspection typically reveals a partially or completely severed body part with hemorrhage and soft-tissue damage. Inspection also discloses the type of amputation. In a clean amputation, the wound has well-defined edges and damage is local. In a crush amputation, damage involves the tissue and arterial intima. In an avulsive amputation, the tissue is torn and vascular and neural structures may become separated near the damaged bone or cartilage. In a partial amputation, palpation detects the status of pulses distal to the amputation.

Diagnostic tests

Ultrasonography is used to monitor the patient's pulse. X-rays of both the amputated part and the stump can help determine the extent of fractures, and arteriography can help evaluate arterial injury.

Treatment

The greatest immediate threat after traumatic amputation is blood loss and hypovolemic shock. Therefore, emergency treatment consists of local measures to control bleeding, fluid replacement with sterile normal saline or lactated Ringer's solution, colloids, and blood replacement as needed.

Reimplantation, especially for straight-edged amputation, is becoming more common and successful because of advances in microsurgery. If reconstruction or reimplantation is possible, the objective of surgery is to preserve the patient's usable joints. When arm or leg amputations are performed, the surgeon creates a stump to be fitted with a prosthesis. A rigid dressing permits early prosthesis fitting and rehabilitation.

Nursing diagnoses

u Altered role performance u Altered tissue perfusion (peripheral) u Body image disturbance u Fear u Fluid volume deficit u Impaired skin integrity u Ineffective individual coping u Knowledge deficit u Pain u Risk for infection u Risk for posttrauma syndrome

Key outcomes

- u The patient's fluid volume will remain within the normal range.
- u The patient's pulses and circulation will be adequate to his extremities.
- u The patient will articulate factors that intensify pain and modify behavior accordingly.
- u The patient will attain the highest degree of mobility possible within the confines of injury.
- u The patient will communicate his feelings about change in body image.

Nursing interventions

- u In emergency treatment, monitor vital signs (especially in hypovolemic shock). If amputation involved an extremity, ensure I.V. access with at least two large-bore catheters (probably not necessary with single-digit involvement). Clean the wound and give tetanus prophylaxis, analgesics, and antibiotics, as ordered.
- u After a complete amputation, wrap the amputated part in a dry, sterile towel. *Don't* place the amputated part directly in formalin, water, ice, or sterile normal saline solution, and *don't* put a tag on the part. These actions can cause further trauma to the amputated part, possibly eliminating the opportunity for reimplantation. Place the amputated part in a dry, clean plastic bag, seal the bag tightly, and label it. Then place the bag on ice (not dry ice). Flush the wound with sterile normal saline solution, apply a sterile pressure dressing, and elevate the limb (don't use a tourniquet). Notify the reimplantation team.
- u After a partial amputation, position the limb in normal alignment and drape it with towels or dressings soaked in sterile normal saline solution.
- u Preoperative care includes thorough wound irrigation and debridement (using local anesthesia). Postoperative dressing changes require sterile technique to help prevent skin infection and ensure skin graft viability.
- u Encourage the patient to verbalize his feelings about his altered body image.
- u Allow the patient to verbalize his concerns and fear about his future after the amputation. If necessary, consult with a rehabilitation counselor to help the patient learn a new skill.
- u If reimplantation isn't viable, inform the patient about community support services and rehabilitation programs.

Patient teaching

- u Reinforce the doctor's explanation of the surgery, as necessary, and clear up any misconceptions the patient or family members have.
- u After surgery, tell the patient to report any drainage through the cast and any warmth, tenderness, or foul odor. Teach him to immediately wrap the stump with an elastic bandage if the cast slips off. Show him how to slip on a custom-fitted, elastic stump shrinker.
- u Teach the patient how to care for his stump. Instruct him to call the doctor if the incision appears to be opening, looks red or swollen, feels warm, is painful to touch, or is seeping drainage.
- u Reinforce the need to follow the prescribed exercise program to minimize complications, maintain muscle tone and strength, and prevent contractures. Also stress the importance of correct positioning to prevent contractures.
- u Caution the patient to protect the stump from additional trauma.

Whole body injuries

A whole body injury affects the entire body and is commonly life-threatening.

ASPHYXIA

Asphyxia is a condition of insufficient oxygen and accumulating carbon dioxide in the blood and tissues. It results from an interference with respiration. Asphyxia leads to cardiopulmonary arrest and is fatal without prompt treatment.

Causes

Asphyxia results from any internal or external condition or substance that inhibits respiration. Some examples include:

- u hypoventilation, stemming from narcotic abuse, medullary disease or hemorrhage, respiratory muscle paralysis, or cardiopulmonary arrest
- u intrapulmonary obstruction, associated with airway obstruction, pulmonary edema, pneumonia, and near drowning
- u extrapulmonary obstruction, as in tracheal compression from a tumor, pneumothorax, strangulation, trauma, or suffocation
- u inhalation of toxic agents, resulting from carbon monoxide poisoning, smoke inhalation, and excessive oxygen inhalation.

Complications

Without timely intervention, asphyxia can lead to neurologic damage and death.

Assessment findings

The patient's history (obtained from a family member, friend, or emergency personnel) reveals the cause of asphyxia. Signs and symptoms depend on the duration and degree of asphyxia.

On general observation, the patient typically appears anxious, agitated or confused, and dyspneic, with prominent neck muscles. Other common signs and symptoms include wheezing, stridor, altered respiratory rate (apnea, bradypnea, occasional tachypnea), and a fast, slow, or absent pulse.

Inspection may reveal little or no air moving in or out of the nose and mouth. You may note intercostal rib retractions as the intercostal muscles pull against resistance. You also may note pale skin and, depending on the severity of the asphyxia, cyanosis in mucous membranes, lips, and nail beds. Trauma-induced asphyxia may cause erythema and petechiae on the upper chest, up to the neck and face. In late-stage carbon monoxide poisoning, mucous membranes appear cherry-red. Auscultation reveals decreased or absent breath sounds.

Diagnostic tests

Arterial blood gas (ABG) analysis, the most important test, indicates decreased partial pressure of arterial oxygen (less than 60 mm Hg) and increased partial pressure of arterial carbon dioxide (more than 50 mm Hg). Chest X-rays may detect a foreign body, pulmonary edema, or atelectasis. Toxicology tests may show drugs, chemicals, or abnormal hemoglobin. Pulmonary function tests may indicate respiratory muscle weakness.

Treatment

Asphyxia requires immediate respiratory support with cardiopulmonary resuscitation (CPR), endotracheal intubation, supplemental oxygen, mechanical ventilation, and pulse oximetry, as needed. It also calls for prompt treatment of the underlying cause: bronchoscopy for extraction of a foreign body; a narcotic antagonist, such as naloxone, for narcotic overdose; and gastric lavage for poisoning.

Nursing diagnoses

u Anxiety u Decreased cardiac output u Impaired gas exchange u Ineffective airway clearance u Ineffective breathing pattern u Risk for aspiration u Risk for suffocation

Key outcomes

- u The patient will maintain adequate ventilation.
- u The patient will maintain patent airway.
- u The patient will maintain cardiac output.
- u The patient will state feelings of anxiety.
- u The patient won't aspirate.
- u The patient and family members will demonstrate knowledge of safety measures to prevent suffocation.

Nursing interventions

- u If a foreign body is blocking the patient's airway, perform abdominal thrust.
- u In an unconscious patient, the tongue may obstruct the airway. You may be able to open the airway by simply repositioning the patient.
- u If the patient has no spontaneous respirations and no pulse, begin CPR.
- u If necessary, assist with endotracheal intubation to provide an airway, and give supplemental oxygen or provide mechanical ventilation as ordered. Monitor ABG levels, the best indicator of oxygenation and acid-base status.
- u Ensure I.V. access, monitor I.V fluids, and obtain laboratory specimens as ordered.
- u If the patient ingested poison, insert a nasogastric tube or an Ewald tube for lavage.
- u Administer medications such as naloxone for narcotic overdose as ordered.
- u Monitor the patient's cardiac status, vital signs, and neurologic status throughout treatment.
- u Continually reassure the patient throughout treatment. Respiratory distress is terrifying.
- u If asphyxia was intentionally induced, such as carbon monoxide poisoning, refer the patient to a psychiatrist.

Patient teaching

- u To prevent drug-induced asphyxia, warn the patient about the danger of taking alcohol with other central nervous system depressants.
- u If the patient works with toxic chemicals, stress the importance of adequate ventilation in the workplace and the use of protective gear supplied by the employer.

BURNS

A major burn is a horrifying injury, requiring painful treatment and a long period of rehabilitation. Burns can be fatal, permanently disfiguring, and incapacitating, both emotionally and physically.

In the United States, more than 2 million people are burned each year. Of these, up to 70,000 are hospitalized and 20,000 require admission into specialized burn units. Infections are a major cause of morbidity and mortality in the seriously burned patient; as many as 10,000 patients in the United States die each year due to burn-related infections.

Causes

Thermal burns, the most common type, frequently result from residential fires, motor vehicle crashes, playing with matches, improperly stored gasoline, space heater or electrical malfunctions, and arson. Other causes include improper handling of firecrackers, scalding accidents, and kitchen accidents (such as a child climbing on top of a stove or grabbing a hot iron). Sometimes burns are traced to child or elder abuse.

Chemical burns result from the contact, ingestion, inhalation, or injection of acids, alkali, or vesicants. Electrical burns commonly occur after contact with faulty electrical wiring or high-voltage power lines, or when electric cords are chewed (by young children). Friction, or abrasion, burns happen when the skin is rubbed harshly against a coarse surface. Sunburn follows excessive exposure to sunlight and improper use of tanning lights.

Complications

The most common complications and leading causes of death are respiratory complications and sepsis. Other possible complications include hypovolemic shock, anemia, malnutrition, and multisystem organ dysfunction.

Assessment findings

The patient's history usually reveals the cause of the burn. It also may disclose a preexisting medical condition—such as a cardiac or pulmonary problem, diabetes mellitus, peripheral vascular disease, chronic alcohol or drug abuse, or a psychiatric disorder—that could complicate burn treatment and recovery. If the patient is under age 5 or over age 65, there is a higher incidence of complications and, consequently, a higher risk of death.

Obtain the patient's history as soon as possible because medications, confusion resulting from the injury, or the use of an endotracheal tube may prevent the patient from giving an accurate history later.

Your assessment provides a general idea of burn severity. First, determine the depth of tissue damage. A partial-thickness burn damages the epidermis and part of the dermis; a full-thickness burn also affects the subcutaneous tissue. The more traditional method is to gauge burns by degree. Most burns include a combination of degrees and thicknesses. (See [Depths of burns](#).)

There are three levels of burn severity:

- u *first-degree (superficial) burns*—erythema appears, and the patient complains of pain; damage is limited to the epidermis
- u *second-degree (partial-thickness) burns*—blisters and mild to moderate edema develop, and the patient reports pain; both the epidermis and the dermis are damaged
- u *third-degree (full-thickness) burns*—tissue appears white, brown, pale yellow, cherry-red, or black and leathery with thrombosed vessels; no blisters appear; both epidermis and dermis are damaged (damage may extend through deeply charred subcutaneous tissue to muscle and bone).

Next, assess the size of the burn. This usually is expressed as the percentage of the body surface area (BSA) covered by the burn. Determine this percentage with an assessment tool, such as the Rule of Nines or the Lund and Browder Chart. (See [Estimating the extent of a burn](#).) You usually don't need to calculate the total BSA in a patient with a first-degree burn.

Estimate the severity of the burn by correlating its depth and size using these classifications:

- u *major*, which includes third-degree burns on more than 10% of the patient's BSA; second-degree burns on more than 25% of an adult's BSA or more than 20% of a child's; burns of the hands, face, feet, or genitalia; burns complicated by fractures or respiratory damage; electrical burns; and all burns in poor-risk patients
- u *moderate*, which covers third-degree burns on 3% to 10% of a patient's BSA and second-degree burns on 15% to 25% of an adult's BSA or 10% to 20% of a child's BSA
- u *minor*, which are third-degree burns that appear on less than 3% of a patient's BSA and second-degree burns that appear on less than 15% of an adult's BSA or 10% of a child's BSA.

Depths of burns

This illustration shows the depth of tissue damage in partial- and full-thickness burns. A partial-thickness burn damages the epidermis and part of the dermis. A full-thickness burn affects the epidermis, dermis, and subcutaneous tissue.

Inspection reveals other characteristics of the burn as well, including location and extent. Keep in mind that burns on the face, hands, feet, and genitalia are most serious because of a possible loss of function or severe impact on body image. Also note the burn's configuration. If the patient has a circumferential burn, he runs the risk of edema totally occluding circulation in his extremity. If he has burns on his neck, he may suffer airway obstruction; burns on the chest can lead to restricted respiratory excursion.

Inspect the patient for other injuries that may complicate his recovery. In particular, look for signs of pulmonary damage from smoke inhalation—singled nasal hairs, mucosal burns, voice changes, coughing, wheezing, soot in the mouth or nose, and darkened sputum. Also, look for respiratory distress and cyanosis—signs of systemic complications from noxious fumes such as cyanide from burning carpets.

Palpation reveals edema and alteration in pulse rate, strength, and regularity, which can signify vascular compromise.

Lung auscultation may reveal respiratory distress, including stridor, wheezing, crackles, and rhonchi. Heart auscultation may reveal adventitious heart sounds, such as S₃, or S₄, gallop or murmur, which is a sign of myocardial injury or decompensation. The patient with severe burns may be hypotensive, indicating hypovolemia and, possibly, shock. (You can take the blood pressure even if all extremities are burned by placing a sterile 4" x 4" gauze pad or sterile towel on the extremity before applying the blood pressure cuff.)

Abdominal auscultation may disclose absent bowel sounds if the patient has an ileus, which usually accompanies a burn that covers more than 25% of the total BSA.

Diagnostic tests

Routine blood work for a patient with a burn injury includes a complete blood count, platelet count, clotting studies, liver function studies, and carboxyhemoglobin, electrolyte, blood urea nitrogen, glucose, and creatinine levels. Urinalysis may reveal myoglobinuria and hemoglobinuria. If the patient is age 35 or over, he'll also need an electrocardiogram. Chest X-ray films and arterial blood gas levels allow the evaluation of alveolar function. Fiberoptic bronchoscopy shows the condition of the trachea and bronchi.

Treatment

The priority in burn treatment is securing an airway, especially for a patient with severe facial burns or suspected pulmonary injury. Initial treatment though to prevent hypoxia includes endotracheal intubation, administration of high concentrations of oxygen, and positive-pressure ventilation.

Treatment for moderate or severe burns includes administering lactated Ringer's solution through a large-bore I.V. line to expand vascular volume. The volume to infuse is calculated according to the extent of the area burned and the amount of time that has elapsed since the burn injury occurred. Several formulas are used as general guidelines for fluid replacement in the first 24 hours after a burn. The specific infusion varies according to the patient's response, especially urine output. Central I.V. lines and arterial lines are inserted as necessary. An adult patient also needs I.V. fluids sufficient to maintain a urine output of 30 to 50 ml/hour; the output of a child under 66 lb (30 kg) should be maintained at 1 ml/kg/hour. An indwelling urinary catheter permits accurate monitoring of urine output.

I.V. morphine (2 to 4 mg) alleviates pain and anxiety. The patient also will need an NG tube to prevent gastric distention and accompanying ileus from hypovolemic shock.

All burn patients need a booster of 0.5 ml of tetanus toxoid administered I.M. Most burn centers don't recommend administering prophylactic antibiotics because

overuse of antibiotics fosters the development of resistant bacteria.

Treatment of the burn wound includes:

- initial debridging by washing the surface of the wound area with mild soap
- sharp debridement of loose tissue and blisters (blister fluid contains agents that reduce bactericidal activity and increase inflammatory response)
- covering the wound with an antimicrobial agent and an occlusive cotton gauze dressing
- escharotomy, if the patient is at risk for vascular, circulatory, or respiratory compromise.

Nursing diagnoses

- Altered nutrition: Less than body requirements
- Altered protection
- Altered tissue perfusion
- Anxiety
- Body image disturbance
- Decreased cardiac output
- Fluid volume deficit
- Hypothermia
- Impaired gas exchange
- Impaired physical mobility
- Impaired skin integrity
- Ineffective airway clearance
- Ineffective individual coping
- Knowledge deficit
- Pain
- Risk for infection
- Risk for posttrauma syndrome
- Sensory or perceptual alterations

Key outcomes

- The patient will achieve pain relief with analgesia or other measures.
- The patient will attain the highest degree of mobility possible within the confines of injury.
- The patient's fluid volume will remain within the acceptable range.
- The patient's wounds and incisions will appear clean, pink, and free of purulent drainage.
- The patient's airway will remain patent.
- The patient's ventilation will remain adequate.
- The patient and family members will communicate understanding of special dietary needs.
- The patient will maintain adequate cardiac output.

Nursing interventions

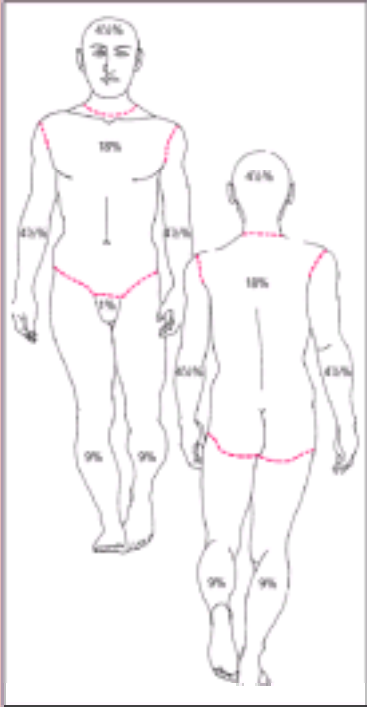

- Provide immediate, aggressive burn treatment to increase the patient's chance for survival. Later, provide supportive measures and use strict aseptic technique to minimize the risk of infection. Keep in mind that good nursing care can make the difference between life and death in a burn patient. Make sure the patient with major or moderate burns has adequate airway, breathing, and circulation. If needed, assist with endotracheal intubation. Administer 100% oxygen as ordered, and adjust the flow to maintain adequate gas exchange. Also draw blood samples as ordered.
- Take steps to control bleeding, and remove any clothing that is still smoldering. If it's stuck to the patient's skin, first soak it in saline solution. Also remove rings and other constricting items.

Estimating the extent of a burn

You can quickly estimate the extent of an adult patient's burns by using the Rule of Nines, shown below at left. This method divides an adult's body surface into percentages.

To use this method, mentally transfer your patient's burns to the body chart shown here. Then add up the corresponding percentages for each burned body section. The totals rough estimate of the extent of your patient's burns enters into the formula to determine his initial fluid replacement needs.

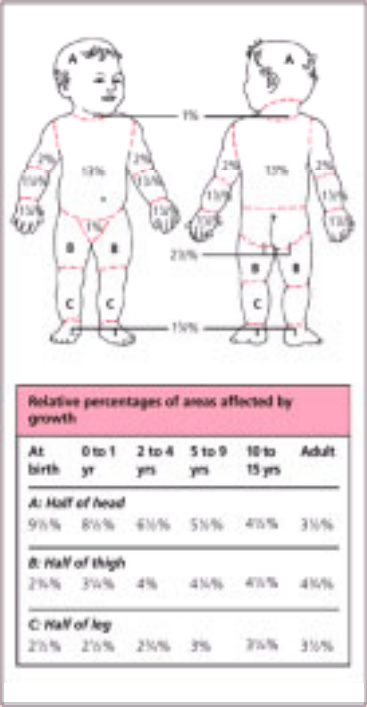

RULE OF NINES

You can't use this method with an infant or a child because his body section percentages differ from those of an adult. (For instance, an infant's head accounts for 17% of his total body surface, compared with 7% for an adult.) Instead, use the Lund and Browder chart (below right).

Another quick method for estimating pediatric burns is the palmar method. Estimate the burn by using the child's palm as a guide, representing a value of 1%.

LUND AND BROWDER CHART

Relative percentages of areas affected by growth					
At birth	0 to 1 yr	2 to 4 yrs	5 to 9 yrs	10 to 15 yrs	Adult
A: Half of head					
9%	8%	6%	5%	4%	3%
B: Half of thigh					
2%	3%	4%	4%	4%	4%
C: Half of leg					
2%	2%	2%	3%	3%	3%

- Cover the burns with a clean, dry, sterile bed sheet. *Never* cover large burns with saline-soaked dressings, which can drastically lower body temperature.
- Start I.V. therapy at once to prevent hypovolemic shock and maintain cardiac output. Use lactated Ringer's solution or a fluid replacement formula as ordered. Closely monitor the patient's intake and output. (See [Fluid replacement: The first 24 hours.](#))

Fluid replacement: The first 24 hours

These formulas are a general guideline for the amount of fluid replacement. Actual replacement amounts vary with facility protocol and the infusions may vary according to the patient's response, especially urine output.

Baxter formula

Administer 4 ml of lactated Ringer's solution per kilogram of body weight per percentage of body surface area (BSA) over 24 hours. Give one-half of the total over the first 8 hours after the burn, one-fourth over the next 8 hours, and the remainder over the last 8 hours.

Modified Brooke formula

Use this formula to administer various fluids:

- u 0.5 ml of a colloid (plasma, plasmanate, or dextran) per kilogram of body weight per percentage of BSA
- u 1.5 ml lactated Ringer's solution per kilogram of body weight per percentage of BSA—2,000 ml dextrose 5% in water for adults (less for children)

Give one-half of the total over the first 8 hours after the burn, one-fourth over the next 8 hours, and the remainder over the last 8 hours.

Parkland formula

Administer 4 ml/kg of crystalloid × % BSA burned (up to 50%) over 24 hours.

Gaveston formula

This formula (for pediatric patients) is based on BSA. Administer 5,000 ml/m² lactated Ringer's solution × % BSA burned + 2,000 ml/m² over 24 hours of maintenance. Half of the total fluid is given in the first 8 hours and the balance is given over the next 16 hours.

- u Assist with the insertion of a central venous pressure line and additional arterial and I.V. lines (using venous cutdown, if necessary) as necessary. Insert an indwelling urinary catheter as ordered.
- u Continue fluid therapy, as ordered, to combat fluid evaporation through the burn and the release of fluid into interstitial spaces (possibly resulting in hypovolemic shock).
- u Check the patient's vital signs every 15 minutes. Maintain his core body temperature by covering him with a sterile blanket and exposing only small areas of his body at a time.
- u Insert an NG tube, as ordered, to decompress the stomach and avoid aspiration of stomach contents.
- u Provide a diet high in potassium, protein, vitamins, fats, nitrogen, and calories to keep the patient's weight as close to his preburn weight as possible. If necessary, feed the patient through a feeding tube (as soon as bowel sounds return if he's had paralytic ileus) until he can tolerate oral feeding. Weigh him every day at the same time.
- u If the patient is to be transferred to a specialized burn care unit within 4 hours after the injury, don't treat the burn wound in the emergency department. Instead, prepare the patient for transport by wrapping him in a sterile sheet and a blanket for warmth and elevating the burned extremity to decrease edema. Then transport him immediately.
- u If the patient has only minor burns, immerse the burned area in cool saline solution (55° F [12.8° C]) or apply cool compresses, making sure he doesn't develop hypothermia. Next, soak the wound in a mild antiseptic solution to clean it, and give ordered pain medication.
- u Debride the devitalized tissue. Cover the wound with an antibacterial agent and a nonstick bulky dressing, and administer tetanus prophylaxis, as ordered.
- u Explain all procedures to the patient before performing them. Speak calmly and clearly to help alleviate his anxiety. Encourage him to actively participate in his care as much as possible.
- u Give the patient opportunities to voice his concerns, especially about altered body image. If appropriate, arrange for him to meet a patient with similar injuries. When possible, show the patient how his bodily functions are improving. If necessary, refer him for mental health counseling.

For a patient with an electrical or a chemical burn:

- u Keep in mind that tissue damage from an electrical burn is difficult to assess because internal destruction along the conduction pathway usually is greater than the surface burn would indicate. An electrical burn that ignites the patient's clothes may cause thermal burns as well.
- u If the electric shock caused ventricular fibrillation and cardiac and respiratory arrest, begin cardiopulmonary resuscitation at once. Get an estimate of the voltage that caused the injury.
- u If the patient has a chemical burn, irrigate the wound with copious amounts of water or normal saline solution. Using a weak base (such as sodium bicarbonate) to neutralize hydrofluoric acid, hydrochloric acid, or sulfuric acid on skin or mucous membranes is controversial, particularly in the emergent phase, because the neutralizing agent can produce more heat and tissue damage.
- u If the chemical entered the patient's eyes, flush them with large amounts of water or normal saline solution for at least 30 minutes. In an alkali burn, irrigate until the pH of the conjunctival culdesacs returns to 7.0. Have the patient close his eyes and cover them with a dry, sterile dressing. Note the type of chemical that caused the burn and any noxious fumes. The patient needs an ophthalmologic examination.

Patient teaching

- u If the patient has only a minor burn, stress the importance of keeping his dressing dry and clean, elevating the burned extremity for the first 24 hours, taking analgesics as ordered, and returning for a wound check in 2 days.
- u For a patient with a moderate or major burn, discharge teaching involves the entire burn team. Teaching topics include wound management; signs and symptoms of complications; use of pressure dressings, exercises, and splints; and resocialization. Make sure the patient understands the treatment plan, including why it's necessary and how it will help his recovery.
- u Explain to the patient that a home health nurse can assist with wound care. Provide the patient with the phone numbers of a doctor or nurse who can answer questions.
- u Give the patient written discharge instructions for later reference.

COLD INJURIES

Cold injuries are caused by overexposure; they occur in two major forms: localized injuries (frostbite) and systemic injuries (hypothermia).

Frostbite may be superficial or deep. Superficial frostbite affects skin and subcutaneous tissue, especially of the face, ears, extremities, and other exposed body areas. Deep frostbite extends beyond the subcutaneous tissue and usually affects the hands and feet. Untreated or improperly treated frostbite can lead to gangrene, requiring amputation.

Hypothermia—core body temperature below 95° F (35° C)—effects chemical changes in the body. Severe hypothermia can be fatal.

The risk of serious cold injury, especially hypothermia, increases with youth, old age, lack of insulating body fat, wet or inadequate clothing, drug abuse, cardiac disease, smoking, fatigue, malnutrition and depletion of caloric reserves, and excessive alcohol intake.

Causes and pathophysiology

Frostbite results from prolonged exposure to freezing temperatures or to cold, wet environments. The cold causes ice crystals to form within and around tissue cells. This in turn causes cell membranes to rupture, interrupting enzymatic and metabolic activities. Increased capillary permeability accompanies the release of histamine, resulting in aggregation of red blood cells and microvascular occlusion.

Hypothermia results from cold-water near drowning and prolonged exposure to cold temperatures. It also can occur in normal temperatures if disease or debility alters the patient's homeostasis. The administration of large amounts of cold blood or blood products can cause hypothermia. In hypothermia, metabolic changes slow the

functions of most major organ systems, resulting in decreased renal blood flow and decreased glomerular filtration.

Complications

Tissue and muscle damage caused by frostbite may lead to renal failure and rhabdomyolysis. Avascular necrosis and gangrene also can result from frostbite.

Common complications associated with hypothermia include severe infection, aspiration pneumonia, cardiac arrhythmias, hypoglycemia or hyperglycemia, metabolic acidosis, pancreatitis, and renal failure.

Assessment findings

The history of a patient with a cold injury reveals the cause, the temperature to which the patient was exposed, and the length of exposure. A patient with superficial frostbite may report burning, numbness, tingling, and itching, although he may not notice symptoms until he returns to a warm place. A patient with deep frostbite reports paresthesia and stiffness while the part is still frozen, a burning pain when the part thaws, and then warmth and numbness.

On inspection, an area with superficial frostbite appears swollen, with a mottled, blue-gray skin color. An area affected by deep frostbite appears white or yellow until it's thawed; then it turns purplish blue. You also may note edema, skin blisters, and necrosis.

Palpation of superficial frostbite reveals the extent and severity of swelling. Palpation of deep frostbite may reveal skin immobility. In either type of frostbite, palpation also reveals the presence or absence of associated peripheral pulses.

ALERT Never rub the injured area. This can aggravate tissue damage. Also, be careful not to rupture any blebs.

Your assessment findings in a patient with hypothermia vary with the patient's body temperature. A patient with mild hypothermia—a core body temperature below 95° F (35° C)—shows severe shivering, slurred speech, and amnesia. A patient with moderate hypothermia—a core body temperature of 86° to 89.6° F (30° to 32° C)—is unresponsive, with peripheral cyanosis and muscle rigidity. If the patient was improperly rewarmed, he may show signs of shock.

ALERT If your patient has hypothermia, use an esophageal or rectal probe that reads as low as 77° F (25° C) to determine an accurate core body temperature. Core body temperature also can be determined using a pulmonary artery catheter .

A patient with severe hypothermia—a core body temperature of 77° to 86° F (25° to 30° C)—appears dead, with no palpable pulse and no audible heart sounds. His pupils may be dilated, and he may appear to be in a state of rigor mortis. Ventricular fibrillation and a loss of deep tendon reflexes commonly occur.

A patient with a body temperature below 77° F (25° C) is at risk for cardiopulmonary arrest.

Diagnostic tests

Technetium pertechnetate scanning shows perfusion defects and deep tissue damage and can be used to identify nonviable bone. Doppler and plethysmographic studies help determine pulses and the extent of frostbite after thawing.

Essential laboratory tests during treatment of moderate or severe hypothermia include a complete blood count, coagulation profile, urinalysis, and serum amylase, electrolyte, hemoglobin, glucose, liver enzyme, blood urea nitrogen, creatinine, and arterial blood gas levels.

Treatment

For frostbite injuries, treatment consists of rapidly rewarming the injured part to slightly above ideal body temperature to preserve viable tissue. Slow rewarming could increase tissue damage. Treatment also includes administration of antibiotics and tetanus prophylaxis, as needed, and narcotic analgesics to relieve pain when the affected part begins to rewarm.

After rewarming, the affected part is kept elevated, uncovered, at room temperature. A regimen of whirlpool treatments for 3 or more weeks cleans the skin and debrides sloughing tissue. After the early stage, active range-of-motion exercises restore mobility. Surgery usually isn't required, but amputation may be necessary if gangrene develops.

Treatment for hypothermia consists of supportive measures and specific rewarming techniques, including:

- passive rewarming (the patient rewarms on his own)
- active external rewarming with heating blankets, warm water immersion, heated objects such as water bottles, and radiant heat
- active core rewarming with heated I.V. fluids; genitourinary tract irrigation; extracorporeal rewarming; hemodialysis; and peritoneal, gastric, and mediastinal lavage.

Any arrhythmias that develop usually convert to normal sinus rhythm with rewarming. If the patient has no pulse or respirations, cardiopulmonary resuscitation (CPR) is needed until rewarming raises the core temperature to at least 89.6° F (32° C).

Administration of oxygen, endotracheal intubation, controlled ventilation, I.V. fluids, and treatment of metabolic acidosis depend on test results and careful patient monitoring.

Nursing diagnoses

▫ Altered tissue perfusion ▫ Anxiety ▫ Decreased cardiac output ▫ Hypothermia ▫ Impaired gas exchange ▫ Impaired physical mobility ▫ Impaired skin integrity ▫ Knowledge deficit ▫ Pain ▫ Risk for disuse syndrome ▫ Risk for infection

Key outcomes

- The patient will maintain adequate ventilation.
- The patient will regain skin integrity.
- The patient will maintain muscle strength and tone and joint range of motion.
- The patient will express feelings of comfort.
- The patient's body temperature will be normal.
- The patient will understand how to prevent recurrent episodes of hypothermia.

Nursing interventions

- If the patient has a localized cold injury, remove all constrictive clothing and jewelry.
- When the affected part begins to rewarm, the patient will feel pain, so give analgesics as ordered. Check for a pulse. Be careful not to rupture any blebs. If the injury is on the foot, place cotton or gauze sponges between the toes to prevent maceration. Instruct the patient not to walk.
- If the injury caused an open skin wound, give antibiotics and tetanus prophylaxis, as ordered.
- Rewarm the affected part by immersing it in tepid water (about 100° F [37.8° C]). Give the patient warm fluids to drink. *Never* rub the injured area—this aggravates tissue damage.
- If the patient has systemic hypothermia, first check for a pulse and respirations. If you can't detect them, begin CPR immediately. Continue CPR until the patient's core body temperature increases to at least 89.6° F (32° C). (Keep in mind that hypothermia helps protect the brain from anoxia, which normally accompanies

- prolonged cardiopulmonary arrest. So even if the patient has been unresponsive for a long time, CPR may resuscitate him, especially after a cold-water near drowning.)
- u Assist with rewarming techniques as necessary. In moderate to severe hypothermia, aggressive rewarming should be attempted only by experienced personnel.
 - u During rewarming, provide supportive measures as ordered. These include mechanical ventilation and heated, humidified therapy to maintain tissue oxygenation, and I.V. fluids that have been warmed with a warming coil to correct hypotension and maintain urine output.
 - u Insert an indwelling catheter to monitor urine output.
 - u Frequently monitor the patient's core body temperature and other vital signs during and after initial rewarming. Also, continuously monitor his cardiac status.

If the patient's core temperature is below 89.6° F, use internal and external warming methods to bring up his body core and surface temperatures 1° to 2° F (0.2° to 1.1° C) per hour.

ALERT Make sure you rewarm the patient internally and externally at the same time; rewarming the surface first could cause rewarming shock with potentially fatal ventricular fibrillation.

Patient teaching

- u Explain medical treatments and therapies.
- u Ensure that the patient verbalizes techniques for avoiding hypothermia. (See [Preventing cold injuries.](#))

PREVENTION

Preventing cold injuries

To prevent cold injuries, teach patients to:

- u wear mittens, not gloves
- u wear windproof, water-resistant layers of clothing
- u wear two pairs of socks (cotton next to the skin and then wool)
- u wear a scarf and a hat that covers the ears (to avoid substantial heat loss through the head).

Before anticipated prolonged exposure to cold, advise the patient not to drink alcohol or smoke, and to get adequate food and rest. If he gets caught in severe cold weather, he should find shelter early or increase physical activity to maintain body warmth.

DECOMPRESSION SICKNESS

Decompression sickness—also known as caisson disease, diver's paralysis, or “the bends”—is a painful condition that results from a too-rapid change from a high- to low-pressure environment (decompression). The victim usually is a scuba diver who ascends too quickly from water deeper than 33' (10 m). Signs and symptoms appear during or within 30 minutes of rapid decompression, but may be delayed for as long as 24 hours.

Causes

Decompression sickness results from an abrupt change in air or water pressure that causes nitrogen to spill out of tissues faster than it can be diffused through respiration. As a result, gas bubbles form in blood and body tissues. These bubbles can accumulate over several dives.

Complications

Massive venous air embolization, intravascular volume depletion, vascular occlusion, and avascular necrosis can complicate decompression sickness.

Assessment findings

Characteristic clinical features vary, depending on the number and location of gas bubbles. The patient's history (obtained, if necessary, from a family member or friend) reveals the cause of the disorder. The history and physical examination may also reveal predisposing factors, such as excessive use of alcohol or drugs, obesity, dehydration, recent injury, exposure to cold temperatures, and hypoxia.

The patient typically complains of “the bends,” which is severe or incapacitating joint, muscle, and bone pain. He may also report urine retention, fecal incontinence, and back pain, as well as neurologic disturbances, such as headache, confusion, dizziness, deafness, and visual disturbances. A detailed neurologic examination of the patient may demonstrate hemiplegia, paresthesia and hyperesthesia of the legs, and an unsteady gait.

The patient also may report signs of respiratory distress, known as “the chokes,” which includes chest pain, retrosternal burning, and a cough that may become paroxysmal and uncontrollable.

Diagnostic tests

The doctor may order laboratory studies, such as arterial blood gas analysis, to evaluate the patient's signs and symptoms.

Treatment

Treatment consists of supportive measures, including recompression and oxygen administration. Recompression takes place in a hyperbaric chamber (not available in all facilities), in which air pressure is increased to 2.8 absolute atmospheric pressure over 1 to 2 minutes. This rapid increase in pressure reduces the size of the circulating nitrogen bubbles and relieves pain and other clinical effects. Analgesics, such as aspirin, also may be given for pain.

During recompression, intermittent oxygen administration, with periodic maximal exhalations, promotes gas bubble diffusion. When signs and symptoms subside and diffusion of gas bubbles is complete, a slow air pressure decrease in the chamber allows for gradual, safe decompression.

Supportive measures may include fluid replacement in hypovolemic shock and sometimes corticosteroids to reduce the risk of spinal edema. Short-acting barbiturates may be given to treat seizures. Narcotics are contraindicated because they may further depress impaired respiration.

Nursing diagnoses

u Altered urinary elimination u Anxiety u Decreased cardiac output u Fluid volume deficit u Hypothermia u Impaired gas exchange u Pain u Sensory or perceptual alterations

Key outcomes

- u The patient will maintain cardiac output.
- u The patient's body temperature will be normal.

- u The patient will maintain adequate ventilation.
- u The patient's airway will remain patent at all times.
- u The patient will express feelings of comfort.

Nursing interventions

- u Administer supplemental 100% oxygen by mask.
- u Give emergency medications as ordered. Ensure I.V. access for drugs and parenteral fluids.
- u Catheterize the patient with bladder paralysis, and accurately monitor intake and output.
- u Continuously monitor neurologic status, cardiac output, and respiratory function to quickly identify changes in the patient's condition.

Patient teaching

- u Explain procedures to the patient and listen to his concerns to help alleviate anxiety.
- u To help prevent decompression sickness, advise divers and fliers to follow the United States Navy's ascent guidelines closely.

ELECTRIC SHOCK

When an electric current passes through the body, the damage it does depends on the intensity of the current (amperes, milliamperes, or microamperes), the resistance of the tissues it passes through, the kind of current (AC, DC, or mixed), and the frequency and duration of current flow.

Mild electric shock can cause a local, unpleasant tingling or a painful sensation. Severe electric shock can cause ventricular fibrillation, asystole, respiratory paralysis, burns, and death. Even the smallest electric current—if it passes through the heart—may induce ventricular fibrillation or another arrhythmia that progresses to fibrillation or myocardial infarction.

In the United States, about 1,000 people die of electric shock each year. Electric shock is a particular hazard in the facility. (See [Preventing electric shock.](#))

The greatest threats to life from electric shock include cardiac arrhythmias, renal failure secondary to the precipitation of myoglobin and hemoglobin in the kidneys, and electrolyte abnormalities, such as hyperkalemia and hypocalcemia from massive muscle breakdown.

The prognosis depends on the site and extent of damage, the patient's state of health, and the speed and adequacy of treatment. Dry, calloused, unbroken skin offers more resistance to electric current than mucous membranes, an open wound, or thin, moist skin.

Causes

Electric shock usually follows accidental contact with an exposed part of an electrical appliance or wiring. It also may result from lightning or the flash of electric arcs from high-voltage power lines or machines.

The current can cause a true electrical injury if it passes through the body. If it doesn't pass through the body, it can cause arc or flash burns. Thermal surface burns can result from associated heat and flames.

Complications

Although complications can occur in almost any part of the body, the most common include sepsis; neurologic, cardiac, or psychiatric dysfunction; renal failure; electrolyte abnormalities; peripheral nerve injuries; vascular disruption; and thrombi.

Assessment findings

The patient's history reveals the source of the electric current and the approximate length of exposure. Varying signs and symptoms depend on the amount and type of current, the duration and area of exposure, and the pathway the current took through the body. If the shock was severe, the patient or an observer may report that the patient lost consciousness. After regaining consciousness, the patient may complain of muscle pain, fatigue, headache, and nervous irritability.

When electric shock results from a high-frequency current (which generates more heat in tissues than a low-frequency current), inspection usually reveals burns and local tissue coagulation and necrosis. Electric shock resulting from low-frequency current may produce serious burns if contact is concentrated in a small area (for example, when a toddler bites into an electric cord). When the electric current passes through the patient's body, inspection reveals entrance and exit injuries that appear as round or oval yellow-brown lesions.

Depending on the action of the current, inspection and palpation may reveal contusions, evidence of fractures, and other injuries that can result from violent muscle contractions or falls during the shock. If ventricular fibrillation occurs, you won't be able to palpate the pulse or auscultate heart sounds, and the patient will be unconscious. Respirations may continue for a short time and then cease.

PREVENTION

Preventing electric shock

Take the following steps to help prevent electric shock in the facility:

- u Check for cuts, cracks, or frayed insulation on electric cords, call buttons (also check for warm call buttons), and electrical devices attached to the patient's bed. Report any problems to maintenance personnel.
- u Keep all electrical devices away from hot or wet surfaces and sharp corners. Also, don't set glasses of water, damp towels, or other wet items on electrical equipment. Wipe up accidental spills before they leak into electrical equipment.
- u Avoid using extension cords because they may circumvent the ground. If they're necessary, don't place them under carpeting or where they'll be walked on.
- u Make sure ground connections on electrical equipment are intact. Line cord plugs should have three prongs; the prongs should be straight and firmly fixed. Check that prongs fit wall outlets properly and that outlets aren't loose or broken. Don't use adapters on plugs.
- u If a machine sparks, smokes, seems unusually hot, or gives you or your patient a slight shock, unplug it immediately, if doing so won't endanger the patient's life. Promptly report such equipment to maintenance personnel. Also, check inspection labels and report equipment that is overdue for inspection.
- u Be especially careful when using electrical equipment near a patient with a pacemaker or direct cardiac line because a cardiac catheter or pacemaker can create a direct, low-resistance path to the heart; even a small shock could cause ventricular fibrillation.
- u Make sure defibrillator paddles are free of dry caked gel before applying fresh gel. Otherwise, the patient could suffer burns from poor electrical contact. Also, don't apply too much gel. If the gel runs over the edge of the paddle and touches your hand, you'll receive some of the defibrillator shock and the patient will lose some of the energy in the discharge.

If respiratory failure occurs, inspection discloses cyanosis, absent respirations, markedly decreased blood pressure, cold skin, and unconsciousness; pulses, however, can still be palpated.

Neurologic examination may reveal numbness or tingling or sensorimotor deficits.

Diagnostic tests

An electrocardiogram (ECG), arterial blood gas analysis, urine myoglobin tests, and X-rays of injured areas are used to evaluate internal damage and guide treatment.

Treatment

The first step in treatment involves separating the victim from the current source by turning it off or unplugging it. If this isn't possible, the victim should be pulled free with a nonconductive device, such as a loop of dry cloth or rubber, a dry rope, or a leather strap.

After interrupting the current source, perform emergency measures, including assessing vital functions and instituting cardiopulmonary resuscitation (CPR) if the patient has no respirations or pulse.

When the patient is revived, treatment includes:

- assessment for shock, acid-base imbalance, cardiac arrhythmias, hemorrhage, myoglobinuria, traumatic injury, and neurologic damage
- use of a cardiac monitor to permit rapid identification and treatment of arrhythmias
- use of a cervical collar and backboard until spinal injury has been ruled out
- vigorous fluid replacement using lactated Ringer's solution, along with central venous pressure and urine output monitoring
- administration of an osmotic diuretic (mannitol) for myoglobinuria after intravascular volume has been replaced
- administration of tetanus prophylaxis
- administration of sodium bicarbonate to prevent arrhythmias.

Nursing diagnoses

▫ Altered tissue perfusion ▫ Anxiety ▫ Decreased cardiac output ▫ Impaired skin integrity ▫ Ineffective breathing pattern ▫ Pain ▫ Risk for injury ▫ Risk for posttrauma syndrome ▫ Sensory or perceptual alterations

Key outcomes

- The patient will have no arrhythmias.
- The patient will maintain cardiac output.
- The patient will regain skin integrity.
- The patient's wounds and incisions will appear clean, pink, and free of purulent drainage.
- The patient will report pain relief with analgesic or other measures.
- The patient will maintain adequate ventilation.

Nursing interventions

- If it hasn't already been done, separate the victim from the current source and then begin emergency treatment. If necessary, start CPR at once. Continue until vital signs return or emergency help arrives with a defibrillator and other life-support equipment.
- After emergency treatment, monitor the patient's cardiac rhythm continuously and obtain a 12-lead ECG.
- Because internal tissue destruction may be much greater than skin damage suggests, give a rapid I.V. infusion of 1 to 2 L of lactated Ringer's solution, as ordered, to maintain a urine output of 75 to 100 ml/hour. Insert an indwelling urinary catheter, and send the first specimen to the laboratory.
- Measure intake and output hourly and watch for tea- or wine-colored urine, which occurs when coagulation necrosis and tissue ischemia liberate myoglobin and hemoglobin. These proteins can precipitate in the renal tubules, causing tubular necrosis and renal shutdown. To promote diuresis and myoglobin excretion, give mannitol as ordered.
- Frequently assess the patient's neurologic status because central nervous system damage can result from ischemia or demyelination. If necessary, institute seizure precautions according to facility policy.
- Because a spinal cord injury may follow cord ischemia or a compression fracture, continue to watch for sensorimotor deficits. Ensure proper spinal immobilization until fractures have been ruled out.
- Check for neurovascular damage in the extremities by assessing peripheral pulses and capillary refill and by asking about numbness, tingling, and pain. Elevate any injured extremities.
- Care for the burned area as indicated. If ordered, apply a sterile dressing and administer topical and systemic antibiotics to help reduce the risk of infection.

Patient teaching

- Reinforce the doctor's explanation of all treatments and procedures. Allow the patient to discuss his experience with you to help decrease his anxiety.
- Tell the patient how to avoid electrical hazards at home and at work. Warn him not to use electrical appliances while showering or wet. Also warn him never to touch electrical appliances while touching faucets or cold water pipes in the kitchen; these pipes may provide the ground for all circuits in the house.
- If the patient is a young child, advise his parents to put safety guards on all electrical outlets and to keep him away from electrical devices.

HEAT SYNDROME

Humans normally adjust to excessive temperatures through complex cardiovascular and neurologic changes, which are coordinated by the hypothalamus. Heat loss offsets heat production to regulate the body temperature. It does this by evaporation (of sweat) or vasodilation, which cools the body's surface by radiation, conduction, and convection.

Sometimes both environmental and internal factors can increase heat production or decrease heat loss beyond the body's ability to compensate. When this happens, heat syndrome results. There are three categories of heat syndrome: heat cramps, heat exhaustion, and heatstroke.

Causes

Heat syndrome may result from conditions that increase heat production, such as excessive exercise, infection, and drugs (for example, amphetamines). It can also stem from factors that impair heat dissipation, including high temperatures or humidity, lack of acclimatization, excess clothing, cardiovascular disease, obesity, dehydration, sweat gland dysfunction, and drugs such as phenothiazines and anticholinergics.

Heatstroke is commonly seen in elderly people on excessively hot summer days, particularly when they are inside with windows and doors closed and no air conditioning. They might not open windows and doors because they are afraid someone may break in and injure them.

Complications

Heatstroke, a medical emergency, can lead to hypovolemic or cardiogenic shock, cardiac arrhythmias, and renal failure caused by rhabdomyolysis, disseminated intravascular coagulation, and hepatic failure.

Assessment findings

Signs and symptoms vary with the type of heat syndrome. (See [Managing heat syndrome](#).)

The history of a patient with *heat cramps* almost always reveals vigorous activity right before onset. He typically appears alert and complains of pain.

On assessment, the patient usually has normal vital signs (except for tachycardia) with a normal or slightly elevated body temperature. Inspection reveals muscle twitching and spasm. Palpation reveals moist, cool skin and muscle tenderness. Involved muscle groups may feel hard and lumpy. The neurologic examination usually is normal, although the patient may appear agitated.

The history of a patient with *heat exhaustion* usually reveals prolonged activity in a very warm or hot environment, without adequate salt intake. He may complain of muscle cramps. More commonly, he reports nausea and vomiting, thirst, weakness, and oliguria. He may complain of headache and fatigue and may be anxious.

Assessment reveals a rectal temperature over 100° F (37.8° C). On inspection, you may note pale skin. The patient's pulse feels thready and rapid, and his skin is cool and moist. Auscultation reveals decreased blood pressure. When heat exhaustion is mainly due to water depletion, examination may reveal mental confusion, giddiness, syncope, impaired judgment, and anxiety paresthesia. Assessment also may reveal hyperventilation, which can lead to respiratory alkalosis. If you note that sweating ceases, the patient may be progressing from heat exhaustion to heatstroke.

The history of a patient with *heatstroke* may reveal the specific cause, such as exposure to high temperature and humidity without any wind. He may exhibit weakness, dizziness, nausea, vomiting, blurred vision, confusion, hallucinations, and decreased muscle coordination.

Your assessment shows a rectal temperature of at least 106° F (41.1° C). On inspection and palpation, the patient's skin is red, diaphoretic, and hot in early stages and gray, dry, and hot in later stages. He may have a rapid pulse rate. On auscultation, his blood pressure is slightly elevated in early stages, and decreases in later stages. The neurologic examination of the conscious patient may reveal dilated pupils, emotional lability, confusion and, as heatstroke progresses, delirium, seizures, collapse and, finally, unconsciousness. You also may note hyperpnea at any time, which leads to respiratory alkalosis and compensatory metabolic acidosis. In late stages, you may note slow, deep respirations, which progress to Cheyne-Stokes respirations.

Diagnostic tests

Serum electrolyte and arterial blood gas levels may reveal respiratory alkalosis, hyponatremia, and hypokalemia in heat exhaustion and heatstroke. In heatstroke, blood studies reveal leukocytosis, elevated blood urea nitrogen levels, hemoconcentration, and decreased serum potassium, calcium, and phosphorus levels. Blood studies also may reveal thrombocytopenia, increased bleeding and clotting times, fibrinolysis, and consumption coagulopathy. Urinalysis results show concentrated urine, with elevated protein levels, tubular casts, and myoglobinuria.

Managing heat syndrome			
TYPE AND PREDISPOSING FACTORS		SIGNS AND SYMPTOMS	MANAGEMENT
Heat cramps			
<ul style="list-style-type: none">Commonly affect young adultsStrenuous activity without training or acclimatizationNormal to high temperature or high humidity	<ul style="list-style-type: none">Muscle twitching and spasms, weakness, severe muscle crampsNauseaNormal temperature or slight feverNormal central nervous system findingsDiaphoresis	<ul style="list-style-type: none">Hospitalization is usually unnecessary.To replace fluid and electrolytes, give a balanced electrolyte drink.Loosen patient's clothing and have him lie down in a cool place. Massage his muscles. If muscle cramps are severe, start an I.V. infusion with normal saline solution.	
Heat exhaustion			
<ul style="list-style-type: none">Commonly affects young peoplePhysical activity without acclimatizationDecreased heat dissipationHigh temperature and humidity	<ul style="list-style-type: none">Muscle cramps (infrequent)Nausea and vomitingDecreased blood pressureThready, rapid pulseCool, pallid skinHeadache, mental confusion, syncope, giddinessOliguria, thirstNo feverSweatingHypertension followed by hypotension	<ul style="list-style-type: none">Hospitalization is usually unnecessary, but patient may need emergency evaluation.Immediately give a balanced electrolyte drink.Loosen patient's clothing and put him in a shock position in a cool place. Massage his muscles. If cramps are severe, start an I.V. infusion.If needed, give oxygen.	
Heat stroke			
<ul style="list-style-type: none">Exertional heatstroke commonly affects young, healthy people who are involved in strenuous activityClassic heatstroke commonly affects elderly, inactive people who have cardiovascular disease or who take drugs that influence temperature regulationHigh temperature and humidity without any wind	<ul style="list-style-type: none">Atrial or ventricular tachycardiaHot, dry, red skin, which later turns gray; no diaphoresisConfusion, progressing to seizures and loss of consciousnessTemperature higher than 104° F (40° C)Dilated pupilsSlow, deep respirations; then Cheyne-Stokes respirations	<ul style="list-style-type: none">Initiate ABCs (airway, breathing, and circulation) of life support.To lower patient's body temperature, cool rapidly with ice packs on arterial pressure points and hypothermia blankets.To replace fluids and electrolytes, start an I.V. infusion.Hospitalization is needed.Insert a nasogastric tube to prevent aspiration.Give a benzodiazepine to control seizures, I.V. chlorpromazine to reduce shivering, or mannitol to maintain urine output.Monitor temperature, intake, output, and cardiac status. Give dobutamine to correct cardiogenic shock. (Vasoconstrictors are contraindicated).	

Treatment

For heat cramps, treatment consists of moving the patient to a cool environment, providing rest, and administering oral or I.V. fluid and electrolyte replacement (for example, Lytren or Rehydralyte for adults and Pedialyte for children). Salt tablets aren't recommended because of their comparatively slow absorption rate.

Treatment for heat exhaustion involves moving the patient to a cool environment, providing rest, and administering oral fluid and electrolyte replacement. If I.V. fluid replacement is necessary, laboratory test results determine the choice of I.V. solution—usually saline or isotonic glucose solution.

Heatstroke therapy focuses on lowering the body temperature as rapidly as possible. The patient's clothing is removed and cool water is applied to the skin, followed by fanning with cool air. Shivering is controlled with diazepam or chlorpromazine. Application of hypothermia blankets and ice packs to the groin and axillae also helps lower body temperature. Treatment continues until the body temperature drops to 102.2° F (39° C). Supportive measures include oxygen therapy, central venous pressure and pulmonary artery wedge pressure monitoring, and, if necessary, endotracheal intubation. The patient is closely observed for complications.

Nursing diagnoses

⌞ Decreased cardiac output ⌞ Fluid volume deficit ⌞ Hyperthermia ⌞ Impaired gas exchange ⌞ Impaired home maintenance management ⌞ Knowledge deficit ⌞ Sensory or perceptual alterations

Key outcomes

- ⌞ The patient will maintain adequate ventilation.
- ⌞ The patient will express feelings of comfort.
- ⌞ The patient's body temperature will be normal.
- ⌞ The patient will understand how to prevent recurrent episodes of hyperthermia.
- ⌞ The patient will express understanding of the need to maintain adequate fluid intake.

Nursing interventions

- ⌞ Monitor the patient's vital signs and pulse oximetry readings. If he's unstable, use a rectal probe to assess his body temperature.
- ⌞ Perform or assist with the cooling procedure as needed. If ordered, place the patient on a cooling mattress and use a rectal probe to assess body temperature.
- ⌞ If the patient has heatstroke, remove his clothing and place him in the lateral recumbent position, or support him in the knee-chest position so that as much skin as possible is exposed to the air. Then spray his entire body with water as cool air is passed over the body. Use fans to provide air movement, which increases heat loss through convection and evaporation. Or, cover the patient with a damp sheet and fan him with cool air.
- ⌞ Assist with supportive measures as necessary. These may include assisting with insertion of an endotracheal tube and caring for it to maintain an adequate airway. Provide supplemental oxygen, as ordered.
- ⌞ Encourage adequate fluid intake as required. If necessary, ensure peripheral I.V. access, as ordered.
- ⌞ Monitor the patient for complications. Note his level of consciousness, cardiac rhythm, and cardiac output. If a central line is in place, monitor central venous pressure and pulmonary artery wedge pressure.
- ⌞ Administer medication as ordered to inhibit shivering.
- ⌞ Monitor urine output. Insert an indwelling urinary catheter as needed, and monitor myoglobin test results as ordered.
- ⌞ Referral to a social service agency may be necessary for an elderly patient who experiences heat syndrome because of a compromised home environment.

Patient teaching

- ⌞ Advise the patient to avoid immediate reexposure to high temperatures. He may remain hypersensitive to heat for a while.
- ⌞ Teach the patient the importance of maintaining an adequate fluid intake, wearing loose clothing, and limiting activity in hot weather.
- ⌞ Advise athletes to monitor fluid losses, replace fluids, and use a gradual approach to physical conditioning.
- ⌞ In hot weather, encourage elderly patients to spend time in air-conditioned areas, such as shopping malls and libraries.
- ⌞ Advise cardiac patients to curb fluid overload by avoiding foods high in sodium, such as canned or commercially prepared foods and dairy products.
- ⌞ Explain to patients on diuretic therapy that potassium level must be replaced by taking a prescribed potassium supplement or potassium-rich foods (such as bananas, apricots, and orange juice).
- ⌞ Tell the patient to promptly report any dizziness, blurred vision, weight gain, shortness of breath, or other abnormal symptoms to avoid complications.

NEAR DROWNING

In near drowning, the victim survives (at least temporarily) the physiologic effects of submersion in fluid. Hypoxemia and acidosis are the primary problems in victims of near drowning.

Near drowning occurs in three forms. In *dry* near drowning, the victim doesn't aspirate fluid but suffers respiratory obstruction or asphyxia (10% to 15% of patients). In *wet* near drowning, the victim aspirates fluid and suffers from asphyxia or secondary changes from fluid aspiration (about 85% of patients). In *secondary* near drowning, the victim suffers recurrence of respiratory distress (usually aspiration pneumonia or pulmonary edema) within minutes or 1 to 2 days after a near-drowning incident.

Causes

Near drowning typically results from an inability to swim. In swimmers, it can result from panic, a boating accident, sudden acute illness (seizure or myocardial infarction), a blow to the head while in the water, venomous stings from aquatic animals, excessive alcohol consumption before swimming, a suicide attempt, or decompression sickness from deep-water diving.

Complications

Near drowning may result in neurologic impairment, seizure disorders, pulmonary edema, renal damage, bacterial aspiration, and pulmonary or cardiac complications, such as arrhythmias and decreased blood pressure.

Assessment findings

The patient's history (obtained from a family member, friend, or emergency personnel, if necessary) reveals the cause of the near drowning. The patient may display any of a host of signs and symptoms. If he's conscious, he may complain of a headache or substernal chest pain.

Your initial assessment of the patient's vital signs may detect fever; rapid, slow, or absent pulse; shallow, gasping, or absent respirations; confusion; and seizures. If the patient was exposed to cold temperatures, he may experience hypothermia.

On initial observation, the patient may be unconscious, semiconscious, or awake. If he's awake, he usually appears apprehensive, irritable, restless, or lethargic, and he may vomit. Inspection may reveal cyanosis or pink, frothy sputum (indicating pulmonary edema). Palpation of the abdomen may disclose abdominal distention.

Auscultation of the lungs may reveal crackles, rhonchi, wheezing, or apnea. You may note tachycardia, an irregular heartbeat (arrhythmias), or cardiac arrest when you auscultate the heart. The patient may also be hypotensive.

Diagnostic tests

Supportive tests include:

- ⌞ arterial blood gas (ABG) analysis to show the degree of hypoxia, intrapulmonary shunt, and acid-base balance

- u serum electrolyte levels to monitor electrolyte balance
- u complete blood count to determine hemolysis
- u blood urea nitrogen and creatinine levels and urinalysis to evaluate renal function
- u cervical spine X-ray to rule out fracture
- u serial chest X-rays to evaluate pulmonary changes
- u electrocardiogram (ECG) to detect myocardial ischemia.

Treatment

Prehospital care includes stabilizing the patient's neck and spine to prevent further injury, cardiopulmonary resuscitation (CPR) as needed, and supplemental oxygen.

After the patient reaches the hospital, resuscitation continues. His oxygenation and circulation are maintained. X-rays confirm cervical spine integrity, and the patient's blood pH and electrolyte imbalances are corrected. If he's hypothermic, steps are taken to rewarm him.

ABG results help guide pulmonary therapy and determine the need for sodium bicarbonate to treat metabolic acidosis.

If the patient can't maintain an open airway, has abnormal ABG levels and pH, or doesn't have spontaneous respirations, he may need endotracheal intubation and mechanical ventilation. If he develops bronchospasm, he may need bronchodilators. Central venous pressure or pulmonary artery wedge pressure indicates the need for fluid replacement and cardiac drug therapy. The patient may also require standard treatment for pulmonary edema. Nasogastric (NG) tube drainage prevents vomiting, and an indwelling urinary catheter allows monitoring of urine output.

Nursing diagnoses

- u Anxiety u Decreased cardiac output u Hypothermia u Impaired gas exchange u Ineffective airway clearance u Ineffective breathing pattern u Ineffective family coping u Knowledge deficit u Risk for aspiration u Risk for infection

Key outcomes

- u The patient will maintain cardiac output.
- u The patient will maintain adequate ventilation.
- u The patient's airway will remain patent at all times.
- u The patient's body temperature will be normal.
- u The patient and family members will develop effective coping mechanisms.
- u The patient will remain free from signs and symptoms of infection.

Nursing interventions

- u Continue CPR as indicated. Assist with endotracheal intubation if necessary and administer supplemental oxygen.
- u If the patient has been submerged in cold water, use a rectal probe to determine the degree of hypothermia.
- u If the patient is hypothermic, start rewarming procedures during resuscitation. Don't stop resuscitation until the patient's body temperature ranges between 86° and 90.3° F (30° to 32.5° C).
- u Protect the cervical spine until fracture is ruled out.
- u Ensure peripheral I.V. access and administer I.V. fluids as necessary.
- u If ordered, insert an NG tube to remove swallowed water and reduce the risk of vomiting and aspiration.
- u Insert an indwelling urinary catheter to monitor urine output. Metabolic acidosis may develop to compensate for impaired renal function.
- u Assess ABG levels and obtain an ECG. The patient probably needs continuous cardiac monitoring.
- u Continually monitor the patient's vital signs and neurologic status. He may have central nervous system damage despite treatment for hypoxia and shock.
- u Obtain baseline serum electrolyte levels; continue monitoring these levels.
- u If the patient has a central line in place, closely monitor all hemodynamic parameters: cardiac output, central venous pressure, pulmonary artery wedge pressure, heart rate, and arterial blood pressure.
- u Administer bronchodilator and antibiotic agents to the patient as ordered.

Patient teaching

- u To prevent near drowning, advise the patient to avoid using alcohol or drugs before swimming, to observe water safety measures (such as the “buddy system”), and to take a water safety course given by the Red Cross, YMCA, or YWCA.

RADIATION EXPOSURE

Expanded use of ionized radiation has vastly increased the incidence of radiation exposure. Cancer patients who receive radiation therapy and nuclear power plant workers are among the most likely victims of radiation exposure.

The amount of radiation absorbed by a human body is measured in radiation absorbed doses (rad), not to be confused with roentgens, which are used to measure radiation emissions. A person can absorb up to 200 rad without fatal consequences. A dose of 450 rad is fatal in about half the cases; more than 600 rad is almost always fatal. When radiation is focused on a small area, the body can absorb and survive many thousands of rads if they're administered in carefully controlled doses over a long period of time. This basic principle is the key to safe and successful radiation therapy.

Causes

Exposure to radiation can occur by inhalation, ingestion, or direct contact. The existence and severity of tissue damage depend on the amount of body area exposed (the smaller, the better), length of exposure, dosage absorbed, distance from the source, and presence of protective shielding. (For guidelines to help minimize radiation exposure, see [Preventing radiation exposure.](#))

Ionized radiation (X-rays, protons, neutrons, and alpha, beta, and gamma rays) may cause immediate cell necrosis or disturbed deoxyribonucleic acid synthesis, which impairs cell function and division.

Rapidly dividing cells—bone marrow, hair follicles, gonads, and lymph tissue—are the most susceptible to radiation damage; highly differentiated cells—nerve, bone, and muscle—can resist radiation more successfully.

Complications

Delayed complications include leukemia and thyroid carcinoma. For people in the childbearing years, long-term exposure can cause fetal growth retardation or genetic defects in offspring.

Assessment findings

The effects of ionized radiation can be immediate and acute or delayed and chronic. Acute effects may be hematopoietic (after 100 to 600 rad), GI (after 600 to 2,000 rad), cerebral (after 1,000 or more rad), or cardiovascular (after 5,000 rad). They depend strictly on the amount of radiation absorbed.

An accurate patient history should reveal the radiation exposure, type, duration, and organs exposed.

A patient with *acute hematopoietic radiation toxicity* may report bleeding from the skin as well as from the GI and genitourinary tracts, the result of thrombocytopenia. During the latent period that follows, pancytopenia develops, and the patient may report no apparent signs or symptoms. As the latent period ends, the patient may report nosebleeds, hemorrhage, and increased susceptibility to infection (from an impaired immune response). Inspection may reveal petechiae, pallor, weakness, and oropharyngeal abscesses.

PREVENTION

Preventing radiation exposure

Proper shielding and other safety precautions can help you minimize the risk of exposing yourself and your patients to radiation.

Protecting yourself

- When caring for a patient exposed to radiation, cover your entire body with disposable, protective clothing. Wear a surgical mask, cap, goggles, gown, pants, bootcaps, and double gloves. Tape all glove, gown, and boot connections.
- Doublebag all equipment and clothing that comes in contact with a radiation-contaminated patient, and attach a label noting that the bag contains radioactive waste. Make sure the label includes the magenta-colored *radiation* insignia to avoid the danger of improper disposal.
- Wear proper shielding devices when performing X-ray or radiation treatments. If you work in areas where radiation is present, also wear a radiation detection badge and periodically have it read.
- If you are or may be pregnant, ask to be excused from caring for a patient with known or suspected radiation contamination.

Protecting your patient

- When performing diagnostic or treatment procedures that use radiation, shield the patient's reproductive organs from exposure, if feasible.
- Perform fluoroscopic examinations as quickly as possible.

Protecting your patient and yourself

- Ensure that areas housing X-ray and nuclear materials are properly shielded.
- Make sure X-ray equipment is periodically checked for reliability of output and filters are used properly.
- If accidental contamination occurs, immediately remove all clothing and wash the body vigorously with soap and water.

A patient with *radiation exposure that affects the GI system* may report intractable nausea, vomiting, and diarrhea. (This may result in severe fluid and electrolyte imbalance.) Inspection of the mouth and throat may reveal ulceration and infection. In later stages of exposure, the breakdown of intestinal villi cause plasma loss that can lead to circulatory collapse and may end in death.

A patient with *cerebral radiation toxicity* may report nausea, vomiting, and diarrhea within hours after brief exposure to large amounts of radiation. Shortly after these signs develop, the patient may complain of lethargy. Inspection may disclose tremors, which may be followed by seizures, confusion, coma, and even death within hours or days.

A patient with *cardiovascular radiation toxicity* may experience hypotension, shock, and cardiac arrhythmias.

Delayed or chronic effects from repeated, prolonged exposure to small doses of radiation over a long time may seriously damage the skin, causing dryness, erythema, atrophy, and malignant lesions. (Such damage also can follow acute exposure.)

Other delayed effects may include alopecia, brittle nails, hypothyroidism, amenorrhea, cataracts, decreased fertility, anemia, leukopenia, thrombocytopenia, malignant neoplasms, bone necrosis and fractures, and a shortened life span.

Diagnostic tests

Supportive laboratory findings show decreased hematocrit, hemoglobin, and platelets; thrombocytopenia, leukopenia, and lymphopenia; and decreased levels of serum electrolytes (potassium and chloride) from vomiting and diarrhea. Bone marrow studies show blood dyscrasia; X-rays may reveal bone necrosis. A Geiger counter may help determine the amount of radiation in open wounds.

Treatment

Initial treatment of a patient exposed to radiation involves managing any life-threatening injuries. After the patient's airway, breathing, and circulation are secure, a Geiger counter helps determine whether radioactive material was ingested or inhaled. Treatment for local radiation depends on the extent, degree, and location of tissue injury. Treatment for systemic effects is symptomatic and supportive.

Chelating agents are used to remove internal radioactive contamination. If contamination remains, the patient's wounds are cleaned, irrigated, debrided, and left open for 24 hours. With severe contamination, amputation, although rare, may be required.

Other treatments may include potassium iodide, which blocks the uptake of radioactive iodine by the thyroid if given within a few hours of exposure; aluminum phosphate gel, which reduces the intestinal absorption of radioactive strontium (by 85%); and barium sulfate, which precipitates radium.

Nursing diagnoses

▫ Altered nutrition: Less than body requirements ▫ Altered oral mucous membrane ▫ Anxiety ▫ Fluid volume deficit ▫ Impaired skin integrity ▫ Knowledge deficit ▫ Risk for infection

Key outcomes

- The patient will maintain weight within an acceptable range.
- The patient will maintain orientation to person, place, and time.
- The patient won't exhibit complications related to trauma to oral mucous membranes.
- The patient will remain free from signs and symptoms of infection.
- Fluid volume will remain within normal range.

Nursing interventions

- u Prepare to intervene as necessary to support respiratory and cardiac functions.
- u To minimize radiation exposure, properly dispose of contaminated clothing. Wear protective clothing when handling contaminated clothing and body fluids. If the patient's skin is contaminated, wash his body thoroughly with mild soap and water. Debride and irrigate open wounds. If the patient recently ingested radioactive material, perform gastric lavage and whole bowel irrigation, and administer activated charcoal, as ordered. Check facility policy to ensure proper disposal of contaminated excrement and body fluids.
- u Monitor intake and output, and maintain fluid and electrolyte balance. Give I.V. fluids and electrolytes, as ordered. If the patient can take oral feeding, encourage a high-protein, high-calorie diet. Tell him to use a soft toothbrush to minimize gum bleeding. Offer lidocaine to soothe painful mouth ulcers.
- u To prevent skin breakdown, make sure the patient avoids extreme temperatures, tight clothing, and drying soaps. Use strict aseptic technique.
- u Prevent complications. Monitor vital signs and watch for signs of hemorrhage.
- u Provide emotional support for the patient and family members, especially after severe exposure. Suggest genetic counseling and screening, as needed.
- u Encourage a patient who was exposed to significant amounts of radiation to receive genetic counseling. Refer him to a genetic counselor.

Patient teaching

- u Teach the patient how to deal with the effects of radiation exposure.
- u If the patient recovers from exposure, teach him how to prevent a recurrence.

Miscellaneous injuries

Common environmental injuries, such as poisoning, poisonous snakebites, and insect bites and stings, affect large numbers of patients. Home, work, or motor vehicle accidents commonly result in open trauma wounds. Finally, acts of violence, such as gunshot wounds, stabbings, and rape, account for injuries such as open trauma wounds and rape-trauma syndrome.

INSECT BITES AND STINGS

Insect bites and stings are among the most common traumatic complaints. The more serious include those from ticks, brown recluse spiders, black widow spiders, scorpions, bees, wasps, yellow jackets, and fire ants. Emergencies develop when a number of stings occur at one time or when the patient develops an allergic response to the protein substances in the insect venom.

With a bee, wasp, or yellow jacket sting, the shorter the interval between the sting and systemic signs and symptoms, the worse the prognosis. Without prompt treatment, signs and symptoms may progress to cyanosis, coma, and death.

Causes

The toxic effects of the injected venom or a hypersensitivity response to it cause reactions to insect bites and stings.

Complications

About 25% of people are hypersensitive to Hymenoptera venoms (bees, wasps, hornets, and yellow jackets) and may develop anaphylaxis.

Assessment findings

With a *tick* bite, the patient may complain of itching at the affected site. After several days, he may develop tick paralysis (acute flaccid paralysis, starting as paresthesia and pain in the legs and resulting in respiratory failure from bulbar paralysis). If the tick carried Rocky Mountain spotted fever or Lyme disease, the patient may develop signs and symptoms of the disease. (For more information, see “[Rocky Mountain Spotted Fever](#),” and “[Lyme Disease](#)”.)

With a *brown recluse (violin) spider* bite, localized vasoconstriction begins 2 to 8 hours after the bite and is the result of a coagulotoxic venom. The small, reddened puncture wound forms a bleb and then becomes ischemic, eventually leading to ischemic necrosis. In about 3 to 4 days, the center darkens and hardens. Within 1 to 2 weeks, an ulcer forms. Rarely, thrombocytopenia and hemolytic anemia develop and lead to death within the first 24 to 48 hours (usually in a child or patient with a history of cardiac disease). In some cases, the bite may result in renal failure, disseminated intravascular coagulation, and cardiogenic shock, which can lead to death.

The patient may complain of minimal initial pain that increases over time. He may also complain of fever, chills, malaise, weakness, nausea, vomiting, and joint pain. Inspection may reveal petechiae.

With a *black widow spider* bite, the patient may report feeling a pinprick sensation, followed by dull, numbing pain. Initially a tiny, edematous, red bite mark may be noted. The injected venom is neurotoxic, and the severity and progression of the signs and symptoms depend on the patient's age, size, and sensitivity.

If the bite is on a leg, the patient may have severe pain and large-muscle cramping. Palpation may reveal a rigid, painful abdomen. If the bite is on an arm, rigidity and pain in the chest, shoulders, and back may occur.

Systemic signs and symptoms may include extreme restlessness, vertigo, sweating, chills, pallor, seizures (especially in children), hyperactive reflexes, hypertension, tachycardia, thready pulse, circulatory collapse, nausea, vomiting, headache, ptosis, eyelid edema, urticaria, pruritus, fever, and urine retention.

With a *scorpion* sting, the patient may experience an anaphylactic or neurotoxic reaction. You may note local swelling and tenderness and skin discoloration at the bite site. The patient may complain of a sharp burning sensation and paresthesia. Palpation may reveal regional lymph gland swelling.

If the reaction is neurotoxic, the patient may experience immediate, sharp pain; hyperesthesia; drowsiness; itching of the nose, throat, and mouth; impaired speech; salivation; lacrimation; diarrhea and gastric cramping; sweating; jaw muscle spasms; laryngospasm; incontinence; seizures; and nausea and vomiting. Death may follow cardiovascular or respiratory failure. These signs and symptoms usually last from 24 to 78 hours. The bite site recovers last.

With a *bee, wasp, or yellow jacket* sting, the patient may have either a localized or a systemic reaction. In a local reaction, you may observe a raised, reddened wheal, possibly with a protruding stinger from the bee. It's usually painful and pruritic.

In a systemic reaction, signs and symptoms of hypersensitivity usually appear within 20 minutes, including weakness, chest tightness, dizziness, nausea, vomiting, abdominal cramps, throat constriction, and wheezing and decreased blood pressure (signs of cardiovascular collapse).

With a *fire ant* sting, the patient reports immediate pain, itching, and burning. Within 4 to 8 hours, clear vesicles develop with surrounding erythema. After 24 hours, the characteristic pustule appears.

Diagnostic tests

Identification of the insect is difficult unless the patient was stung by a honeybee or a bumblebee. These insects usually leave a stinger (with venom sac) in the lesion. Tests showing hemolytic anemia or thrombocytopenia may indicate a brown recluse spider bite; hematuria and an increased white blood cell count may point to a

black widow spider bite.

Treatment

For a *tick* bite, treatment involves removing the tick, applying antipruritics for itching, and providing symptomatic therapy for severe symptoms, such as assisted ventilation for respiratory failure. Treatment for Rocky Mountain spotted fever and Lyme disease includes such antibiotics as tetracycline, erythromycin, and penicillin.

No known specific treatment exists for a *brown recluse spider* bite. Combination therapies including corticosteroids, antibiotics, antihistamines, tranquilizers, I.V. fluids, and tetanus prophylaxis reduce signs and symptoms and prevent complications. Lesion excision in the first 10 to 12 hours may relieve pain. A split-thickness skin graft closes the wound. Without grafting, healing may take 6 to 8 weeks. A large chronic ulcer may require skin grafting.

For a *black widow spider* bite, treatment consists of antivenin I.V. to neutralize the venom and ice packs applied to the bite area. When skin or eye tests show sensitivity to horse serum, desensitization precedes antivenin treatment.

Symptomatic treatment may include calcium gluconate I.V. to control muscle spasms, diazepam for severe muscle spasms, adrenaline or antihistamines for hypersensitivity symptoms, oxygen by nasal cannula or mask for respiratory difficulty, and tetanus immunization and antibiotics to prevent infection.

For a *scorpion* sting, antivenin (made from goat serum) may be used if available. (For information on how to obtain this agent, contact the Arizona Poison and Drug Information Center, [602] 626-6016.) Symptomatic treatment may include calcium gluconate I.V. for muscle spasm and phenobarbital I.M. for seizures.

For *bee*, *wasp*, *yellow jacket*, or *fire ant* stings, treatment of local reactions includes applying ice to the affected area. If the entire extremity shows signs, treatment involves elevating the affected extremity and administering 25 to 50 mg oral diphenhydramine every 4 hours. More severe reactions may require administration of prednisone for 5 to 7 days.

For patients who are extremely allergic to stings, self-treatment with injectable epinephrine as soon as possible after the sting may prevent anaphylaxis and respiratory obstruction. The patient should then seek immediate medical attention.

Supportive treatment includes airway management, I.V. fluids for volume expansion, vasopressors, theophylline for bronchospasm, and corticosteroids to reduce allergic response. Venom immunotherapy may be indicated for patients with a history of severe reactions who are at increased risk for repeated stings.

Nursing diagnoses

u Altered tissue perfusion u Fluid volume deficit u Impaired skin integrity u Ineffective airway clearance u Ineffective breathing pattern u Knowledge deficit u Pain u Risk for poisoning u Sensory or perceptual alterations

Key outcomes

- u The patient will maintain adequate ventilation.
- u The patient will maintain a patent airway.
- u The patient will express feelings of comfort.
- u The patient will regain skin integrity.
- u The patient's fluid volume will remain within normal range.

Nursing interventions

- u Monitor the patient's vital signs, general appearance, and any changes at the bite or sting site.
- u Keep the patient quiet and warm and the affected part immobile.
- u Clean the bite or sting site with antiseptic, and apply ice to relieve pain, reduce swelling, and slow circulation.
- u Have epinephrine and emergency resuscitation equipment on hand in case of anaphylactic reaction.
- u When giving analgesics, monitor respiratory status.
- u To remove a tick, cover it with mineral, salad, or machine oil, or alcohol on a gauze pad. This blocks the tick's breathing pores, causing it to withdraw from the skin. Don't squeeze or crush the tick when removing it. If it doesn't disengage after the pad has been in place for 30 minutes, carefully remove all parts of it with tweezers.
- u For a brown recluse spider bite, clean the lesion with a 1:20 Burow's aluminum acetate solution and, as ordered, apply antibiotic ointment. Reassure the patient with a disfiguring ulcer that skin grafting can help.
- u If a bee, wasp, or yellow jacket stinger is in place, scrape it off. Don't pull or squeeze it; squeezing releases more toxin. Clean the site and apply ice.

Patient teaching

- u To reduce the risk of being bitten by a tick, tell the patient to keep away from wooded areas, to wear protective clothes, and to examine the body carefully for ticks after being outdoors.
- u Teach the patient how to safely remove ticks.
- u To prevent brown recluse and black widow spider bites, advise the patient to spray infested areas, tuck pant legs into socks in such areas, wear gloves and heavy clothes when working around woodpiles or sheds, inspect outdoor work clothes for spiders before use, and discourage children from playing near infested areas.
- u Tell the patient who is allergic to bee stings to wear a medical identification bracelet or carry a card and to carry an anaphylaxis kit. Explain how to use the kit and refer him to an allergist for hyposensitization.
- u To prevent bee stings, warn the patient to avoid using fragrant cosmetics during insect season, wearing bright colors, going barefoot, and touching flowers and fruits that attract bees. Advise using an insect repellent.

OPEN TRAUMA WOUNDS

Open trauma wounds include abrasions, lacerations, avulsions, crush wounds, puncture wounds, and missile injuries resulting from accidental injury or acts of violence.

Causes

Most commonly, open wounds result from an accidental injury at home or work or from a motor vehicle crash. Other open wounds, such as stab and gunshot wounds, may be intentionally inflicted by the victim or by someone else. Open wounds occasionally are self-inflicted by patients with psychiatric disorders or suicidal ideations.

Complications

Complications depend on the site of the open wound and whether any organs are directly or indirectly affected. Infection is the major complication. Organ tissue damage, scarring, and dysfunction may also occur. In the case of a gunshot wound to the head or other serious wounds, death can occur.

Assessment findings

The patient's history (possibly obtained from witnesses) may include such details as the mechanism and time of injury and any treatment already provided. Inspection usually reveals the extent of injury, level of consciousness, obvious skeletal damage, local and generalized neurologic deficits, and the patient's general condition.

Inspection of an abrasion may reveal epidermal scrapes, reddish welts, embedded dirt and debris, and bruises in the affected area. The patient usually complains of

pain at the site.

With a *laceration*, there is an open skin area extending deep into the epithelium. The edges may be even (possibly indicating a knife wound) or torn and ragged.

With an *avulsion*, torn tissue or skin appears peeled away. Bleeding usually is significant, depending on the location and size.

In a *crush wound*, you may observe severe ecchymoses, hematomas, edema, hemorrhage and, possibly, split skin over the affected area. Damage to the underlying tissues may not be evident.

With a *puncture wound* or a *missile injury*, external damage may be minimal. The entrance site is visible and bleeding varies. Sometimes, no bleeding is present. If the object causing the puncture is still in place, its presence may maintain hemostasis, preventing extensive external blood loss.

Depending on the cause of injury, the wound may contain foreign bodies, such as stones or dirt. You may detect peripheral nerve damage, a common complication in lacerations and other open trauma wounds, as well as fractures and dislocations. Signs of peripheral nerve damage vary with location:

- u *radial nerve* — weak wrist extension, inability to extend thumb in a hitchhiker's sign, numbness in dorsum of thumb
- u *median nerve* — numbness in index finger tip, finger abduction, and apposition of thumb and fingers
- u *ulnar nerve* — numbness in little finger tip, finger fanning (abduction)
- u *peroneal nerve* — inability to extend foot or big toe, footdrop, numbness in lateral dorsum and first toe web space
- u *sciatic and tibial nerves* — plantar flexion, weakness in leg, numbness in sole.

Diagnostic tests

X-rays, magnetic resonance imaging, and computed tomography scans help determine bone involvement and soft-tissue injury, particularly organ injury. A complete blood count aids blood loss evaluation. In patients with suspected nerve involvement, electromyography, nerve conduction, and electrical stimulation tests can provide more detailed information about possible peripheral nerve damage.

Treatment

For all types of traumatic wounds, treatment includes stabilizing the airway and immobilizing the victim if you suspect spinal injuries. I.V. lines are established and the patient should be treated for hypovolemic shock if present. When airway, breathing, and circulation are stable, apply direct pressure to obvious bleeding (especially arterial bleeding).

The patient should be evaluated neurologically and other major trauma evaluated. When the patient is stable, the wounds are evaluated and treated according to type. Thorough cleaning and irrigation of the affected area and administration of tetanus prophylaxis may be indicated. (See [Managing open trauma wounds](#).)

Small avulsions require a nonadhesive pressure dressing. Larger avulsed areas may be repaired by reattaching the avulsed tissue or by split-thickness grafting.

ADVANCED PRACTICE

<div><div>Managing open trauma wounds</div></div>	
TYPE	CLINICAL ACTION

Abrasion

- Open surface wounds (scrapes) of epidermis, resulting from friction; nerve endings exposed
 - Diagnosis based on scratches, reddish welts, bruises, pain, and history of friction injury
- Obtain a history to distinguish injury from second-degree burn.
 - Clean the wound gently with topical germicide and irrigate it. Vigorously scrubbing abrasions will increase tissue damage.
 - Remove all imbedded foreign objects. Apply a local anesthetic if cleaning is very painful.
 - Apply a light, water-soluble antibiotic cream to prevent infection.
 - If the wound is severe, apply a loose protective dressing that allows air to circulate.
 - Administer tetanus prophylaxis if necessary.

Avulsion

- Complete tissue loss that prevents approximation of wound edges, resulting from cutting, gouging, or complete tearing of skin; frequently affects nose tip, earlobe, fingertip, and penis.
 - Diagnosis based on full-thickness skin loss, hemorrhage, pain, history of trauma; X-ray required to rule out bone damage; complete blood count (CBC) before surgery.
- Check the patient's history for bleeding tendencies and use of anticoagulants.
 - Record the time of injury to help determine whether tissue is salvageable. Preserve tissue (if available) in cool saline solution for a possible splint-thickness graft or flap.
 - Control hemorrhage with pressure, an absorbable gelatin sponge, or topical thrombin.
 - Clean the wound gently, irrigate it with saline solution, and debride it if necessary. Cover with a bulky dressing.
 - Tell the patient to leave the dressing in place until return visit, to keep the area dry, and to watch for signs of infection (pain, fever, redness, swelling).
 - Administer analgesics and tetanus prophylaxis if necessary.

Crush injury

- Heavy falling object splits skin and causes necrosis along split margins and damages tissue underneath. May look like a laceration.
 - Diagnosis based on history of trauma, edema, hemorrhage, massive hematomas, damage to surrounding tissues (fractures, nerve injuries, loss of tendon function), shock, pain, history of trauma; X-rays required to determine extent of injury to surrounding structures. CBC and electrolyte count also required.
- Check the patient's history for bleeding tendencies and use of anticoagulants.
 - Clean open areas gently with soap and water.
 - Control hemorrhage with pressure and cold pack.
 - Apply a dry, sterile bulky dressing; wrap the entire extremity in a compression dressing.
 - Immobilize the injured extremity and encourage the patient to rest. Monitor vital signs and check peripheral pulses and circulation often.
 - Administer tetanus prophylaxis if necessary.
 - A severe injury may require I.V. infusion of lactated Ringer's or saline solution with a large-bore catheter as well as surgical exploration, debridement, and repair.

Puncture wound

- Small-entry wounds that probably damage underlying structures, resulting from sharp, pointed objects.
 - Diagnosis based on hemorrhage (rare), deep hematomas (in chest or abdominal wounds), ragged wound edges (in bites), small-entry wound (in very sharp objects), pain, and history of trauma; X-rays can detect retention of injuring object.
- Check the patient's history for bleeding tendencies and use of anticoagulants.
 - Obtain a description of the injury, including force of entry.
 - Assess the extent of the injury.
 - Don't remove impaling objects until the injury has been completely evaluated (if the eye is injured, call an ophthalmologist immediately).
 - Thoroughly clean the injured area with soap and water. Irrigate all minor wounds with saline solution after removing a foreign object.

Missile injury

- High-velocity tissue penetration, such as a gunshot wound.
 - Diagnosis based on entry and possibly exit wounds, signs of hemorrhage, shock, pain, and history of trauma; X-rays, CBC, and electrolyte levels required to assess extent of injury and estimate blood loss.
- Check the patient's history for bleeding tendencies and use of anticoagulants.
 - Control hemorrhage with pressure if possible. If the injury is near vital organs, use large-bore catheters to start two I.V. lines, using lactated Ringer's solution, normal saline solution, or blood transfusions for volume replacement. Prepare for possible exploratory surgery.
 - Maintain a patent airway, and monitor for signs of hypovolemia, shock, and cardiac arrhythmias. Check vital signs and neurovascular response often.
 - Cover a sucking chest wound during exhalation with a petroleum gauze and an occlusive dressing.
 - Clean the wound gently with saline solution or water; debride as necessary.
 - If damage is minor, apply a dry, sterile dressing.
 - Administer tetanus prophylaxis if necessary.
 - Obtain X-rays to detect retained fragments.
 - If possible, determine the caliber of the weapon.
 - Report the injury to the police department.

Grossly contaminated lacerations require treatment with a broad-spectrum antibiotic. Lacerations are closed by suture or Steri-Strips. Crush and puncture wounds may require surgery, debridement, and repair.

Missile injuries and some puncture wounds require stabilization of life-threatening insults. Endotracheal intubation, volume replacement (with lactated Ringer's solution), and surgery may be necessary.

Nursing diagnoses

- u Altered tissue perfusion (renal, cerebral, cardiopulmonary, GI, peripheral)
- u Anxiety
- u Decreased cardiac output
- u Impaired gas exchange
- u Impaired physical mobility
- u Impaired skin integrity
- u Pain
- u Risk for fluid volume deficit
- u Risk for infection
- u Risk for posttrauma syndrome

Key outcomes

- u The patient will maintain adequate ventilation.
- u The patient will report pain relief with analgesia or other measures.
- u The patient will maintain hemodynamic stability.
- u The patient will maintain adequate cardiac output.
- u The patient's risk factors for altered cerebral perfusion and complications will be reduced as much as possible.
- u The patient's wounds and incisions will appear clean, pink, and free of purulent drainage.

Nursing interventions

- u Assess airway, breathing, and circulation. Assess vital signs and monitor closely for signs of hemodynamic compromise (racing pulse, increased respiratory rate, decreased level of consciousness (LOC), thirst, cool clammy skin, decreasing blood pressure).
- u Administer oxygen as necessary.
- u Monitor neurologic status and determine LOC.
- u Send blood samples to the laboratory and monitor results.
- u Prepare the patient for surgery if needed.
- u As much as possible, tell the patient about the procedures and provide reassurance.
- u Establish I.V. access and administer I.V. fluids and blood products as laboratory studies denote and according to protocol.
- u Assist with inserting a central venous pressure or other type of central device as necessary.
- u Check for bleeding tendencies and anticoagulant use.
- u Administer analgesics and tetanus prophylaxis if necessary.
- u Thoroughly clean the injured area with soap and water. Irrigate all minor wounds with normal saline solution after removing any foreign objects.
- u Assess for neuromuscular, tendon, and circulatory damage.
- u If injury resulted from foul play, notify the police.
- u Assist with the treatment of specific wounds (abrasion, avulsion, crush wound, puncture wound, laceration, or missile injury).

Patient teaching

- u Teach the patient how to care for the wound at home. Tell him to report any swelling, numbness, or tingling, which may indicate neurovascular compromise.
- u Direct him to use an ice pack as indicated.
- u Tell the patient to take analgesics, as prescribed, and to complete the course of prescribed antibiotics.
- u Stress the need for follow-up care and suture removal.
- u Point out the signs and symptoms of infection: redness, warmth, drainage, swelling, increased pain. If the patient suspects an infection, tell him to notify the doctor. If soaks are ordered, instruct the patient to soak the wound in warm, soapy water for 15 minutes, three times daily, and to return for follow-up care every 2 to 3 days until the wound heals.

POISONING

Inhalation, ingestion, or injection of or skin contamination from any harmful substance is a common problem. In the United States, about 1 million people are poisoned annually, 800 of them fatally. The prognosis depends on the amount of poison absorbed, its toxicity, and the time interval between poisoning and treatment.

Causes

Because of their curiosity and ignorance, children are the most common poison victims. In fact, accidental poisoning, usually from the ingestion of salicylates (aspirin), cleaning agents, insecticides, paints, cosmetics, and plants, is the fourth leading cause of death in children.

In adults, poisoning is most common among chemical company employees, particularly those in companies that use chlorine, carbon dioxide, hydrogen sulfide, nitrogen dioxide, and ammonia, and in companies that ignore safety standards. Other causes of poisoning in adults include improper cooking, canning, and storage of food; ingestion of or skin contamination from plants (for example, dieffenbachia, mistletoe, azalea, and philodendron); and accidental or intentional drug overdose (usually barbiturates) or chemical ingestion.

Complications

Depending on the poison, possible complications vary widely but can include hypotension, cardiac arrhythmias, seizures, coma, and death.

Assessment findings

The patient's history should reveal the source of poison and the form of exposure (ingestion, inhalation, injection, or skin contact). Assessment findings vary with the poison. (See [Pinpointing poison's effects.](#))

Diagnostic tests

Toxicologic studies (including drug screens) of poison levels in the mouth, vomitus, urine, stool, or blood or on the victim's hands or clothing confirm the diagnosis. If possible, have the family or patient bring the container holding the poison to the emergency department for comparable study. In inhalation poisoning, chest X-rays may show pulmonary infiltrates or edema in petroleum distillate inhalation, X-rays may show aspiration pneumonia. Abdominal X-rays may reveal iron pills or other radiopaque substances.

ABG and serum electrolyte levels and a complete blood count are used to evaluate oxygenation, ventilation, and the metabolic status of seriously poisoned patients.

Treatment

Initial treatment includes emergency resuscitation; support for the patient's airway, breathing, and circulation; and prevention of further absorption of poison. After this, treatment consists of continuing supportive or symptomatic care and, when possible, administration of a specific antidote.

A poisoning victim who exhibits an altered level of consciousness (LOC) routinely receives oxygen, glucose, and naloxone. Activated charcoal is effective in eliminating many toxic substances. The specific treatment depends on the poison.

Nursing diagnoses

- u Altered thought processes
 - u Anxiety
 - u Diarrhea
 - u Fluid volume deficit
 - u Impaired skin integrity
 - u Ineffective breathing pattern
 - u Knowledge deficit
 - u Pain
 - u Risk for aspiration
 - u Risk for injury
 - u Sensory or perceptual alterations
-

Pinpointing poison's effects

Review the assessment findings and possible toxins listed below to help you determine what type of poison is causing your patient's signs and symptoms.

Agitation, delirium

Alcohol, amphetamines, atropine, barbiturates, physostigmine, scopolamine

Coma

Atropine, barbiturates, bromide, carbon monoxide, chloral hydrate, ethanol, ethchlorvynol, paraldehyde, salicylates, scopolamine

Constricted pupils

Barbiturates, chloral hydrate, morphine, propoxyphene

Diaphoresis

Alcohol, fluoride, insulin, physostigmine

Diarrhea, nausea, vomiting

Alcohol (ethanol, methanol, ethylene glycol), digitalis glycosides, heavy metals (lead, arsenic), morphine and its analogues, salicylates

Dilated pupils

Alcohol, amphetamines, belladonna alkaloids (such as atropine and scopolamine), botulin toxin, cocaine, cyanide, ephedrine, glutethimide, meperidine, parasympathomimetics

Dry mouth

Antihistamines, belladonna alkaloids, botulin toxin, morphine, phenothiazines, tricyclic antidepressants

Extrapyramidal tremor

Phenothiazines

Hematemesis

Fluoride, mercuric chloride, phosphorus, salicylates

Kussmaul's respirations

Ethanol, ethylene glycol, methanol, salicylates

Partial or total blindness

Methanol

Pink skin

Atropine (flushed and dry skin), carbon monoxide, cyanide, phenothiazines

Seizures

Alcohol (ethanol, methanol, ethylene glycol), amphetamines, carbon monoxide, cholinesterase inhibitors, hydrocarbons, phenothiazines, propoxyphene, salicylates, strychnine

Key outcomes

- u The patient will maintain orientation to person, place, and time.
- u The patient will maintain adequate ventilation.
- u The patient's airway will remain patent at all times.
- u The patient will express feelings of comfort and relief of pain.
- u The patient will identify factors that increase potential for injury.

Nursing interventions

- u Carefully monitor the patient's vital signs and LOC. If necessary, begin CPR.
- u Prevent further absorption of ingested poison by inducing emesis, using syrup of ipecac, or by administering gastric lavage and cathartics (magnesium sulfate). For specific treatment, contact the poison center (local or national). The effectiveness of treatment depends on the speed of absorption and the time elapsed between ingestion and removal. With syrup of ipecac, give warm water (usually less than 1 qt [1 L]) until vomiting occurs, or give another dose of ipecac as ordered.
- u Never induce emesis if you suspect corrosive acid poisoning, if the patient is unconscious or has seizures, or if the gag reflex is impaired even in a conscious patient. Instead, neutralize the poison by instilling the appropriate antidote by NG tube. Common antidotes include milk, magnesium salts (milk of magnesia), activated charcoal, or other chelating agents (such as deferoxamine or edetate disodium).
- u When possible, add the antidote to water or juice.

ALERT Methods for removing a poisonous hydrocarbon are controversial. In the conscious patient, because there is a lower risk of aspiration with ipecac-induced emesis than with lavage, emesis may be the preferred treatment, but some doctors still use lavage. Moreover, some believe that because of poor absorption, kerosene (a hydrocarbon) doesn't require removal from the GI tract; others believe that removal depends on the amount ingested.

- u When you do want to induce emesis and the patient has already taken syrup of ipecac, don't give activated charcoal to neutralize the poison until *after* emesis; activated charcoal absorbs ipecac.
- u To perform gastric lavage, instill 30 ml of fluid by NG tube; then aspirate the liquid. Repeat until the aspirate is clear. Save vomitus and aspirate for analysis. (To prevent aspiration in the unconscious patient, an endotracheal tube should be in place before lavage.)
- u If several hours have passed since the patient ingested the poison, use large quantities of I.V. fluids to diurese the patient. The kind of fluid you use depends on the patient's acid-base balance and cardiovascular status and on the flow rate necessary for effective diuresis of poison.
- u If ingested poisoning is severe and peritoneal dialysis or hemodialysis is necessary, assist as necessary.
- u To prevent further absorption of inhaled poison, remove the patient to fresh or uncontaminated air. Provide supplemental oxygen and, if needed, intubation. To prevent further absorption from skin contamination, remove the clothing covering the contaminated skin and immediately flush the area with large amounts of water.
- u If the patient is in severe pain, give analgesics, as ordered; frequently monitor fluid intake and output, vital signs, and LOC.
- u Keep the patient warm and provide support in a quiet environment.
- u If the poison was ingested intentionally, refer the patient for counseling to help prevent future attempts at suicide.

Patient teaching

- u To prevent accidental poisoning, instruct the patient to read the label before he takes the medication. Tell him to store all medications and household chemicals properly, keep them out of reach of children, and discard old medications. Warn him not to take medications prescribed for someone else, not to transfer medications

from their original containers to other containers without labeling them properly, and never to transfer poisons to food containers. Parents should avoid taking medication in front of their young children or calling medication “candy” to get children to take it.

- u Syrup of ipecac should be available in households with children. Emphasize the importance of understanding the directions for proper use.
- u Advise parents to use childproof caps on medication containers.
- u Make sure the patient understands the importance of using toxic sprays only in well-ventilated areas and of following instructions carefully. Tell him to use pesticides carefully and to keep the number of his poison control center handy.
- u Make sure the patient is aware that household chemicals should never be mixed because a harmful chemical reaction can occur.

POISONOUS SNAKEBITES

Each year, poisonous snakes bite about 8,000 people in the United States. Snakebites occur most during summer afternoons in grassy or rocky habitats. A poisonous snakebite is a medical emergency. With prompt, correct treatment, it need not be fatal. However, antivenin against an exotic venomous snake isn't always readily available.

Causes

The only poisonous snakes found in nature in the United States are pit vipers (Crotalidae) and coral snakes (Elapidae). Pit vipers include rattlesnakes, water moccasins (cottonmouths), and copperheads. They have a pitted depression between their eyes and nostrils, and two fangs ¾" to 1¼" (1.9 to 3.2 cm) long. Because a snake's fangs may break off or grow behind old ones, a pit viper can have anywhere from one to four fangs. (See [Pit viper.](#))

Because coral snakes are nocturnal and placid, their bites are less common than pit viper bites; pit vipers are also nocturnal but are more active. Coral snake fangs are short but have teeth behind them. Coral snakes have distinctive red, black, and yellow bands (yellow bands always border red ones), tend to bite with a chewing motion, and may leave multiple fang marks, small lacerations, and extensive tissue destruction.

Many snakebites are associated with activities involving amateur snake keeping and handling and commonly result from carelessness or daring on the part of the snake handler. Handling snakes that appear to be dead can lead to a venomous snakebite secondary to postmortem reflex action of the snake's head. Snakebite can occur even by inadvertently striking a finger against a fang of a preserved snake.

Pit viper
A pitted depression between the eyes and nostrils and two long fangs are characteristic of a pit viper, the most common type of poisonous snake.

Complications

In a pit viper bite, delayed administration of specific antivenin may result in extensive vasculitis, necrosis, and sloughing of the skin and subcutaneous tissue. An untreated coral snake bite can result in respiratory arrest and, if shock develops, cardiovascular collapse and death.

Assessment findings

Inspection usually reveals evidence of the bite on the arm or leg or below the elbow or knee. Bites to the head or trunk or into a blood vessel are dangerous.

Most pit viper bites that result in envenomation cause immediate and progressively severe pain and edema. The entire extremity may swell within a few hours. (See [Severe edema in snakebite.](#))

Additional assessment findings may include local elevation in skin temperature, fever, discoloration of the skin, petechiae, ecchymoses, blebs, blisters, and bloody wound discharge, as well as local necrosis.

The patient may have several complaints, including headache, a metallic or rubber taste in the mouth, nausea, vomiting, and diarrhea. Because pit viper venom is neurotoxic, he also may report local and facial numbness and tingling, fasciculation, and twitching skeletal muscles.

You may note seizures (especially in children), extreme anxiety, difficulty speaking, fainting, weakness, dizziness, excessive sweating, tachycardia, hypotension, occasional paralysis, mild to severe respiratory distress, blurred vision, and marked thirst. Severe envenomation may result in coma and death. Pit viper venom may also impair coagulation and cause hematemesis, hematuria, melena, bleeding gums, and internal bleeding. Palpation may reveal lymphadenopathy.

The patient's reaction to a coral snake bite usually is delayed, perhaps up to several hours. These snakebites cause little or no local tissue reaction, such as local pain, swelling, or necrosis. However, because a coral snake's venom is neurotoxic, the reaction can progress swiftly, producing such wide-ranging effects as local paresthesia, weakness, euphoria, drowsiness, nausea, vomiting, difficulty swallowing, marked salivation, dysphonia, ptosis, blurred vision, miosis, respiratory distress and possible respiratory failure, loss of muscle coordination, abnormal reflexes, peripheral paralysis and, possibly, shock with cardiovascular collapse and death. Coral snake bites also can cause coagulotoxicity. (See [Assessing snakebites.](#))

Diagnostic tests

Laboratory test values can help to identify the extent of envenomation and to provide guidelines for supportive treatment. Abnormal test results may include prolonged bleeding time and partial thromboplastin time, decreased hemoglobin and hematocrit levels, sharply decreased platelet count (less than 200,000/mm ³), urinalysis showing hematuria and, in infection (snake mouths contain gram negative bacteria), increased white blood cell count.

Chest X-rays may show pulmonary edema or emboli; an electrocardiogram may show tachycardia and ectopic beats; and severe envenomation may produce abnormal findings on an electroencephalogram.

Treatment

- u Prompt, appropriate first aid can reduce venom absorption and prevent severe symptoms. Antivenin administration and other treatments should follow.
- u If possible, identify the snake, but don't waste time trying to find it.
- u Immediately immobilize the patient's limb below heart level in a horizontal position, and instruct the victim to remain as quiet as possible.
- u If indicated, apply a slightly constrictive band (one that obstructs only lymphatic and superficial venous blood flow) about 4" (10 cm) above the fang marks or just above the first joint proximal to the bite. The band should be loose enough to allow a finger's width between the band and the skin. Don't apply a constrictive band if more than 30 minutes have elapsed since the bite. Also, total constrictive band time shouldn't exceed 2 hours, nor should it delay antivenin administration. When the band is in place, don't remove it until the doctor examines the patient.
- u Wash the skin over the fang marks.
- u Never give the victim alcoholic drinks or stimulants; these speed venom absorption. Never apply ice to a snakebite: It increases tissue damage. Don't incise and suction the affected area. The risk of trauma to underlying structures caused by unskilled performance of this technique is greater than the amount of venom that can be recovered.
- u Transport the victim as quickly as possible, keeping him warm and quiet. Record the signs and symptoms of progressive envenomation and when they develop.
- u Antivenin administration is required in life-threatening circumstances. Prepare and administer the antivenin according to the manufacturer's directions. Watch the patient closely for signs of sensitivity and anaphylaxis. Keep emergency epinephrine on hand in case the patient develops such problems.
- u Other treatments include tetanus toxoid or tetanus immune globulin (human); broad-spectrum antibiotics; and codeine, morphine, or meperidine, depending on respiratory status, severity of pain, and type of snakebite (narcotics are contraindicated in coral snake bites).

- u All snakebites require administration of I.V. isotonic fluids. If bleeding is severe, blood transfusions also may be necessary. Antihistamines help relieve pruritus and urticaria.
- u Most necrotic tissue resulting from a snakebite needs surgical debridement after 3 or 4 days. Although controversial, fasciotomy may be required within 2 or 3 hours of the bite if intense, rapidly progressive edema develops. Extreme envenomation may require limb amputation and subsequent reconstructive surgery, rehabilitation, and physical therapy.

Nursing diagnoses

- u Altered tissue perfusion
- u Anxiety
- u Decreased cardiac output
- u Diarrhea
- u Fear
- u Fluid volume deficit
- u Impaired skin integrity
- u Ineffective breathing pattern
- u Pain
- u Risk for infection
- u Risk for injury
- u Risk for posttrauma syndrome
- u Sensory or perceptual alterations

Severe edema in snakebite
After a snakebite, the affected extremity develops severe edema within hours.

Key outcomes

- u The patient will maintain adequate ventilation.
- u The patient will maintain cardiac output.
- u The patient's fluid volume will remain within acceptable range.
- u The patient will regain skin integrity.
- u The patient will remain free from signs and symptoms of infection.
- u The patient will express feelings of comfort and relief of pain.

Nursing interventions

- u When the patient arrives at the facility, immobilize the extremity if this hasn't already been done. If a tight tourniquet has been applied within the past hour, apply a loose tourniquet proximally and remove the first tourniquet. Release the second tourniquet gradually during antivenin administration, as ordered. A sudden release of venom into the bloodstream can cause cardiopulmonary collapse, so keep emergency equipment handy.
- u On a flow sheet, document vital signs, level of consciousness, skin color, swelling, respiratory status, description of the bite and surrounding area, and symptoms. Monitor vital signs every 15 minutes, and check for a pulse in the affected limb.
- u Start an I.V. line with a large-bore needle for antivenin administration. Severe bites that result in coagulotoxic signs and symptoms may require two I.V. lines: one for antivenin, the second for blood products.
- u Have blood samples drawn for clotting studies, platelet count, fibrinogen levels, fibrin split products, type and cross matching, and other ordered tests.
- u Before antivenin administration, obtain a patient history of allergies (especially to horse serum) and other medical problems. Do hypersensitivity tests as ordered, and assist with desensitization as needed. During antivenin administration, keep epinephrine, oxygen, and vasopressors available to combat anaphylaxis from an allergic reaction to horse serum.
- u If signs of hypersensitivity occur during antivenin administration, stop the infusion and administer diphenhydramine, cimetidine, or ranitidine as ordered. Start the infusion at a slower rate and closely monitor the patient.
- u Administer packed red blood cells, whole blood, I.V. fluids and, possibly, fresh frozen plasma or platelets as ordered to counteract any coagulotoxicity and maintain the patient's blood pressure. If he develops respiratory distress, assist with endotracheal intubation or tracheotomy as ordered.
- u Give analgesics as needed. Don't give narcotics to victims of coral snake bites.
- u Clean the snakebite using sterile technique. Open, debride, and drain any blebs and blisters because they may contain venom. Be sure to change dressings daily.
- u If the patient requires hospitalization for longer than 24 to 48 hours, position him carefully to avoid contractures. Perform passive range-of-motion exercises until the 4th day after the bite and then active exercises and whirlpool treatments as ordered.
- u For information on the proper antivenin for exotic snakes, contact the Arizona Poison and Drug Information Center at (602) 626-6016.
- u For those likely to encounter venomous snakes, additional protection is given by pretesting for sensitivity to horse serum.

Assessing snakebites
When examining a patient who sustained a poisonous snakebite, keep in mind the following hints: <ul style="list-style-type: none">u Absence of fang marks precludes envenomation.u Marks without bleeding or with clotted blood probably denote a lack of envenomation or an insect bite, or the marks are factitious.u In the presence of venom injection, the fang marks continue oozing nonclotting blood.u A pit viper bite produces immediate, severe, burning pain. Soon after the bite, mild ecchymoses appear around the fang marks.u Absence of microhematuria after a pit viper bite indicates a lack of severe envenomation.

Patient teaching

- u Stress the importance of protecting extremities in snake infested areas, as many venomous snakes have long, sharp fangs that can easily penetrate clothing.
- u For snake owners, proper handling techniques should be learned and observed. The snake should be kept in proper containment at all times to avoid the danger of exposing the snake to others

RAPE-TRAUMA SYNDROME

The term rape refers to illicit sexual intercourse without consent. In this violent assault, sexual intercourse is used as a weapon. Rape inflicts varying degrees of physical and psychological trauma. Rape-trauma syndrome occurs after the rape or attempted rape; it refers to the victim's early-stage (short-term) and later-stage (long-term) reactions and to the methods the victim uses to cope with this trauma.

In the United States, the justice department estimates that 8% of American women are victims of rape or attempted rape in their lifetime. Known victims of rape range in age from 2 months to 97 years. (This covers all types of rape, including incest, child sexual abuse, and date rape.) Women ages 16 to 19 are 84 times more likely to be raped than women age 50 or older.

In most cases, the rapist is a man and the victim is a woman. However, rapes do occur between people of the same sex, especially in prisons, schools, hospitals, and other facilities. Children are also victims of rape; most of these cases involve manual, oral, or genital contact with the child's genitals. The rapist usually is a member of the child's family. A man or child can also be sexually abused by a woman.

The prognosis for rape-trauma syndrome is good if the rape victims receive physical and emotional support and counseling to help them deal with their feelings. Victims who articulate their feelings are able to cope with their fears, interact with others, and return to normal routines faster than those who don't.

CULTURAL TIP In many Eastern cultures, females are submissive and may be resistant to divulge information. It's important to document objective information in these cases and to be supportive and nonjudgmental.

Causes

Rape-trauma syndrome results from rape or attempted rape.

Complications

As with other posttraumatic stress syndromes, possible complications of rape-trauma syndrome include lasting psychiatric problems (such as depression, guilt, and anxiety) and, in some cases, suicide.

Assessment findings

If the patient is in the early stage of rape-trauma syndrome, a complete history and physical examination usually are necessary. The patient's history may reveal information pertinent to physical assessment. (Furthermore, assessment notes may be used as evidence if the rapist is tried.)

The patient's history also may disclose information pertinent to treatment, such as allergies to penicillin and other drugs and any recent illnesses (especially a sexually transmitted disease [STD]). If the victim is a woman, her history should include whether she was pregnant at the time of the attack, the date of her last menstrual period, and details of her obstetric and gynecologic history.

Record the victim's statements in the first person, using quotation marks. Also document objective information provided by others. In your assessment notes, include the time the victim arrived at the facility, the date and time of the alleged rape, and the time the victim was examined.

Depending on the specific body areas attacked, the patient may complain of a sore throat, difficulty swallowing, vaginal pain, rectal pain, or pain from other injuries incurred during the assault.

If the patient is in the early stage of rape-trauma syndrome, she may exhibit psychological signs and symptoms, such as disbelief, panic, severe anxiety, anger, self-blame, humiliation, and depression. Alternatively, she may appear outwardly calm, compliant, glib, and talkative.

Even if the victim wasn't beaten, physical examination will probably identify signs of physical trauma, especially if the assault was prolonged. General observation will reveal the patient's general physical appearance and demeanor. Inspection of clothing may reveal signs of bleeding. General inspection of the victim's body may reveal signs of physical trauma, such as injuries and bleeding. Depending on the specific body areas attacked, inspection also may show a reddened (sore) throat, mouth irritation, ecchymoses, or rectal pain and bleeding.

If the victim is a female, a vaginal examination is used to determine injury. Inspection may reveal lacerations, contusions, and abrasions to the vulva, cervix, and the vaginal walls. A bimanual examination determines the size of the ovaries and the uterus. A speculum examination is performed when necessary. If the victim is a male, a full genital examination and anal examination may disclose lacerations, contusions, and abrasions.

If additional physical violence accompanied the rape, physical examination may identify hematomas, lacerations, bleeding, fractures, severe internal injuries, and hemorrhage. If the rape occurred outdoors, examination may reveal that the patient is suffering from exposure.

If the assessment is performed several weeks after the rape, mental status findings may include a history of anxiety, nightmares, flashbacks, depression, anger, disinterest in sex, anorgasmia, and suicidal ideation.

Diagnostic tests

The victim should be examined as soon as possible after the rape. Evidence for deoxyribonucleic acid testing should be collected within 48 hours. Recent advances in laboratory evaluation include acid phosphatase detection in vaginal washings; the male-specific semen protein p30; and MHS-5, a sperm-coating antigen from human seminal vesicles. As appropriate, specimens are obtained from the cervical canal, throat, or rectum.

Routine laboratory tests include an STD screen and a rapid plasma reagin test. A pregnancy test, a drug screen, and an alcohol level determination also may be performed. Other tests are determined by patient injuries (for example, X-rays are performed if fractures are suspected).

Laboratory tests that detect consequences of sexual contact (such as STD or pregnancy) and provide evidence for possible assault charges are usually processed by the police laboratory. If the rape occurred in the past 7 days, specimens obtained may include a blood sample; hair samples that are a different color from that of the victim or that are obviously out of place; fiber samples, such as paint or wool; any soiled or torn material; and body fluids, such as blood or semen, not belonging to the victim.

Treatment

Abrasions, lacerations, and other physical injuries receive standardized care, as appropriate. Tetanus prophylaxis is given when indicated. In addition, all sexual assault victims receive STD prophylaxis, according to guidelines established by the Centers for Disease Control and Prevention. Women should receive information on pregnancy prevention.

Long-term treatment includes crisis intervention and counseling. Also, female patients should schedule a follow-up gynecologic examination after 7 to 14 days to ensure adequate pregnancy and STD prophylaxis; male patients should have a follow-up urologic examination.

Nursing diagnoses

u Altered oral mucous membrane u Anxiety u Body image disturbance u Ineffective individual coping u Pain u Powerlessness u Rape-trauma syndrome u Risk for infection u Self-esteem situational low u Sleep pattern disturbance

Key outcomes

- u The patient won't exhibit complications related to trauma to oral mucous membranes.
- u The patient will remain free from signs and symptoms of infection.
- u The patient will reports feelings of anxiety.
- u The patient will report achieving pain relief with analgesia or other measures.
- u The patient will relate feelings related to current situation and its effect on self-esteem.

Nursing interventions

- u If the rape victim isn't seriously injured, allow her to remain clothed and take her to a private room, where she can talk with you or a counselor before the necessary physical examination. Immediate reactions to rape differ and include crying, laughing, hostility, confusion, withdrawal, and outward calm. Anger and rage commonly don't surface until later. During the assault, the victim may have felt demeaned, helpless, and afraid for her life; afterward, she may feel ashamed, guilty, shocked, and vulnerable, and experience a sense of disbelief and lowered self-esteem.
- u Offer emotional support, reassurance, and acceptance. Help the patient explore her feelings; listen, convey trust and respect, and remain nonjudgmental. Don't leave the patient alone unless requested.
- u Monitor the patient's mental status. Reorient her to her surroundings and help her interpret reality as needed.
- u Thoroughly explain the examination and why it's necessary (to rule out internal injuries, obtain a specimen for STD testing, and acquire evidence for possible prosecution). Obtain informed consent for treatment and for the police report. Allow the victim some control, if possible; for instance, ask if she's ready to be examined or if she'd rather wait.
- u Before the examination, ask the victim whether she douched, bathed, or washed before coming to the facility. Note this on her chart. Have her change into a hospital

gown, and place her clothing in *paper bags*. (Never use plastic bags because secretions and seminal stains mold, destroying valuable evidence.) Label each bag and its contents.

- u Tell the victim she may urinate (preferably after the examination), but warn her not to wipe or otherwise clean the perineal area. Stay with her, or ask a counselor to stay with her, throughout the examination.
- u Assist throughout the examination, providing support and reassurance and carefully labeling all possible evidence. Before the victim's pelvic area is examined, take vital signs and, if the patient is wearing a tampon, remove it, wrap it, and label it as evidence. This examination is commonly distressing to the rape victim. Reassure her, and allow her as much control as possible.
- u During the examination, assist in specimen collection, including those for semen and STDs. Carefully label all specimens with the patient's name, the doctor's name, and the site from which the specimen was obtained. List all specimens in your notes. If the case comes to trial, specimens will be used for evidence, so accuracy is vital.
- u Carefully collect and label fingernail scrapings and foreign material obtained by combing the victim's pubic hair; these also provide valuable evidence. Note to whom these specimens are given.
- u For a male victim, be especially alert for injury to the mouth, perineum, and anus. As ordered, obtain a pharyngeal sample for a gonorrhea culture and rectal aspirate for acid phosphatase or sperm analysis.
- u Assist in photographing the patient's injuries (this may be delayed for a day or repeated when bruises and ecchymoses are more apparent).
- u Most states require facilities to report all incidents of rape. The patient may elect not to press charges or assist in the police investigation. Remember that your notes may be used as evidence if the rapist is tried. Write the victim's statements in first person, using quotation marks. Also document objective information provided by others. Never speculate as to what may have happened or record subjective impressions or thoughts. Remember to include in your notes the time the victim arrived at the facility, date and time of the alleged rape, and time the victim was examined.
- u If the police interview the patient in the facility, stay with the patient, be supportive, and encourage her to recall the details of the rape. Your kindness and empathy are invaluable.
- u If requested, notify the patient's family. Help the patient verbalize anticipation of her family's response.
- u If severe injuries require hospitalization, introduce the patient to her primary nurse, if possible.
- u If the patient is having trouble sleeping, administer medications, as ordered, to promote sleep, educate the patient in relaxation techniques, create a quiet environment conducive to sleep, and discourage excessive napping.

Patient teaching

- u Before discharge, provide clear verbal and written instructions. If antibiotics were prescribed to prevent STDs, stress the importance of completing the course of medication.
- u Explain to the patient the need for follow-up care to safeguard against acquired immunodeficiency syndrome, pregnancy, and STDs.
- u Encourage the patient not to stay alone. Inform her of self-help groups in the community, and refer her to an appropriate follow-up agency (medical clinic, rape counseling center, or psychiatric service). Also advise her how to contact a 24-hour crisis intervention service, if one is available.

INTRODUCTION

Cancer is primarily a disease of older adults, second only to cardiovascular disease as the leading cause of death in the United States, with more than 550,000 deaths annually. More than 67% of patients who die from cancer are over age 65. The most common types in the United States are prostate, breast, lung, and colorectal cancer.

Cancer results from malignant transformation or carcinogenesis of normal cells, causing them to enlarge and divide more rapidly than normal and serve no useful purpose. Cancer cells characteristically grow and spread rapidly, uncontrollably, and independently, spreading from the primary site to other tissues where it establishes secondary foci called metastases. Cancer cells metastasize by way of circulation through the blood or lymphatics, by accidental transplantation from one site to another during surgery, and by local extension. (See [How cancer metastasizes.](#))

Malignant tumors are classified by histologic origin: tumors derived from epithelial tissues are called *carcinomas*; from epithelial and glandular tissues, *adenocarcinomas*; from connective, muscle, and bone tissues, *sarcomas*; from glial cells, *gliomas*; from pigmented cells, *melanomas*; and from plasma cells, *myelomas*. When tumors are derived from erythrocytes, they are called *erythroleukemia*; from lymphocytes, *leukemia*; and from lymphatic tissue, *lymphoma*.

What causes cancer?

Researchers think that cancers have genetic origins; they've identified about 100 cancer genes. Some are *oncogenes*, which activate cell division and influence embryonic development; some are *tumor suppressor genes*, which halt cell division. These cells are typically found in normal human cells, but certain kinds of mutations transform the normal cells. Inherited defects may cause a genetic mutation; exposure to a carcinogen can cause an acquired mutation. Evidence indicates that carcinogenesis results from a complex interaction of carcinogens and accumulated mutations in several genes.

In animal studies of viral ability to transform cells, some human viruses show carcinogenic potential. For example, researchers currently link the Epstein-Barr virus, which causes infectious mononucleosis, with lymphomas and nasopharyngeal cancer.

Of the known carcinogens, scientists consider radiation the most dangerous because it damages the genetic material, deoxyribonucleic acid (DNA), possibly inducing genetically transferable abnormalities. Other factors, such as a person's tissue type and hormonal status, interact to potentiate radiation's carcinogenic effect.

Many substances commonly found in the environment may induce carcinogenesis by damaging cellular DNA. Some proven carcinogens in humans include:

- ▮ asbestos (mesothelioma of the lung)
- ▮ vinyl chloride (angiosarcoma of the liver)
- ▮ airborne aromatic hydrocarbons and benzpyrene (lung cancer)
- ▮ alkylating agents (leukemia)
- ▮ tobacco (lung, mouth and upper airways, esophagus, pancreas, kidneys, and bladder).

Diet has been implicated in the development of GI cancer as a result of high-protein and high-fat diets. Food additives, such as nitrates, and certain food preparation methods, particularly charbroiling, also may induce carcinogenesis.

The role of hormones in carcinogenesis is controversial. Excessive use of some hormones, especially estrogen, produces cancer in animals. Synthetic diethylstilbestrol causes vaginal cancer in some daughters of women who were treated with it. In fact, changes in human hormone levels may retard or stimulate cancer development.

Some cancers and precancerous lesions result from genetic predisposition either directly (as in Wilms' tumor and retinoblastoma) or indirectly (as in Down syndrome and inherited immunodeficiency diseases). Expressed as autosomal recessive, X-linked, or autosomal dominant disorders, their common characteristics include:

- ▮ early onset of malignant disease
- ▮ increased incidence of bilateral cancer in paired organs (breasts, adrenal glands, kidneys, and eighth cranial nerves—acoustic neuroma, for example)
- ▮ increased incidence of multiple primary cancers in nonpaired organs
- ▮ abnormal chromosome complement in tumor cells.

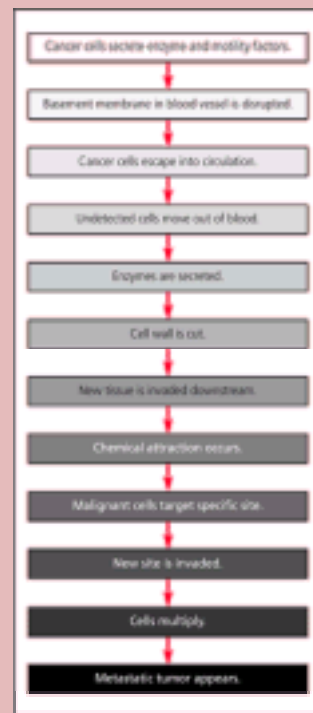

Ineffective immune response

Other factors that interact to increase susceptibility to cancer include immunologic competence, age, nutritional status, and response to stress. Theoretically, the body develops cancer cells continuously, but the immune system recognizes them as foreign cells and destroys them. This defense mechanism, *immunosurveillance*, has two major components: the humoral immune response and the cell-mediated immune response. Their interaction promotes antibody production, cellular immunity, and immunologic memory. Presumably, the intact human immune system is responsible for spontaneous regression of tumors.

PATHOPHYSIOLOGY

**How cancer metastasizes**

Metastasis usually occurs through the bloodstream to other organs and tissues, as shown here.

Theoretically, the *cell-mediated immune response* begins when T lymphocytes, also known as T cells, become sensitized by contact with a specific antigen. After repeated contacts, the sensitized T cells release chemical factors called *lymphokines*, some of which begin to destroy the antigen. This reaction transforms the additional T cells into “killers” of antigen-specific cells—in this case, cancer cells.

Similarly, the *humoral immune response* reacts to an antigen by triggering the release of antibodies from plasma cells and activating the serum-complement system, which destroys the antigen-bearing cell. An opposing immune factor, a “blocking antibody,” enhances tumor growth by protecting cancer cells from immune destruction. Theoretically, cancer arises when any one of several factors disrupts the immune system, for example:

- u *Aging cells*, when reproducing their genetic material, may err, giving rise to mutations. The aging immune system may not recognize these mutations as foreign, thereby allowing them to proliferate and form a cancerous tumor.
- u *Cytotoxic drugs* or *steroidal agents* decrease antibody production and destroy circulating lymphocytes.
- u Extreme *stress* or *certain viral infections* can depress the immune system.
- u *Increased susceptibility to infection* (resulting from radiation, cytotoxic drug therapy, or lymphoproliferative and myeloproliferative diseases, such as lymphatic and myelocytic leukemia) may cause bone marrow depression, which may impair leukocyte function.
- u *Acquired immunodeficiency syndrome* (AIDS) weakens cell-mediated immunity.
- u *Cancer* suppresses the immune system. Advanced cancer exhausts the immune response and leads to *anergy*, the absence of immune reactivity.

Cancer assessment

Careful cancer assessment is crucial. In most cancers, the earlier the detection, the more effective the treatment and the better the prospect for cure. To perform the assessment, you'll need to learn about the patient's risk factors, such as cigarette smoking and hazardous working conditions. You'll also need to be alert for cancer's warning signs. Use *CAUTION*, the American Cancer Society's mnemonic device, to assess for the following cancer signs in your patients:

- u Change in bowel or bladder habits
- u A sore that doesn't heal
- u Unusual bleeding or discharge
- u Thickening or lump in the breast or elsewhere
- u Indigestion or difficulty swallowing
- u Obvious change in a wart or mole
- u Nagging cough or hoarseness.

Patient health history

Remember that the patient may be worried that he has cancer, so establish rapport and keep the interview as open as possible.

First, obtain biographical information, including the patient's current and previous occupations, his ethnic background, and his previous places of residence. These factors may inform you about the patient's exposure to possible carcinogens.

Investigate the patient's current complaints. What are the symptoms? How long has he had them? What precipitates, exacerbates, or relieves the symptoms? Typically, the chief complaint is one of the cancer warning signs set forth by the American Cancer Society.

Examine the patient's medical history for additional clues. Does he have allergies? Has he undergone medical treatments, been hospitalized, or had surgery? Because of a link with melanoma or other skin cancer, even the removal of a tiny mole may be important. Investigate whether he's had chemotherapy or ionizing radiation, procedures associated with secondary cancers.

Ask the patient about previous drug therapy and any current drug regimen. Taken over prolonged periods, some medications, such as phenytoin (an anticonvulsant), azathioprine (an immunosuppressant), and estrogen (a hormone commonly used postmenopausally), may lead to cancer.

Question the patient about family members' history. Have family members or other relatives had cancer, such as breast, colorectal, or lung cancer (suggesting a possible genetic susceptibility)? Ask about the incidence of specific inherited conditions, such as colonic polyposis, which almost always develops into cancer.

Review the patient's lifestyle for behaviors that predispose him to cancer. Discuss his food habits, for example. Diets high in fiber and vitamins A, C, and E and low in animal fats and proteins may support cancer prevention. Diets that feature heavy meat consumption place the patient at added risk for breast, colon, and uterine cancer.

Physical examination

- u Take the patient's vital signs. Note whether his temperature is above or below normal. Also note any hypertension, tachycardia or bradycardia, and tachypnea. Keep in mind that intermittent fever occurs in leukemia.
- u Inspect the patient's skin for abnormal masses, lesions, or unusual pigmentation. Note any moles that show evidence of bleeding. Look for bruises, petechiae, or purpura, which may indicate bleeding tendencies. Observe the patient's color for pallor, cyanosis, jaundice, and redness. Check the patient's hair distribution; unusual patterns may suggest endocrine tumors. Palpate the skin and note its temperature; cool limbs may indicate a circulation problem caused by a tumor.

CULTURAL TIP In dark-skinned individuals, it may be difficult to identify color changes that occur with skin eruptions. At times, only a change in texture may be detected.

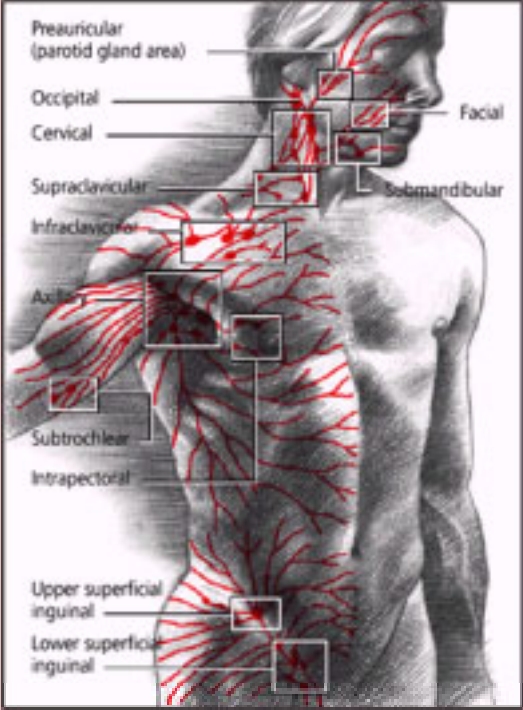

- u Inspect the patient's face for signs of paralysis, which may result from a tumor with nerve involvement. Look at the patient's eyes. Observe conjunctival color for

signs of anemia. Check the sclera for icterus. Jaundice may indicate cancer of the pancreas, liver, or biliary tract. Check the ears for drainage that may signal cancer.

- u Observe the breasts for symmetry. Look for dimpling, flattening, puckering, erythema, edema, ulceration, and venous patterns. Check for nipple inversion, masses, discharge, and retraction. Note the color, consistency, and amount of any discharge. Palpate the breasts for a lump or thickening with the patient seated and again with the patient reclining.
- u Inspect the patient's chest for respiratory fremitus. Weak or absent fremitus suggests fluid, a mass, or obstruction in the pleural space. Percuss the chest, checking for dullness over the lungs, which may indicate a mass. Auscultate the lungs. Decreased or absent breath sounds point to fluid or tissue obstruction.
- u Inspect the abdomen. Consider shape, tone, and symmetry. A distorted contour may indicate tumor growth or organ enlargement. Palpate the abdomen for abnormal masses and the lymph nodes for enlargement that may indicate spreading cancer. (See [Evaluating the lymph nodes.](#)) Auscultate the abdomen for hyperactive, tinkling, or high-pitched rushes, which point to intestinal obstruction. A harsh bruit over the liver can signal a vascular tumor, such as a hepatoma. A friction rub may indicate surface tumor nodules. Percuss the abdomen for ascites; malignant ascites typically occur with ovarian, endometrial, breast, and colon cancers. Next, percuss the liver. A span of dullness greater than 4¾" (12 cm) along the midclavicular line indicates hepatomegaly and possibly cancer.

Evaluating the lymph nodes

Cells from a primary tumor can spread, or metastasize, to other body areas through the lymphatic system. Lymph nodes normally aren't palpable. Those that are usually result from an inflammatory response to infection. However, superficial or gross adenopathy occurs in a high percentage of patients with lymphoma and metastatic disease. To palpate lymph nodes, begin in the preauricular, or parotid gland, area (shown below). Proceed downward from the head and neck to the axillary and inguinal areas.

- u Observe the extremities. Note any signs of immobility or fractures, which may indicate bone metastasis.
- u Inspect female genitalia for growths, lesions, inflammation, and discharge. Inspect male genitalia, noting any ulcers, nodules, or discharge.
- u Perform the neurologic assessment with the patient sitting upright. Cancer patients commonly experience various neurologic problems, such as spinal cord compression and peripheral neuropathies.

Diagnosing cancer

A thorough medical history and physical examination should precede sophisticated diagnostic procedures. Useful tests for detecting early cancerous lesions include X-rays, lymphangiography, mammography, endoscopy, barium studies, isotope and computed tomography scans, and magnetic resonance imaging.

The single most important diagnostic tool is a biopsy for direct histologic study of tumor tissue. Biopsy tissue samples can be taken by curettage, fluid aspiration (pleural effusion), needle aspiration biopsy (breast), dermal punch (skin or mouth), endoscopy (rectal polyps), and surgical excision (visceral tumors and nodes).

Although it doesn't confirm a diagnosis by itself, a tumor marker—carcinoembryonic antigen (CEA)—can signal cancer that affects the large bowel, stomach, pancreas, lungs, or breasts, and sometimes sarcomas, such as leukemias and lymphomas, as well. CEA titers range from normal levels (less than 5 ng/ml) to suspicious levels (5 to 10 ng/ml) to very suspicious levels (more than 10 ng/ml). During chemotherapy, CEA values provide a valuable baseline for evaluating the tumor's spread, regulating drug dosage, predicting the effectiveness of surgery or radiation, and detecting tumor recurrence.

Although no more specific than CEA, alphafetoprotein, a fetal antigen rare in adults, can suggest testicular, ovarian, gastric, pancreatic, and primary lung cancers. Beta-human chorionic gonadotropin may point to testicular cancer or choriocarcinoma. The test for prostate-specific antigen helps detect and evaluate prostatic cancer, whereas CA125 is useful for monitoring ovarian cancer.

Staging and grading cancer

Choosing effective therapeutic options depends on correct staging of malignant tumors. Although cancer staging systems vary according to cancer site and pathologists' preferences, the widely used TNM (tumor, node, metastasis) staging system quantifies cancer and allows reliable comparison of cancer treatments and survival rates among large populations. The TNM system describes the tumor, lymph node involvement, and metastasis to other areas. (See [Staging cancer by the TNM system.](#))

Grading, another objective way to define a tumor, takes into account the resemblance of tumor tissue to normal cells (differentiation) and the tumor's estimated growth rate. Grading has its limitations; results reflect only a portion of the tumor. Most tumors have cells in various stages of development, so as a tumor develops, the grade may change.

Grading also names the lesion according to corresponding normal cells, such as lymphoid or mucinous lesions. (See [Differences between benign and malignant tumors.](#))

Cancer treatments

Treatment options include surgery, radiation, chemotherapy, immunotherapy (biotherapy), and hormone therapy, used independently or in combination. In each patient, treatment depends on the type, stage, localization, and responsiveness of the tumor, as well as the patient's limitations.

Surgery

Once the mainstay of cancer treatment, surgery is now regularly combined with radiation, chemotherapy, and immunotherapy. Surgery removes the bulk of the tumor, and the other treatments discourage residual cell proliferation. Surgery can also relieve pain, correct obstruction, and alleviate pressure. Less radical surgery (for example, a lumpectomy instead of a radical mastectomy) is more acceptable to patients.

Radiation therapy

This treatment aims to destroy the rapidly dividing cancer cells and, at the same time, damage normal cells as little as possible. Two types of radiation therapy are common: ionizing radiation and particle radiation. Both target cellular DNA, but particle radiation causes less skin damage.

Treatment approaches include external beam radiation and intracavitary and interstitial implants (requiring personal radiation protection for all staff members who come in contact with the patient). (See [Preparing for external radiation therapy.](#))

Normal and malignant cells respond to radiation differently, depending on blood supply, oxygen saturation, previous irradiation, and immune status. In most instances, normal cells recover from radiation faster than malignant cells. The success of the treatment and damage to normal tissue vary with radiation's intensity. Although a large single dose of radiation has greater cellular effects than fractions of the same amount delivered sequentially, a protracted schedule allows time for normal tissue to recover in the intervals between individual sublethal doses.

Radiation may be chosen for palliative therapy to relieve pain, obstructions, malignant effusions, cough, dyspnea, ulcerative lesions, and hemorrhage. It also can promote the repair of pathologic fractures and delay tumor spread. Radiation can give a cancer patient an important psychological lift just by shrinking a visible tumor.

Staging cancer by the TNM system
Most diagnosticians stage cancer by the internationally recognized TNM (tumor, node, metastasis) system developed by the American Joint Committee on Cancer. This system offers a convenient structure to guide treatment, present a prognosis, and standardize research by ensuring reliable comparisons of patients in various institutions. Some differences in classification may occur, depending on the primary cancer site.
T for primary tumor The anatomic extent of the primary tumor depends on its size, depth of invasion, and surface spread. Tumor stages progress from TX to T4 as follows: TX — primary tumor can't be assessed T0 — no evidence of primary tumor Tis — carcinoma in situ T1, T2, T3, T4 — increasing size, local extent, or both of the primary tumor.
N for nodal involvement Nodal involvement reflects the tumor's spread to the lymph nodes, as follows: NX — regional lymph nodes can't be assessed N0 — no evidence of regional lymph node metastasis N1, N2, N3 — increasing involvement of regional lymph nodes.
M for distant metastasis Metastasis denotes the extent (or spread) of disease. Levels range from MX to M1 as follows: MX — distant metastasis can't be assessed M0 — no evidence of distant metastases M1 — distant metastasis.

Combining radiation and surgery can minimize radical surgery, prolong survival, and preserve physiologic function. For example, small preoperative doses of radiation can shrink a tumor, making it removable by surgery while preventing further spread of the disease during surgery. After the wound heals, larger postoperative doses of radiation prevent residual cancer cells from multiplying or metastasizing.

Systemic adverse effects of radiation include weakness, fatigue, and possibly anorexia, nausea, vomiting, anemia, and diarrhea. (See [Managing adverse effects of radiation.](#)) These adverse effects may subside after treatment with antiemetics, sedatives, corticosteroids, frequent small meals, fluid maintenance, medications to control diarrhea, and rest. Systemic effects are seldom severe enough to require discontinuation of treatment; however, they may require a readjustment of radiation dosage. Radiation therapy also requires frequent blood counts (with particular attention to white blood cells and platelets).

Differences between benign and malignant tumors		
FACTOR	BENIGN	MALIGNANT
Growth	Expands slowly, pushing aside surrounding tissues but not infiltrating	Usually infiltrates surrounding tissues expanding in all directions
Limitation	Typically encapsulated	Seldom encapsulated and commonly poorly delineated
Recurrence	Seldom recurs after surgical removal	Commonly recurs when removed surgically because of infiltration into surrounding tissues
Morphology	Closely resembles tissue of origin	Differs considerably from tissue of origin
Differentiation	Well-differentiated cells	Poorly differentiated or undifferentiated cells
Mitotic activity	Slight	Extensive
Tissue destruction	Usually slight	Extensive, owing to infiltration and metastatic lesion
Spread	No metastasis	Metastasis by way of blood or lymph system or both, with establishment of secondary tumors
Effect on body	Cachexia rare; usually not fatal but may obstruct vital organs, exert pressure, produce excess hormones; can become malignant	Cachexia typical anemia, weight loss, weakness, general ill health; fatal if untreated

Chemotherapy

Treatment with antineoplastic drugs may induce tumor regression and prevent or delay metastasis. Useful for controlling residual disease or as an adjunct to surgery or radiation therapy, chemotherapy can induce long remissions and possibly cures, especially in patients with childhood leukemia, Hodgkin's disease, choriocarcinoma, and testicular cancer. As palliative treatment, chemotherapy aims to improve the patient's quality of life by relieving pain and other symptoms. The

major cancer chemotherapeutic agents include the following:

- *Alkylating agents and nitrosoureas* inhibit cell growth and division by reacting with DNA. Nitrosoureas can cross the blood-brain barrier.
- *Antimetabolites* prevent cell growth by competing with metabolites in producing nucleic acid.
- *Antitumor antibiotics* block cell growth by binding with DNA and interfering with DNA-dependent RNA synthesis.
- *Plant alkaloids* prevent cellular reproduction by disrupting cell mitosis.
- *Steroidal hormones* inhibit hormone-susceptible tumor growth by changing the chemical environment.

Antineoplastic drugs that kill cancer cells can also kill cells in normal tissues, especially in tissues that contain rapidly proliferating cells. For example, antineoplastic drugs typically depress bone marrow function, causing anemia, leukopenia, and thrombocytopenia. They irritate GI epithelial cells, causing ulceration, bleeding, and vomiting. What is more, they destroy hair follicles and skin cells, causing alopecia and dermatitis. Many I.V. anticancer drugs may irritate the vein, causing venous sclerosis and, if extravasated, deep cutaneous necrosis that requires debridement and skin grafting. Only nurses with special preparation and certification in chemotherapy should administer chemotherapeutic drugs.

In addition to encouragement and support, all patients who undergo chemotherapy need special nursing care to prevent infection, maintain hydration, promote safety, and help them cope with drug adverse effects.

- Watch for signs of infection, especially in a patient who is receiving simultaneous radiation treatment. Be alert for a low-grade fever when the granulocyte count falls below 500/mm³. Take the patient's temperature frequently. Even a slight fever may indicate sepsis. At the same time, keep in mind that the patient's temperature may not rise significantly. This phenomenon may result from few or no granulocytes or from steroid therapy.
- Increase the patient's fluid intake before and throughout chemotherapy.
- Inform the patient that he may have some hair loss if his drug regimen causes alopecia. Reassure him that his hair should grow back after therapy ends (although it may return in a different color and texture). If the patient expresses interest in a hairpiece or wig, encourage him to obtain one before therapy begins. This way, he can match his current hair color and style.
- Check skin for petechiae, ecchymoses, and chemical cellulitis and for secondary infection during treatment.
- Minimize possible tissue irritation and damage by checking I.V. needle placement before and during drug infusion. Instruct the patient to report any discomfort, burning sensation, or pain during the infusion.
- Frequently check for blood return, and observe the I.V. site during the infusion for signs of infiltration. If you're infusing a vesicant and you suspect infiltration (extravasation), stop the infusion. Then aspirate the drug from the I.V. needle, and give the appropriate antidote according to established protocol. (These protocols must be established for each drug to allow for immediate treatment.)
- Administer chemotherapeutic drugs by the recommended route (orally, subcutaneously, I.M., I.V., intracavitarily, intrathecally, intraperitoneally, or intra-arterially), depending on the drug and its action. You'll usually follow procedures for intermittent administration to allow for bone marrow recovery between doses.
- Check the dosage, which usually is calculated according to the patient's body surface area, with adjustments for general condition and degree of myelosuppression. Be sure that dosage calculation is based on current information because the dosages could change as a consequence of research findings.
- Encourage apprehensive patients to express their concerns and fears. Provide simple, truthful information. Explain that not all patients who receive chemotherapy experience nausea and vomiting. For those who do, antiemetic drugs, relaxation therapy, and diet can minimize discomfort.

Preparing for external radiation therapy

Follow these guidelines to help relieve your patient's anxiety before he undergoes his first radiation treatment:

- Show the patient the radiation therapy department and introduce him to the staff.
- Before treatment, help him remove all metal objects (pens, buttons, jewelry) that may interfere with therapy. Explain that the areas to be treated will be marked with ink. Tell him not to wash these areas because the markings ensure that radiation reaches the same target at each treatment.
- Reinforce the doctor's explanation of the procedure, and answer questions as honestly as you can. Realistically explain the benefits and adverse effects of radiation therapy. If you don't know the answer to a question, refer the patient to the doctor.
- Discuss the adverse effects to watch for and report. Because radiation therapy may increase susceptibility to infection, warn the patient to avoid people with colds or other infections during therapy.
- Reassure the patient that the actual treatment is painless and won't make him radioactive. Stress that he'll be under constant surveillance during radiation administration and can call the therapist if he needs anything.

Immunotherapy (biotherapy)

Immunotherapy— usually combined with surgery, chemotherapy, or radiation—may be most effective in early cancer stages. Because much immunotherapy remains investigational, its availability may depend on the treatment facility. Adverse effects may be unpredictable. The following immunotherapies offer promise:

- *Nonspecific immunostimulation* uses biological agents, such as bacille Calmette-Guerin (BCG) vaccine and *Corynebacterium parvum*, to stimulate the reticuloendothelial system, thereby augmenting the patient's immune system and combating the immunosuppressive effects of cancer and treatment.
- *Intralesional stimulation* involves injecting a biological agent directly into the tumor. This initiates specific and nonspecific responses that trigger local cancer cell destruction.
- *Active specific immunostimulation*: uses specific tumor antigen vaccines to stimulate the patient's immune system to control or reject malignant cells by producing antibodies and lymphocytes.
- *Adoptive transfer of immunity* involves transferring immunologically active cells from a donor with established immunity to stimulate active immunity in the patient.

Managing adverse effects of radiation		
AREA TREATED	EFFECT	MANAGEMENT

Abdominopelvic	Cramps, diarrhea	Administer loperamide and diphenoxylate with atropine; provide a low-residue diet; maintain fluid and electrolyte balance.
Chest	Pulmonary irritation	Tell the patient to stop smoking and to avoid people with upper respiratory tract infections; administer steroid therapy, as ordered; provide humidifier, if necessary.
	Pericarditis, myocarditis	Control arrhythmias with appropriate agents (procainamide, disopyramide), as ordered; provide pain relief; monitor for heart failure.
	Esophagitis	Provide total parenteral nutrition; maintain fluid balance.
Head	Alopecia	Protect the scalp with gentle combing and grooming; avoid frequent shampooing. Provide a soft head covering (scarf, hat, wig) to conserve body heat and protect the scalp from sunburn and injuries.
	Mucositis	Provide mouthwash with viscous lidocaine; offer cool liquids, ice pops, and a soft, nonirritating diet. Avoid spicy food and alcohol.
	Monilia	Provide medicated mouthwash (avoid commercial mouthwash).
	Dental caries	Apply fluoride to teeth prophylactically; provide gingival care.
	Xerostomia	Encourage fluid intake, especially water; offer commercially available saliva substitutes.
Kidneys	Nephritis, hypertensive nephropathy, lassitude, headache, edema, dyspnea, azotemia, anemia	Maintain fluid and electrolyte balance; watch for signs of renal failure.

Additional advances in three other areas of immunotherapy are promising. *Interferons*, once confined to antiviral applications, are now used to stimulate antibody production and cell-mediated immunity. *Bone marrow transplantation*, usually combined with other treatments, restores hematologic and immunologic function in some cancer patients. A third treatment involves injecting *monoclonal antibodies* tagged with radioisotopes into the body. These agents help detect cancer by attaching to tumor cells. Some findings indicate a link between monoclonal antibodies and certain toxins that destroy specific cancer cells without disturbing healthy cells.

Although not used to treat cancer directly, colony-stimulating factors may be used to support the patient with low blood counts related to chemotherapy.

Adverse effects of biotherapeutic agents include fever and flulike symptoms, fatigue, central nervous system effects (especially from interferons), and capillary leak syndrome (most commonly associated with IL-2).

Hormonal therapy

Hormonal therapy is based on studies showing that certain hormones affect the growth of certain cancer types. For example, the luteinizing hormone-releasing hormone analogue leuprolide is used to treat prostate cancer. With long-term use, the hormone inhibits testosterone release and tumor growth; tamoxifen, an antiestrogen hormonal agent, blocks estrogen receptors in breast tumor cells that require estrogen to survive. Some adverse effects of these hormonal therapies include hot flashes, sweating, impotence, and decreased libido (with leuprolides) and nausea, vomiting, and blood dyscrasias (with tamoxifen).

Nursing interventions

Strive to provide adequate nutrition and maintain fluid balance. Keep in mind that tumors grow at the expense of normal tissue by competing for nutrients; this leaves some patients with a protein deficiency. Cancer treatments themselves may produce nutritional and fluid and electrolyte disturbances, resulting from vomiting, diarrhea, draining fistulas, altered taste sensations, and anorexia.

Implement measures to relieve pain and increase comfort. Help the patient with terminal cancer deal with his diagnosis and explore hospice care, if appropriate.

Maintaining nutrition and hydration

- u Base nutritional planning on the patient's dietary history. Pinpoint possible nutritional problems and their causes (such as diabetes) before the patient selects a menu.
- u Ask the dietitian to provide a liquid, high-protein, high-carbohydrate, high-calorie diet if the patient can't tolerate solid foods. If the patient has stomatitis, provide soft, bland foods.
- u Encourage the patient's family to bring foods from home if he requests them and if appropriate.
- u Provide a relaxed, pleasant mealtime. Encourage visitors to eat with the patient or, if possible, encourage him to dine with other patients. Let him choose from a varied menu.
- u If appropriate, suggest a glass of wine or a cocktail before dinner to promote relaxation and stimulate appetite. Urge the patient to drink juice and other calorie-rich beverages instead of water.
- u If the patient is unable to eat a large meal, suggest small, frequent meals instead.
- u Avoid highly aromatic foods. Therapy may alter the patient's sense of smell and inhibit appetite. On the other hand, if he complains that food tastes bland or metallic, try adding mild seasonings to food. Sugar counteracts some metallic flavors, as do sour candies.
- u Experiment with foods. Because treatments may alter the chemical receptors on the tongue, foods that normally displease the patient may appeal to him.
- u Deliver nourishment by nasogastric (NG) tube if the patient can't eat, accept table food (after head, neck, or GI surgery, for example), or swallow easily. If he needs the tube after discharge, teach him how to insert it, how to test its position in his stomach by aspirating stomach contents, and how to instill the nutritional supplement. Alternatives to NG tube feeding may involve gastrostomy, jejunostomy, and, occasionally, esophagostomy tubes.
- u Caution the patient that gastric or intestinal juices that spill on the skin cause excoriation if not washed off immediately. Flush the tube well with water after each feeding.
- u Provide adequate hydration by instilling up to 6 oz (177 ml) of water or another clear liquid between meals. After jejunostomy, begin with very small feedings, slowly and carefully increasing the amount of nutritional supplement. Provide additional fluids and calories during limited feeding periods by supplementing jejunostomy feedings with I.V. fat emulsions.
- u Total parenteral nutrition (TPN) is an important component of cancer care if the patient can't tolerate enteral nutrition. TPN can improve a severely debilitated patient's protein balance. Discuss the advantages and disadvantages of parenteral feeding if your patient needs it, especially during aggressive chemotherapy or radiation therapy. Tell him that patients who receive parenteral nutrition during cancer therapy experience less nausea, vomiting, diarrhea, and weight loss than patients who don't. Because of their improved nutritional status, such patients may respond better to treatment. Explain also that parenteral nutrition can restore

protein balance to help him better tolerate surgery, if it's indicated. Other advantages include a slight weight gain, better wound healing, and decreased risk for infection after radical surgery.

Controlling pain

Most cancer patients fear overwhelming pain, making pain control a major concern at every cancer stage—from localized cancer to advanced metastasis. Cancer pain may result from inflammation or from pressure of the tumor on pain sensitive structures, tumor infiltration of nerves or blood vessels, or metastatic extension to bone. Chronic and unrelenting pain can undermine the patient's tolerance, interfere with eating and sleeping, and lead to feelings of anger, despair, and anxiety.

Opioid analgesics (also called narcotic analgesics), either alone or combined with nonnarcotic analgesics or antianxiety agents, are the mainstay of pain relief in advanced cancer. In terminal illness, drug dosages may be high, especially for the patient who develops drug tolerance and whose addiction danger is unimportant.

Patient-controlled analgesia

Cancer care centers across the United States report encouraging results with the pain relief system known as patient-controlled analgesia (PCA).

How PCA works
This system permits the patient to self-administer an analgesic at the press of a button. The button, stationed at bedside, activates a pump fitted with a prefilled analgesic-containing syringe. Small, intermittent doses of the analgesic administered I.V., subcutaneously, or epidurally maintain medication levels in the bloodstream to ensure the patient's comfort and minimize sedation.
Locked safely inside the pump, the medication syringe or cassette dispenses only preset doses at preset intervals. This allows the patient to achieve his maximum comfort level but not to overdose. The computerized system usually includes a “breakthrough” option for additional doses that the nurse or patient can activate.

Advantages of PCA
Clinical studies show that patients who use a PCA system deliver analgesic drugs effectively and maintain comfort without oversedation. They use less of the drug than the amount normally given by I.M. injection.
PCA provides other significant advantages. Patients using this system:

- u stay alert and active during daytime hours
- u need not endure pain while waiting for an injection
- u have reduced anxiety levels
- u remain free from pain caused by injections
- u need not call the nurse away from other clinical duties.

Use the following guidelines for pain relief:

- u Provide analgesics generously, as needed and as ordered. Anticipate the need for pain relief, and schedule it so that pain doesn't become unbearable. Make an agreement with the patient that you'll provide pain medication before pain becomes severe. This decreases the patient's anxiety level and helps in pain control. If possible, use patient-controlled analgesia. (See [Patient-controlled analgesia.](#))
- u Initiate noninvasive pain-relief techniques, as needed. Tell the patient that these can be used alone or with drug therapy. Popular noninvasive techniques include cutaneous stimulation, relaxation, biofeedback, distraction, and guided imagery.
- u Explain palliative treatments, if ordered. These measures can relieve pressure and discomfort caused by inflamed necrotic tissue. Radiation therapy can shrink metastatic tissue and control bone pain. When a tumor invades nervous system tissues, pain control may require anesthetics, destructive nerve blocks, electronic nerve stimulation with a dorsal column or transcutaneous electrical nerve stimulator, rhizotomy, or chordotomy.

Exploring hospice care

Hospice care is a holistic approach to patient care modeled after St. Christopher's Hospice in London. The hospice program provides comprehensive physical, psychological, social, and spiritual care for terminally ill patients. Many hospices are associated with facilities, but some are independent or provide home care programs. As a variation of the hospice approach, several large cities in the United States have facilities that offer children with leukemia and their families a home-like environment during outpatient treatment at a nearby facility.

When referring the patient to hospice care:

- u Explain that the hospice care goal is to help each patient live his remaining life to the fullest, without pain and surrounded by those whom he chooses. Pain control is a priority and is provided through all possible avenues to the patient. Morphine is the drug of choice for pain control.
- u Urge family members to assume an active role in patient care. Point out that hospice care relies on a coordinated team effort to overcome the anxiety, fear, and depression that typically affect the terminally ill patient.
- u Provide a warm and secure setting to help family members work out their grief before the patient dies.
- u Encourage everyone involved in hospice care (staff, patient, and family) to be committed to high-quality care, accept emotional involvement, and feel comfortable with personal feelings about death and dying.
- u Foster open communication to evaluate patient care and to help staff members cope with their own feelings.

Cancer and emotions

Few illnesses evoke as profound an emotional response as cancer. Patients express this response in several ways. A few face this difficult reality immediately. Many initially use denial as a coping mechanism and refuse to accept the diagnosis. As evidence of cancer becomes inescapable, the patient may plunge into depression. Family members may express denial by encouraging unproven treatments. This can delay effective care.

Some patients cope by intellectualizing their disease, enabling them to obscure its reality and to regard it as unrelated to themselves. For most patients, intellectualization is a more productive coping behavior than denial because the patient is receiving treatment.

Watch for these behavioral responses so you can identify them and offer support. In many cases, you can offer realistic hope for long-term survival or remission. Even when patients have advanced disease, you can offer short-term, achievable goals, such as a comfortable afternoon or a pleasant visit with a loved one.

To help a patient cope with cancer, first try to understand your own feelings about it. Then listen sensitively to the patient so that you can offer genuine understanding and comfort. When caring for a patient with terminal cancer, increase your own effectiveness by seeking others to help you through your grieving.

Head, neck, and spinal neoplasms

Cancers in the head, neck, and spine are among the deadliest and most disfiguring. Involvement of speech and sense organs, as well as the central nervous system, can have an enormous impact on the patient's quality of life.

LARYNGEAL CANCER

Squamous cell carcinoma constitutes about 95% of laryngeal cancers. Rare laryngeal cancer forms—adenocarcinoma and sarcoma—account for the rest. The

disease affects men about nine times more often than women, and most victims are between ages 50 and 65.

An intrinsic tumor is on the true vocal cords and tends not to spread because underlying connective tissues lack lymph nodes. An extrinsic tumor is on some other part of the larynx and tends to spread easily. Laryngeal cancer is classified by its location:

- u supraglottis (false vocal cords)
- u glottis (true vocal cords)
- u subglottis (rare downward extension from vocal cords).

Causes

The cause of laryngeal cancer is unknown. Major risk factors include smoking and alcoholism. Minor risk factors include chronic inhalation of noxious fumes and familial disposition.

Complications

If untreated, laryngeal cancer causes increasing swallowing difficulty and pain.

Assessment findings

Varied assessment findings in laryngeal cancer depend on the tumor's location and its stage.

With stage I disease, the patient may complain of local throat irritation or hoarseness that lasts about 2 weeks. In stages II and III, he usually reports hoarseness. He may also have a sore throat, and his voice volume may be reduced to a whisper. In stage IV, he typically reports pain radiating to his ear, dysphagia, and dyspnea. In advanced (stage IV) disease, palpation may detect a neck mass or enlarged cervical lymph nodes.

Diagnostic tests

The usual workup includes laryngoscopy, xeroradiography, biopsy, laryngeal tomography and computed tomography scans, and laryngography to visualize and define the tumor and its borders. Chest X-ray findings can help detect metastases.

Treatment

Early lesions may respond to laser surgery or radiation therapy; advanced lesions to laser surgery, radiation therapy, and chemotherapy. Treatment aims to eliminate cancer and preserve speech. If speech preservation isn't possible, speech rehabilitation may include esophageal speech or prosthetic devices. Surgical techniques to construct a new voice box are experimental. (See [Reviewing alternative speech methods.](#))

In early disease, laser surgery destroys precancerous lesions; in advanced disease, it can help clear obstructions. Other surgical procedures vary with tumor size and include corpectomy, partial or total laryngectomy, supraglottic laryngectomy, and total laryngectomy with laryngoplasty.

Radiation therapy alone or combined with surgery can create complications, including airway obstruction, pain, and loss of taste (xerostomia).

Chemotherapeutic agents may include methotrexate, cisplatin, bleomycin, fluorouracil, and lomustine.

Nursing diagnoses

- u Anxiety u Body image disturbance u Energy field disturbance u Impaired gas exchange u Impaired skin integrity u Impaired swallowing u Impaired verbal communication u Ineffective airway clearance u Ineffective breathing pattern u Ineffective individual coping u Pain u Risk for infection

Reviewing alternative speech methods

During convalescence, your patient may work with a speech pathologist who can teach him new ways to speak using various communication techniques, such as those below.

Esophageal speech
By drawing air in through the mouth, trapping it in the upper esophagus, and releasing it slowly while forming words, the patient can again communicate by voice. With training and practice, a highly motivated patient can master esophageal speech in about a month. Recognize that speech will sound choppy at first, but with increasing skill, words will flow more smoothly and understandably.
Because esophageal speech requires strength, an elderly patient or one with asthma or emphysema may find it too physically demanding to learn. Because it also requires frequent sessions with a speech pathologist, a chronically ill patient may find esophageal speech overwhelming.

Artificial larynges
The throat vibrator and the Cooper-Rand device are basic artificial larynges. Both types vibrate to produce speech that is easy to understand, although it sounds monotonous and mechanical.
Tell the patient to operate a throat vibrator by holding it against his neck. A pulsating disk in the device vibrates the throat tissue as the patient forms words with his mouth. The throat vibrator may be difficult to use immediately after surgery, when the patient's neck wounds are still sore.
The Cooper-Rand device vibrates sounds piped into the patient's mouth through a thin tube, which the patient positions in the corner of his mouth. Easy to use, this device may be preferred soon after surgery.

Surgically implanted prostheses
Most surgical implants generate speech by vibrating when the patient manually closes the tracheostomy, forcing air upward. One such device is the Blom-Singer voice prosthesis. Only hours after it's inserted through an incision in the stoma, the patient can speak in a normal voice. The surgeon may implant the device when radiation therapy ends or within a few days (or even years) after laryngectomy.
To speak, the patient covers his stoma while exhaling. Exhaled air travels through the trachea, passes through an airflow port on the bottom of the prosthesis, and exits through a slit at the esophageal end of the prosthesis. This creates the vibrations needed to produce sound.
Not all patients are eligible for tracheoesophageal puncture, the procedure in which the prosthesis is inserted. Considerations include the extent of the laryngectomy; pharyngoesophageal muscle status; stomal size and location; and the patient's mental and emotional status, visual and auditory acuity, hand-eye coordination, bimanual dexterity, and self-care skills.

Key outcomes

- u The patient will recognize limitations imposed by the illness and will express feelings about these limitations.
- u The patient will continue to function in usual roles as much as possible.
- u The patient will express positive feelings about himself.
- u The patient will report feeling less tension or pain.
- u The patient will express an increased sense of well-being.
- u The patient will express his needs and desires without frustration.

- u The patient will maintain a patent airway.

Nursing interventions

- u Provide supportive psychological, preoperative, and postoperative care to minimize complications and speed recovery.
- u Encourage the patient to voice his concerns before surgery. Help him choose a temporary, alternative way to communicate, such as writing or using sign language or an alphabet board. If appropriate, arrange for a laryngectomee to visit him. Prepare him for functional losses (inability to smell, blow his nose, whistle, gargle, sip, or suck on a straw).

After partial laryngectomy:

- u Give I.V. fluids and, usually, tube feedings for the first 2 days after surgery; then resume oral fluids. Keep the tracheostomy tube (inserted during surgery) in place until tissue edema subsides.
- u Make sure the patient doesn't use his voice until the doctor gives permission (usually 2 to 3 days postoperatively). Then caution the patient to whisper until he heals completely.

After total laryngectomy:

- u As soon as the patient returns to his room from surgery, position him on his side and elevate his head 30 to 45 degrees. When you move him, remember to support the back of his neck to prevent tension on sutures and possible wound dehiscence.
- u If the patient has a laryngectomy tube in place, care for it as you would a tracheostomy tube. Shorter and thicker than a tracheostomy tube, the laryngectomy tube stays in place until the stoma heals (about 7 to 10 days).
- u Watch the stoma for crusting and secretions, which can cause skin breakdown. To prevent crusting, provide adequate room humidification. Remove crusts with petrolatum, antimicrobial ointment, and moist gauze.
- u Monitor vital signs. Be especially alert for fever, which indicates infection. Record fluid intake and output, and watch for dehydration. Also, be alert for and report postoperative complications. (See [Recognizing and managing complications of laryngeal surgery.](#))
- u Provide frequent mouth care. Clean the patient's tongue and the sides of his mouth with a soft toothbrush or a terry washcloth, and rinse his mouth with a deodorizing mouthwash.
- u Suction gently. Unless ordered otherwise, don't attempt deep suctioning, which could penetrate the suture line. Suction through both the tube and the patient's nose because the patient can no longer blow air through his nose. Suction his mouth gently.
- u After inserting a drainage catheter (usually connected to a blood drainage system or a GI drainage system), don't stop suction without the doctor's consent. After removing the catheter, check the dressings for drainage.
- u Give analgesics, as ordered. Keep in mind that opioid analgesics depress respiration and inhibit coughing.
- u If the doctor orders nasogastric (NG) tube feeding, check tube placement, and elevate the patient's head to prevent aspiration. Be ready to perform suction after NG tube removal or oral fluid intake because the patient may have difficulty swallowing.
- u Support the patient through inevitable grieving. If his depression becomes severe, consider referring him for appropriate counseling.

Patient teaching

- u Before partial or total laryngectomy, instruct the patient in good oral hygiene practices. If appropriate, instruct a male patient to shave off his beard to facilitate postoperative care.
- u Explain postoperative procedures, such as suctioning, NG tube feeding, and laryngectomy tube care. Carefully discuss the effects of these procedures (breathing through the neck and speech alteration, for example).
- u Also, prepare the patient for other functional losses. Forewarn him that he won't be able to smell aromas, blow his nose, whistle, gargle, sip, or suck on a straw.
- u Reassure the patient that speech rehabilitation measures (including laryngeal speech, esophageal speech, an artificial larynx, and various mechanical devices) may help him communicate again.

WARNING

Recognizing and managing complications of laryngeal surgery

Once your patient returns from surgery, you'll need to monitor his recovery, watching carefully for complications, such as fistula formation, a ruptured carotid artery, and stenosis of the tracheostomy site.

Fistula formation
Warning signs of fistula formation include redness, swelling, and secretions on the suture line. The fistula may form between the reconstructed hypopharynx and the skin. This eventually heals spontaneously, although the process may take weeks or months.
Feed the patient who has a fistula through a nasogastric tube. Otherwise, food will leak through the fistula and delay healing.

Ruptured carotid artery
Bleeding, a cardinal sign of a ruptured carotid artery, may occur in a patient who received preoperative radiation therapy or in a patient with a fistula that constantly bathes the carotid artery with oral secretions.
If rupture occurs, apply pressure to the site. Call for help immediately, and take the patient to the operating room for carotid ligation.

Tracheostomy stenosis
Constant shortness of breath alerts you to this complication, which may occur weeks to months after laryngectomy.
Management includes fitting the patient with successively larger tracheostomy tubes until he can tolerate insertion of a full-sized one.

- u Encourage the patient to take advantage of services and information offered by the American Speech-Learning-Hearing Association, the International Association of Laryngectomees, the American Cancer Society, or the local chapter of the Lost Chord Club.

MALIGNANT BRAIN TUMORS

Slightly more common in men than in women, malignant brain tumors (gliomas, meningiomas, and schwannomas) have an overall incidence of 4.5 per 100,000. They cause central nervous system (CNS) changes by invading and destroying tissues and by secondary effect—mainly compression of the brain, cranial nerves, and cerebral vessels; cerebral edema; and increased intracranial pressure (ICP).

Tumors can occur at any age. In adults, incidence is highest between ages 40 and 60, and the most common tumor types are gliomas and meningiomas. They usually occur above the covering of the cerebellum (supratentorial tumors).

Most tumors in children occur before age 1 or between ages 2 and 12. The most common are astrocytomas, medulloblastomas, ependymomas, and brain stem gliomas. Brain tumors are one of the most common causes of cancer death in children.

Causes

The cause of brain tumors is unknown.

Complications

In malignant brain tumors, life-threatening complications from increasing ICP include coma, respiratory or cardiac arrest, and brain herniation.

Assessment findings

The patient's history usually reveals an insidious onset of signs and symptoms. If the brain tumor has already been diagnosed, the history may also show an early misdiagnosis.

Signs and symptoms result from increased ICP. Specific assessment findings vary with the type of tumor, its location, and the degree of invasion. Neurologic assessment findings often help to pinpoint the location of the tumor. (See [Brain tumors: Site-specific signs and symptoms](#) and [Assessment findings in malignant brain tumors](#).)

Diagnostic tests

In many cases, a definitive diagnosis follows a tissue biopsy performed by stereotactic surgery. In this procedure, a head ring is affixed to the skull, and an excisional device is guided to the lesion by computed tomography scanning or magnetic resonance imaging.

Other diagnostic tools include a patient history, a neurologic assessment, skull X-rays, a brain scan, and cerebral angiography.

The patient also may receive a lumbar puncture, which shows increased cerebrospinal fluid (CSF) pressure, which reflects ICP; increased protein levels; decreased glucose levels; and, occasionally, tumor cells in CSF.

Treatment

Specific treatments vary with the tumor's histologic type, radiosensitivity, and location. Such treatments may include surgery, radiation therapy, chemotherapy, and decompression of increased ICP (with diuretics, corticosteroids, or, possibly, ventriculoatrial or ventriculoperitoneal shunting of the CSF).

Treatment of a glioma usually consists of resection by craniotomy. Radiation therapy and chemotherapy follow resection. The combination of carmustine, lomustine, or procarbazine with radiation therapy is more effective than radiation alone.

For low-grade cystic cerebellar astrocytomas, surgical resection permits long-term survival. For other astrocytomas, treatment consists of repeated surgery, radiation therapy, and shunting of fluid from obstructed CSF pathways. Radiation therapy works best in radiosensitive astrocytomas; some astrocytomas are radioresistant.

Treatment for oligodendrogliomas and ependymomas includes surgical resection and radiation therapy. Medulloblastomas call for surgical resection and, possibly, intrathecal infusion of methotrexate or another antineoplastic drug. Meningiomas require surgical resection, including dura mater and bone. (Operative mortality may reach 10% because of large tumor size.)

For schwannomas, microsurgical technique allows complete resection of the tumor and preservation of the facial nerve. Although schwannomas are moderately radioresistant, treatment still calls for postoperative radiation therapy.

Treatment for malignant brain tumors also includes chemotherapy with nitrosoureas, which cross the blood-brain barrier and allow other chemotherapeutic drugs to go through as well. Intrathecal and intra-arterial administration maximizes drug action.

Palliative measures for gliomas, astrocytomas, oligodendrogliomas, and ependymomas include dexamethasone for cerebral edema and antacids and histamine receptor antagonists for stress ulcers. These tumors and schwannomas may also require anticonvulsants.

Treatment of brain tumors can cause several complications. Surgery can result in immediate or delayed CNS infections, with symptoms that mimic tumor progression or recurrence. If fever or rapidly progressive neurologic symptoms develop, bacterial and fungal cultures will confirm the infection.

Early delayed radiation encephalopathy may stem from temporary demyelination. Anorexia, somnolence, lethargy, and headache occur 2 to 6 weeks after the therapy but resolve spontaneously in about 6 weeks.

Brain tumors: Site-specific signs and symptoms

A brain tumor usually produce signs and symptoms specific to its location. Recognizing the effects helps identify the tumor site and guide treatment before and after surgery and can help you spot life-threatening complications, such as increasing intracranial pressure and imminent brain herniation. A brain tumor may cause all, some, or none of the effects shown below.

Hypothalamus

- Possible pituitary area tumor extending upward
- Endocrine imbalances
- Temperature control loss

Frontal lobe

- Depression or Broca's aphasia (dominant hemisphere)
- Contralateral weakness
- Contralateral sensory weakness
- Personality and behavioral changes

Subfrontal lobe

- Contralateral hemiparesis
- Sensory loss

Pituitary stalk/sellar

- Amenorrhea
- Cushingoid signs and symptoms
- Galactorrhea
- Impotence
- Visual field defects

Temporal lobe

- Auditory hallucinations
- Impaired memory (with bilateral tumor)
- Personality changes
- Epileptic seizures
- Visual field defects
- Receptive or Wernicke's aphasia (dominant hemisphere)
- Dysphasia

Parietal lobe

- Aphasia (left side)
- Hemispheric loss
- Perceptual problems
- Contralateral sensory disturbances
- Visual field defects

Occipital lobe

- Visual agnosia (ability to name objects)
- Visual field defects

Cerebellopontine angle

- Contralateral ataxia
- Ipsilateral facial nerve drooping
- Contralateral vestibular loss
- Tremor
- Hearing loss

Cerebellum

- Disordered gait
- Impaired balance
- Incoordination

Medulla

- Contralateral ataxia/hypertonia
- Difficulty swallowing
- Contralateral ataxia
- Difficulty swallowing
- Tremor
- Respiratory weakness
- Contralateral ataxia/hypertonia
- Difficulty to shrug shoulders or turn head toward tumor side
- Contralateral ataxia/hypertonia
- Tongue protrusion (deviating toward tumor side)
- Respiratory pattern changes

Pons

- Contralateral ataxia/hypertonia
- Ipsilateral facial or forehead anesthesia
- Contralateral ataxia
- Contralateral ataxia/hypertonia
- Ipsilateral inability to gaze outward
- Contralateral ataxia/hypertonia
- Ipsilateral facial muscle drooping

Assessment findings in malignant brain tumors

TUMOR AND CHARACTERISTICS

ASSESSMENT FINDINGS

Glioblastoma multiforme (spongioblastoma multiforme)

u Most common; accounts for 60% of all gliomas

u Peak incidence between ages 50 and 60; more common in men than in women

u Unencapsulated, highly malignant; grows rapidly and infiltrates the brain extensively; may become enormous before diagnosed

u Occurs most often in cerebral hemispheres, especially frontal and temporal lobes (rarely in brain stem and cerebellum)

u Occupies more than one lobe of affected hemisphere; may spread to opposite hemisphere by corpus callosum or metastasize into cerebral spinal fluid (CSF), producing tumors in distant parts of the central nervous system (CNS)

General

u Increased intracranial pressure (ICP) (nausea, vomiting, headache, papilledema)

u Mental and behavioral changes; speech and sensory disturbances
u Altered vital signs (increased systolic pressure, widened pulse pressure, respiratory changes)

u In children, irritability and projectile vomiting

Localizing

u Midline: headache (bifrontal or bioccipital) that is worse in morning; intensified by coughing, straining, or sudden head movements

u Temporal lobe: psychomotor seizures

u Central region: focal seizures

u Optic and oculomotor nerves: visual defects

u Frontal lobe: abnormal reflexes and motor responses

Astrocytoma

u Second most common malignant glioma, accounting for 10% of all gliomas

u Occurs at any age; incidence higher in males than in females

u Occurs most often in central and subcortical white matter; may originate in any part of the CNS

u Cerebellar astrocytomas usually confined to one hemisphere

General

u Headache and mental activity changes

u Decreased motor strength and coordination
u Seizures and scanning speech

u Altered vital signs

Localizing

u Third ventricle: changes in mental activity and level of consciousness, nausea, pupillary dilation and sluggish light reflex; paresis or ataxia in later stages of the disease

u Brain stem and pons: ipsilateral trigeminal, abducens, and facial nerve palsies in early stages; cerebellar ataxia, tremors, and other cranial nerve deficits as the disease progresses

u Third or fourth ventricle or aqueduct of Sylvius: secondary hydrocephalus

u Thalamus or hypothalamus: various endocrine, metabolic, autonomic, and behavioral changes

Oligodendroglioma

u Third most common glioma that accounts for less than 5% of all gliomas Occurs in middle adult years; more common in women than in men

u Slow-growing

General

u Mental and behavioral changes
u Decreased visual acuity and other visual disturbances

u Increased ICP

Localizing

u Temporal lobe: hallucinations and psychomotor seizures

u Central region: seizures (confined to one muscle group or unilateral)

u Midbrain or third ventricle: pyramidal tract symptoms (dizziness, ataxia, paresthesia of the face)

u Brain stem and cerebrum: nystagmus, hearing loss, dizziness, ataxia, paresthesia of the face, cranial nerve palsies, hemiparesis, suboccipital tenderness, loss of balance

Ependymoma

u Rare glioma

u Most common in children and young adults

u Located most often in fourth and lateral ventricles

General

u Increased ICP and obstructive hydrocephalus, depending on tumor size

u Other assessment findings similar to those of oligodendroglioma

Medulloblastoma

Medulloblastoma

u Rare glioma	General
u Most common in children and young adults	u Increased ICP
u Incidence highest in children ages 4 to 6	Localizing
u Affects males more than females u Frequently metastasizes by way of CSF	u Brain and cerebrum: papilledema, nystagmus, hearing loss, perception of flashing lights, dizziness, ataxia, paresthesia of the face, cranial nerve palsies (V, VI, VII, IX, X, primarily sensory), hemiparesis, suboccipital tenderness; compression of supratentorial area produces other general and focal symptoms

Meningioma

u Most common nongliomatous brain tumor, constituting 15% of primary brain tumors	General u Headache
u Occurs most frequently among people in their 50s; rare in children; more common in females than in males (ratio 3:2)	u Seizures (in two-thirds of patients) u Vomiting u Change in mental activity
u Arises from the meninges	u Other assessment findings similar to those of schwannomas
u Common locations include parasagittal area, sphenoidal ridge, anterior part of the base of the skull, cerebellopontine angle, and spinal canal	Localizing u Skull changes (bony bulge) over tumor u Sphenoidal ridge, indenting optic nerve: unilateral
u Benign, well-circumscribed, highly vascular tumor that compresses underlying brain tissue by invading overlying skull	u Visual changes and papilledema u Prefrontal parasagittal: personality and behavioral changes u Motor cortex: contralateral motor changes u Anterior fossa compressing both optic nerves and frontal lobes: headaches and bilateral vision loss u Pressure on cranial nerves, causing varying symptoms

Schwannoma (acoustic neurinoma, neurilemoma, cerebellopontine angle tumor)

u Accounts for about 10% of all intracranial tumors	General u Unilateral hearing loss with or without tinnitus
u Onset of symptoms between ages 30 and 60; higher incidence in women than in men	u Stiff neck and suboccipital discomfort u Secondary hydrocephalus
u Affects the craniospinal nerve sheath, usually cranial nerve VIII; also, V and VII, and to a lesser extent, VI and X on the same side as the tumor	u Ataxia and uncoordinated movements of one or both arms due to pressure on brain stem and cerebellum Localizing
u Benign, but often classified as malignant because of its growth patterns; slow-growing; may be present for years before symptoms occur	u V: early signs including facial hypoesthesia and paresthesia on the side of hearing loss; unilateral loss of corneal reflex u VI: diplopia u VII: paresis progressing to paralysis (Bell's palsy) u X: weakness of palate, tongue, and nerve muscles on same side as tumor

Late delayed radiation encephalopathy stems from brain necrosis and small-vessel occlusion. Symptoms can mimic disease advancement and may include intracranial hypertension and focal neurologic dysfunction. Both are irreversible and potentially fatal complications.

Corticosteroid therapy predisposes the patient to cushingoid symptoms and GI ulceration.

Nursing diagnoses

u Activity intolerance u Altered role performance u Anxiety u Body image disturbance u Energy field disturbance u Fear u Hopelessness u Impaired physical mobility u Impaired skin integrity u Ineffective breathing pattern u Ineffective family coping: Disabling u Ineffective individual coping u Ineffective thermoregulation u Pain u Powerlessness u Self-care deficit u Sensory or perceptual alterations

Key outcomes

- u The patient will state his desire to increase activity.
- u The patient will express feelings about his diminished capacity to perform usual roles.
- u The patient will recognize limitations imposed by his illness and express his feelings about these limitations.
- u The patient will continue to function in his usual roles as much as possible.
- u The patient will express positive feelings about himself.
- u The patient will report feeling less tension and pain.
- u The patient will express an increased sense of well-being.

Nursing interventions

- u Carefully document the occurrence, nature, and duration of seizure activity.
- u Maintain a patent airway.
- u Take steps to protect the patient's safety
- u Administer anticonvulsant drugs, as ordered.
- u Monitor for changes in the patient's neurologic status, and watch for increased ICP.

ALERT If your patient develops sudden unilateral pupillary dilation with loss of light reflex, notify the doctor at once. This ominous change indicates imminent transtentorial herniation.

- u Monitor respiratory changes carefully. An abnormal respiratory rate and depth may point to rising ICP or herniation of the cerebellar tonsils from expanding infratentorial mass.
- u Monitor the patient's temperature carefully. Fever commonly follows hypothalamic anoxia, but it can also indicate meningitis. Use hypothermia blankets before and after surgery to keep the patient's temperature down and minimize cerebral metabolic demands.
- u As ordered, administer steroids and osmotic diuretics, such as mannitol, and restrict fluid intake to reduce cerebral edema. Monitor the patient's fluid and electrolyte balance to avoid dehydration.
- u Observe and report signs of stress ulcers: abdominal distention, pain, vomiting, and tarry stools. Administer antacids as ordered.
- u If the patient requires surgery, he'll need special care. After a craniotomy, monitor the patient's general neurologic status, and watch for signs of increased ICP, such as an elevated bone flap and typical neurologic changes. To reduce the risk of increased ICP, restrict fluids to 1,500 ml/24 hours, as ordered.

To promote venous drainage and reduce cerebral edema after supratentorial craniotomy, elevate the head of the bed about 30 degrees. Position the patient on his side to allow drainage of secretions and prevent aspiration. As appropriate, instruct him to avoid Valsalva's maneuver and isometric muscle contractions when moving or sitting up in bed; these can increase intrathoracic pressure and ICP. Withhold oral fluids, which may provoke vomiting and, consequently, increase ICP.

After infratentorial craniotomy, keep the patient flat for 48 hours, but logroll him every 2 hours to minimize complications of immobilization. Prevent other complications by paying careful attention to ventilatory status and to cardiovascular, GI, and musculoskeletal functions.

- u The patient usually doesn't receive radiation therapy until after the surgical wound heals, but it can induce wound breakdown even then. Observe the wound carefully for signs of infection and sinus formation. Because radiation may cause brain inflammation, also watch for signs of increasing ICP.
- u Before chemotherapy, give prochlorperazine or another antiemetic, as ordered, to minimize nausea and vomiting.
- u Because brain tumors may cause residual neurologic deficits that handicap the patient physically or mentally, begin rehabilitation early. Consult with occupational and physical therapists to encourage independence in daily activities. As necessary, provide aids for self-care and mobilization, such as bathroom rails for wheelchair patients. If the patient is aphasic, arrange for a consultation with a speech pathologist.
- u Throughout therapy, provide emotional support to help the patient and family members cope with the treatment, potential disabilities, and changes in lifestyle resulting from his tumor.

Patient teaching

- u Because some of the antineoplastic agents (carmustine, lomustine, semustine, and procarbazine, for example) used as adjuncts to radiation therapy and surgery can cause delayed bone marrow depression, tell the patient to watch for and immediately report any signs of infection or bleeding that appear within 4 weeks after the start of chemotherapy.
- u As appropriate, explain the adverse effects of chemotherapy and other treatments. Explain what actions the patient can take to alleviate them.
- u Teach the patient and family members the early signs of tumor recurrence, and encourage their compliance with the treatment regimen.
- u Refer the patient to resource and support services, such as the social service department, home health care agencies, and the American Cancer Society.

PITUITARY TUMORS

Pituitary tumors originate most often in the anterior pituitary (adenohypophysis) and constitute 10% of intracranial neoplasms. They occur in adults of both sexes, usually between ages 30 and 40.

The most common tumor tissue types include chromophobe adenoma (90%), basophil adenoma, and eosinophil adenoma. As pituitary adenomas grow, they replace normal glandular tissue and enlarge the sella turcica, which houses the pituitary gland. The prognosis is fair to good, depending on the extent to which the tumor spreads beyond the sella turcica.

Pituitary tumors are also associated with certain hereditary disorders (see [Multiple endocrine neoplasia](#)).

Causes

The exact cause is unknown, but a predisposition to a pituitary tumor may be inherited through an autosomal dominant trait. A pituitary tumor isn't malignant in the strict sense; however, its invasive growth categorizes it as a neoplastic condition.

Chromophobe adenoma may be associated with production of corticotropin, melanocyte-stimulating hormone, growth hormone, and prolactin; basophil adenoma, with excess corticotropin production and, consequently, with Cushing's syndrome; and eosinophil adenoma, with excessive growth hormone.

Multiple endocrine neoplasia

Multiple endocrine neoplasia (MEN) causes hyperplasia, adenoma, or carcinoma of the endocrine glands. This hereditary disorder affects males and females, appearing any time from adolescence to old age.

MEN I (Werner's syndrome) affects the parathyroid glands, pancreatic islet cells, pituitary, and rarely, adrenal glands and thyroid gland. MEN II (Sipple's syndrome) is less common and involves medullary thyroid carcinoma, with hyperplasia and adenomatosis of the adrenal medulla and parathyroid glands.

Signs and symptoms vary. With MEN I, peptic ulcers are common and hypoglycemia may develop. With parathyroid gland involvement, symptoms are usually absent. With pituitary tumor, amenorrhea and infertility, decreased beard and body hair, cold intolerance, fatigue, weight loss, and anorexia occur.

With medullary carcinoma of the thyroid in MEN II, note a history of fractures, signs of Cushing's syndrome, and enlarged thyroid. With adrenal tumor, headaches and an irregular, rapid pulse rate and hypertension can occur. With adenomatosis or hyperplasia of the parathyroid glands, there may be a history of renal calculi or urinary tract infection.

MEN may be diagnosed while investigating pituitary tumor, hypoglycemia, hypercalcemia, or GI hemorrhage. Family members must also be tested if MEN is confirmed.

Treatment involves tumor eradication, commonly by partial pancreatectomy, sometimes with partial parathyroidectomy and transsphenoidal hypophysectomy. With MEN II, treatment for adrenal medullary tumor includes antihypertensive drugs and tumor resection.

Complications

The loss of pituitary hormone action results in endocrine abnormalities throughout the body if lost hormones aren't replaced. Tumor compression of the hypothalamus may result in diabetes insipidus.

Assessment findings

The patient's history may reveal complaints related to neurologic and endocrine abnormalities. Typically, the patient complains of a frontal headache and visual

disturbances (blurred vision progressing to field cuts and, eventually, blindness). Members of the patient's family may describe personality changes or dementia. The patient may also report amenorrhea, decreased libido, impotence, lethargy, weakness, increased fatigability, sensitivity to cold, constipation (from decreased production of corticotropin and thyroid-stimulating hormone), and seizures.

Inspection may reveal rhinorrhea, a sign that the tumor has eroded the base of the skull. History and inspection may reveal cranial nerve (III, IV, VI) involvement from lateral extension of the tumor. With cranial nerve involvement, the patient typically reports diplopia and dizziness. You may observe head tilting to compensate for diplopia, conjugate deviation of gaze, nystagmus, eyelid ptosis, and limited eye movements.

Inspection may also disclose skin changes that indicate endocrine involvement. Examples include a waxy appearance, fewer wrinkles (which the patient may report during the history), and pubic and axillary hair loss.

Inspection of the eyes may reveal strabismus.

Diagnostic tests

Skull X-rays with tomography may show an enlarged sella turcica or erosion of its floor. If growth hormone secretion predominates, X-ray findings show enlarged paranasal sinuses and mandible, thickened cranial bones, and separated teeth.

Carotid angiography may identify displacement of the anterior cerebral and internal carotid arteries from tumor enlargement. This study can also rule out an intracerebral aneurysm.

A computed tomography scan may confirm an adenoma and accurately depict its size. Cerebrospinal fluid (CSF) analysis may disclose increased protein levels. Endocrine function tests may or may not contribute helpful information. In many cases, results are ambiguous and inconclusive. Magnetic resonance imaging differentiates healthy, benign, and malignant tissues and blood vessels.

Treatment

Surgical options include transfrontal removal of large tumors impinging on the optic apparatus and transsphenoidal resection for smaller tumors confined to the pituitary fossa. Radiation therapy is the primary treatment for small, nonsecretory tumors confined to the sella turcica or for patients considered poor surgical risks. Otherwise, radiation is an adjunct to surgery, especially when only part of the tumor can be removed.

Postoperative measures include replacement therapy with corticosteroids or thyroid or sex hormones, correction of electrolyte imbalances and, as necessary, insulin therapy. Other drug therapy may include bromocriptine, an ergot derivative that shrinks prolactin-secreting and growth hormone-secreting tumors. Cyproheptadine, an antiserotonin drug, can reduce increased corticosteroid levels in Cushing's syndrome.

Cryohypophysectomy (freezing the area with a probe inserted transsphenoidally) is an alternative to surgical resection.

Nursing diagnoses

⌞ Fatigue ⌞ Impaired social interaction ⌞ Ineffective family coping ⌞ Ineffective individual coping ⌞ Pain ⌞ Risk for injury ⌞ Sensory or perceptual alterations ⌞ Sexual dysfunction

Key outcomes

- ⌞ The patient will express positive feelings about himself.
- ⌞ The patient will report feeling less tension or pain.
- ⌞ The patient will report feeling an increased sense of well-being.
- ⌞ The patient will verbally express increased energy.
- ⌞ The patient will remain free from injury.
- ⌞ The patient and family members will participate in care and prescribed therapies.

Nursing interventions

- ⌞ Use the patient's comprehensive health history and physical assessment data as the baseline for later comparison.
- ⌞ Establish a supportive, trusting relationship with the patient and family to help them cope with the diagnosis, treatment, and potential long-term consequences of this disease. Make sure they understand the need for lifelong health evaluations and, possibly, hormone replacement.
- ⌞ Maintain a safe, clutter-free environment for the visually impaired or acromegalic patient. Reassure him that treatment will probably restore his eyesight.
- ⌞ Provide periods of rest to avoid undue fatigue.
- ⌞ Administer analgesics, as ordered, to relieve headache.

For a supratentorial or transsphenoidal hypophysectomy:

- ⌞ Elevate the patient's head about 30 degrees to promote venous drainage from the head and reduce cerebral edema.
- ⌞ Position the patient on his side to let secretions drain and to prevent aspiration.
- ⌞ Withhold oral fluids, which may trigger vomiting and subsequently increase intracranial pressure (ICP). Don't allow a patient recovering from transsphenoidal surgery to blow his nose. Watch for CSF drainage from the nose, and monitor for signs of infection from the contaminated upper respiratory tract.

For a craniotomy:

- ⌞ Monitor vital signs.
- ⌞ Perform a baseline neurologic assessment to use for planning further care and evaluating progress. Continuously assess level of consciousness.
- ⌞ Maintain a patent airway, and suction as necessary.
- ⌞ Give the patient nothing by mouth for 24 to 48 hours to prevent aspiration or vomiting, which increases ICP.
- ⌞ Observe for cerebral edema, bleeding, and CSF leakage.
- ⌞ Provide a restful, quiet environment.
- ⌞ Monitor intake and output to detect fluid and electrolyte imbalances.
- ⌞ Reassure the patient that some symptoms caused by pituitary dysfunction, such as altered sex drive, impotence, infertility, hair loss, and emotional instability, will subside with treatment.

Patient teaching

- ⌞ Provide necessary preoperative instruction, taking care that the patient understands the information and recognizes possible postoperative problems. Inform the patient having transsphenoidal surgery that he'll lose his sense of smell.
- ⌞ If surgery (such as transsphenoidal hypophysectomy) will disrupt the patient's dura, caution him to avoid such activities as coughing, sneezing, and bending over. These may increase ICP or cause CSF leakage.
- ⌞ Instruct the patient to immediately report a persistent postnasal drip or constant swallowing—signs of CSF drainage, not necessarily nasal drainage.
- ⌞ Encourage the patient to wear a medical identification bracelet that identifies his hormonal condition and its proper treatment.

Spinal neoplasms are similar to intracranial tumors but involve the spinal cord or its roots. Untreated spinal neoplasms can eventually cause paralysis. As primary tumors, they originate in the meningeal coverings, the parenchyma of the cord or its roots, the intraspinal vasculature, or the vertebrae. They can also occur as metastatic foci from primary tumors, but death usually results from the primary condition.

Primary tumors of the spinal cord may be extramedullary (occurring outside the spinal cord) or intramedullary (occurring within the cord). Extramedullary tumors may be intradural (meningiomas and schwannomas) and account for about 60% of all primary spinal cord neoplasms. Extramedullary tumors may also be extradural (metastatic tumors from breasts, lungs, prostate, leukemia, or lymphomas) and account for about 25% of these neoplasms.

Intramedullary tumors, or gliomas (astrocytomas or ependymomas), are comparatively rare and account for only about 10% of spinal neoplasms. In children, these lesions are low-grade astrocytomas.

Spinal cord tumors are rare compared with intracranial tumors (ratio of 1:4). They occur with equal frequency in men and women, except for meningiomas, which occur more often in women. Spinal cord tumors can grow anywhere along the cord or its roots.

The prognosis depends on tumor control and the extent of residual neurologic deficit.

Causes

Little is known about the cause of spinal cord tumors. They have been associated with central von Recklinghausen's disease.

Complications

Motor and sensory deficits range from weakness to paralysis as the disease progresses. They may lead to loss of sphincter control and subsequent bladder and bowel dysfunction.

In late stages of disease, especially with paralysis, the complications of immobility, such as skin breakdown, may occur. Other complications depend on the tumor's location. For example, respiratory problems occur in high cervical tumors, whereas chronic urinary tract problems are associated with tumors lower in the spine.

Assessment findings

Because the spinal cord adjusts to a slow-growing tumor, a tumor may grow for several years and produce minimal neurologic signs. The patient's history, however, may reveal pain described as most severe directly over the tumor and radiating around the trunk or down the limb on the affected side. The patient may report that few measures relieve the pain, not even bed rest. Some patients also complain of constipation.

In the early stages, the patient may express difficulty in emptying the bladder or notice changes in the urinary stream. If you suspect a spinal cord tumor, ask the patient about bladder emptying because many patients overlook or dismiss this sign.

In later stages, urine retention is an inevitable sign of spinal cord compression. If the patient has a cauda equina tumor, he may report bladder and bowel incontinence, usually resulting from flaccid paralysis.

On inspection and palpation, you may find symmetrical spastic weakness, decreased muscle tone, exaggerated reflexes, and a positive Babinski's sign. If the tumor is at the cauda equina level, you may notice muscle wasting. Palpation may reveal muscle flaccidity, wasting, weakness, and progressive diminution in tendon reflexes.

Neurologic examination may disclose contralateral loss of sensation to pain, temperature, and touch (Brown-Sequard's syndrome). These losses are less obvious to the patient than functional motor changes. Caudal lesions invariably produce paresthesia in the nerve pathways of the involved roots.

Diagnostic tests

Lumbar puncture reveals clear yellow cerebrospinal fluid (CSF), resulting from increased protein levels if the flow is completely blocked. If the flow is partially blocked, protein levels rise, but the fluid appears only slightly yellow in proportion to the CSF protein level. A Papanicolaou test of the CSF may show malignant cells of metastatic carcinoma.

X-rays show distortions of the intervertebral foramina; changes in the vertebrae or collapsed areas in the vertebral body; and localized enlargement of the spinal canal, indicating an adjacent blockage.

Myelography identifies the lesion's level by outlining the tumor if it causes a partial obstruction. The myelogram shows the anatomic relation to the cord and the dura. If the tumor causes a complete obstruction, the injected contrast agent can't flow past the tumor. This study is dangerous in instances of nearly complete cord compression because withdrawn or escaping CSF will allow the tumor to exert greater pressure against the cord.

Radioisotope bone scan demonstrates metastatic invasion of the vertebrae by detecting a characteristic increase in osteoblastic activity.

Computed tomography scanning and magnetic resonance imaging show cord compression and tumor location.

Frozen section biopsy performed during surgery identifies the tissue type.

Treatment

Spinal cord tumors are treated with decompression or radiation therapy. Not usually indicated for metastatic tumors, laminectomy may be done for primary tumors that produce spinal cord or cauda equina compression. If the tumor progresses slowly or if it's treated before the cord degenerates from compression, signs and symptoms are likely to subside, and function may be restored.

In a patient with metastatic carcinoma or lymphoma who suddenly experiences complete transverse myelitis with spinal shock, functional improvement is unlikely, even with treatment. This patient's prognosis is poor.

If the patient has incomplete paraplegia of rapid onset, emergency surgical decompression may save cord function. Steroid therapy may minimize cord edema until the patient undergoes surgery.

Partial removal of intramedullary gliomas, followed by radiation therapy, may temporarily ease signs and symptoms. Metastatic extradural tumors can be controlled with radiation therapy, analgesics, and, in hormone-mediated tumors (breast and prostate), appropriate hormone therapy.

Transcutaneous electrical nerve stimulation (TENS) may relieve radicular pain from spinal cord tumors and is a useful alternative to opioid analgesics. TENS works by applying an electrical charge to the skin, thereby stimulating large-diameter nerve fibers and inhibiting the transmission of pain impulses along nerve fibers.

The risk of infection is increased by treatment in many cases, but the risk also increases as the patient's condition deteriorates.

Nursing diagnoses

u Altered urinary elimination u Anxiety u Constipation u Impaired physical mobility u Impaired skin integrity u Ineffective breathing pattern u Ineffective family coping u

Ineffective individual coping Pain Risk for infection Risk for injury

Key outcomes

- The patient will maintain adequate fluid balance.
- The patient's bowel patterns will return to normal.
- The patient will maintain muscle strength and joint range of motion.
- Family members will identify their needs.
- Family members will participate to the extent possible in aspects of patient care without evidence of unusual conflict.
- The patient will remain free from injury.
- The patient will maintain skin integrity.

Nursing interventions

- Set up the patient's care plan to foster emotional support and skilled intervention during acute and chronic disease phases. Aim for early recognition of recurrence, prevention or treatment of complications, and maintenance of the quality of life.
- Use the baseline data from the initial neurologic evaluation to help plan future care and evaluate changes in the patient's clinical status.
- Encourage the patient to voice his concerns about his illness and treatment. Answer any questions. Provide brief, easy-to-understand explanations before performing procedures.
- Recognize that the patient needs emotional support, rehabilitation (including bowel and bladder retraining), and medications and other measures to relieve pain. Prevent infection and skin breakdown.
- If the patient experiences urine retention, provide necessary care, such as intermittent catheterization or indwelling urinary catheter care. Monitor intake and output as needed. If the patient has constipation, administer laxatives and enemas, as ordered.
- After laminectomy, perform neurologic checks frequently. Change the patient's position by logrolling. Administer analgesics, as ordered; monitor for signs of infection; and assist the patient in early walking.
- Institute safety precautions for the patient with impaired sensation and motor deficits. Use side rails if the patient is bedridden. If he's not, encourage him to wear flat shoes for walking. Remove scatter rugs and clutter to prevent falls.
- Encourage the patient to perform daily activities as independently as possible. To avoid aggravating pain, move the patient slowly, making sure his body is aligned properly when you give personal care.
- If the patient has respiratory problems, provide rest periods between activities. Provide oxygen, as ordered, and assist him into a position that allows maximal chest expansion.
- After radiation therapy, administer steroid and antacid medications, as ordered, for spinal cord edema. Monitor for sensory or motor dysfunction (which indicates the need for increased steroid therapy).
- Enforce bed rest for the patient who has vertebral body involvement until the doctor says he can safely walk. Body weight alone can cause vertebral column collapse and cord laceration from bone fragments.
- Logroll and position the patient on his side every 2 hours to prevent pressure ulcers and other complications of immobility.
- If the patient requires a back brace, make sure he wears it whenever he gets out of bed.
- Help the patient and family members to understand and cope with the spinal tumor diagnosis, treatment, potential disabilities, and necessary changes in lifestyle.

Patient teaching

- Refer the patient, family members, and close friends to support groups, the social service department, and home health care agencies, as appropriate.
- Instruct the patient and family members in the care the patient requires, including how to administer medications, maintain skin integrity, reduce discomfort (for example, by using TENS to block radicular pain), prevent infection and injury, and cope with incontinence.

THYROID CANCER

Although thyroid cancer occurs in all age-groups, patients who have had radiation therapy in the neck area are especially susceptible. Papillary and follicular carcinomas are the most common forms of thyroid cancers and are usually associated with the longest survival times.

Papillary carcinoma accounts for about half of thyroid cancer in adults. It can occur at any age but is most common in young adult females. Usually multifocal and bilateral, it metastasizes slowly into regional nodes of the neck, mediastinum, lungs, and other distant organs. It is the least virulent form of thyroid cancer.

Less common, follicular carcinoma is more likely to recur and metastasize to the regional lymph nodes and spread through blood vessels into the bones, liver, and lungs.

Medullary (solid) carcinoma originates in the parafollicular cells derived from the last branchial pouch and contains amyloid and calcium deposits. It can produce calcitonin, histaminase, corticotropin (producing Cushing's syndrome), and prostaglandin E₂ and F₃ (producing diarrhea). This form of thyroid cancer is familial, possibly inherited as an autosomal dominant trait, and usually associated with pheochromocytoma and is curable when detected before it causes symptoms. Untreated, it grows rapidly, frequently metastasizing to bones, liver, and kidneys.

Anaplastic carcinoma (giant and spindly cell cancer) resists radiation and is almost never curable by resection. This cancer metastasizes rapidly, causing death by invading the trachea and compressing adjacent structures.

Causes

Besides exposure to radiation, suspected causes of thyroid cancer include prolonged secretion of thyroid-stimulating hormone (TSH) through radiation or heredity, familial predisposition, and chronic goiter.

Anaplastic thyroid cancer

The most disfiguring, destructive, and deadly form of thyroid cancer, anaplastic carcinoma has the poorest prognosis. Although this tumor rarely metastasizes to distant organs, its rapid growth and size produce severe anatomic distortion of nearby structures. Treatment usually consists of total thyroidectomy, which seldom is successful.

Complications

Dysphagia and stridor are typical complications of thyroid cancer, especially in untreated disease. They usually result from pressure caused by a space-occupying lesion that extends into neck structures. Additional complications include hormone alterations and distant metastases.

Assessment findings

The first indication of disease may be a painless nodule discovered incidentally or detected during physical examination.

If the tumor grows large enough to destroy the thyroid gland, the patient's history may include sensitivity to cold and mental apathy (hypothyroidism). If the tumor triggers excess thyroid hormone production, the patient may report sensitivity to heat, restlessness, and overactivity (hyperthyroidism). The patient may also complain of diarrhea, dysphagia, anorexia, irritability, and ear pain. When speaking with the patient, you may hear hoarseness and vocal stridor.

On inspection, you may detect a disfiguring thyroid mass, especially if the patient is in the later stages of anaplastic thyroid cancer. (See [Anaplastic thyroid cancer](#).)

Palpation may disclose a hard nodule in an enlarged thyroid gland or palpable lymph nodes with thyroid enlargement.

By auscultation, you may discover bruits if thyroid enlargement results from an increase in TSH, which increases thyroid vascularity.

Diagnostic tests

Fine-needle aspiration biopsy may help to differentiate benign from malignant thyroid nodules. Histologic analysis helps stage the disease and guide treatment.

Thyroid scan may differentiate functional nodes (rarely malignant) from hypofunctional nodes (commonly malignant) by measuring how readily nodules trap isotopes compared with the rest of the thyroid gland. In thyroid cancer, scintigraphy findings may demonstrate a “cold,” nonfunctioning nodule.

Ultrasonography evaluates changes in the size of thyroid nodules after thyroxine suppression therapy, guides fine-needle aspiration, and detects recurrent disease.

Magnetic resonance imaging and computed tomography scanning provide information for treatment planning because they establish the extent of the disease within the thyroid and in surrounding structures.

Calcitonin assay is a reliable clue to silent medullary carcinoma. The calcitonin level is measured during a resting state and during a calcium infusion (15 mg/kg) over a 4-hour period. An elevated fasting calcitonin level and an abnormal response to calcium stimulation—a high release of calcitonin from the node in comparison with the rest of the gland—are indicative of medullary cancer.

Treatment

Surgery is recommended initially for all forms of thyroid cancer, but the extent of surgery and the postoperative treatments vary. Ideally before surgery, the patient should have normal thyroid function (euthyroid) as demonstrated by normal thyroid function tests, pulse rate, and electrocardiogram.

Treatment may include one or a combination of the following:

- total or subtotal thyroidectomy with modified node dissection (bilateral or homolateral) on the side of the primary cancer (for papillary or follicular cancer)
- total thyroidectomy and radical neck excision (for medullary or anaplastic cancer)
- radioisotope (^{131}I) therapy with external radiation (sometimes postoperatively in lieu of radical neck excision) or alone (for metastasis)
- adjunctive thyroid suppression (with exogenous thyroid hormones suppressing TSH production) and simultaneous administration of an adrenergic blocking agent such as propranolol, to increase tolerance to surgery and radiation therapy
- chemotherapy limited to treating symptoms of widespread metastasis, as a palliative measure; doxorubicin has some antitumor activity in about 20% of cases.

Nursing diagnoses

- Altered nutrition: Less than body requirements
- Anxiety
- Body image disturbance
- Diarrhea
- Impaired gas exchange
- Impaired skin integrity
- Impaired swallowing
- Impaired verbal communication
- Pain

Key outcomes

- The patient will maintain current weight without further loss.
- The patient will express positive feelings about himself.
- The patient won't aspirate.
- The patient will express feelings and needs without frustration.
- The patient will express feelings of comfort and relief of pain.

Nursing interventions

- Prepare the patient for scheduled surgery.

- u Encourage the patient to voice his concerns, and offer reassurance.
- u Before surgery, establish a way for the patient to communicate postoperatively (pad and pencil, head nodding for yes and no, or other ways).

Take the following steps postoperatively:

- u When the patient regains consciousness, keep him in the semi-Fowler's position. To avoid pressure on the suture line, his head should be neither hyperextended nor flexed. Support his head and neck with sandbags and pillows. When you move him, continue this support with your hands.
- u After monitoring vital signs, check the patient's dressing, neck, and back for blood. If he complains that the dressing feels tight, loosen it and call the doctor immediately.
- u Check serum calcium levels daily because hypocalcemia may develop if the parathyroid glands were removed.
- u Watch for and report other complications, for example, hemorrhage and shock (elevated pulse rate and hypotension), tetany (carpopedal spasm, twitching, seizures), thyroid storm (high fever, severe tachycardia, delirium, dehydration, and extreme irritability), and respiratory obstruction (dyspnea, crowing respirations, retraction of neck tissues).
- u Keep a tracheotomy set and oxygen equipment handy for use if respiratory obstruction occurs. Use continuous steam inhalation in the patient's room until his chest sounds clear. Administer pain medications as ordered, and make sure that the patient feels as comfortable as possible.
- u Provide I.V. fluids or a soft diet, as needed. Many patients can tolerate a regular diet within 24 hours of surgery.
- u Provide the same postsurgical care after extensive tumor and node excision as you would after radical neck surgery.

Patient teaching

- u Preoperatively, advise the patient to expect temporary voice loss or hoarseness for several days after surgery. Also, explain the operation and postoperative procedures and positioning.
- u Before discharge, ensure that the patient knows the date and time of his next appointment. Answer his questions about his treatment and home care. Be sure he understands the purpose of his medications, dosage, administration times, and possible adverse effects.
- u Refer the patient to resource and support services, such as the social service department, home health care agencies, hospices, and the American Cancer Society.

Thoracic neoplasms

The lung and breast are the most common sites for thoracic cancer. Although rare, soft-tissue sarcomas may also develop in the chest region.

BREAST CANCER

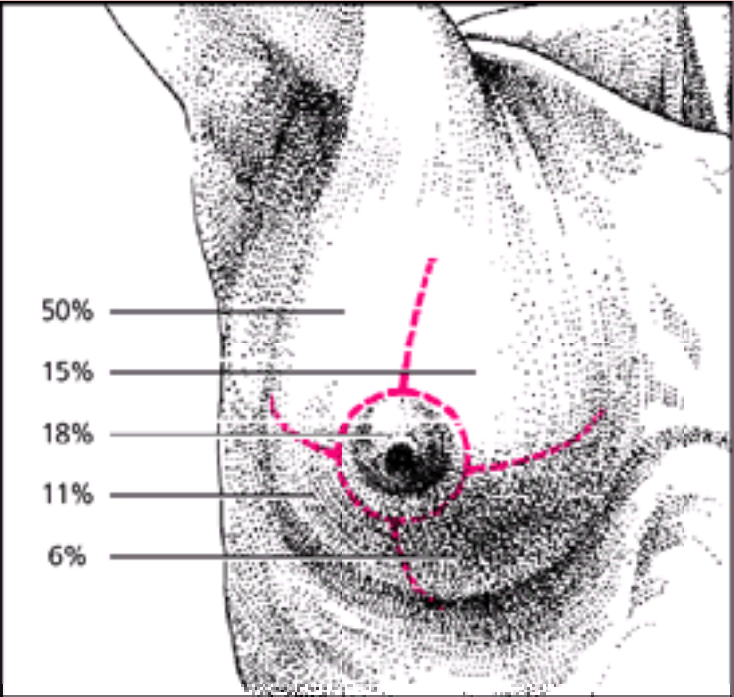

Along with lung cancer, breast cancer is a leading killer of women ages 35 to 54. Breast cancer strikes about 10% of all women. The disease seldom occurs in men. Although breast cancer may develop any time after puberty, it's most common after age 50.

Breast tumor sources and sites

About 90% of all breast tumors arise from the epithelial cells lining the ducts. About half of all breast cancers develop in the breast's upper outer quadrant—the section containing the most glandular tissue.

The second most common cancer site is the nipple, where all of the breast ducts converge.

The next most common site is the upper inner quadrant, followed by the lower outer quadrant and, finally, the lower inner quadrant.

Early detection and treatment influences the prognosis considerably. The most reliable breast cancer detection method is regular breast self-examination, followed by immediate professional evaluation of any abnormality. With adjunctive therapy, 70% to 75% of women with negative nodes survive 10 years or more, compared to 20% to 25% of women with positive nodes.

Causes and pathophysiology

The causes of breast cancer remain elusive. Significant risk factors include a family history of breast cancer (mother, sister, grandmother, aunt) and being a woman over age 45 and premenopausal. Other risk factors may include a long menstrual cycle, early onset of menses, or late menopause; first pregnancy after age 31; a high-fat diet; endometrial or ovarian cancer; radiation exposure; estrogen therapy; antihypertensive therapy; alcohol and tobacco use; and preexisting fibrocystic disease. The recent discovery of the breast cancer gene BRCA 1 confirms the theory that the disease can be inherited from either the mother or the father.

About half of all breast cancers develop in the upper outer quadrant. (See [Breast tumor sources and sites](#).) Growth rates vary. Theoretically, slow-growing breast cancer may take up to 8 years to become palpable at $\frac{3}{8}$ " (1 cm). It spreads by way of the lymphatic system and the bloodstream through the right side of the heart to the lungs and to the other breast, chest wall, liver, bone, and brain.

The estimated breast cancer growth rate is called its *doubling time*, or the time it takes malignant cells to double in number. Survival time is based on tumor size and the number of involved lymph nodes.

Classified by histologic appearance and the lesion's location, breast cancer may be described as:

- u *adenocarcinoma* (ductal)—arising from the epithelium
- u *intraductal*— developing within the ducts (includes Paget's disease)
- u *infiltrating*— occurring in the breast's parenchymal tissue
- u *inflammatory* (rare)—growing rapidly and causing overlying skin to become edematous, inflamed, and indurated
- u *lobular carcinoma in situ*— involving the lobes of glandular tissue

↳ *medullary* or *circumscribed*— enlarging tumor with rapid growth rate.

Coupled with a staging system, these classifications provide a clearer picture of the cancer's extent. The most common system for staging, both before and after surgery, is the TNM (tumor, node, metastasis) system.

Assessment findings

The most reliable way to detect breast cancer is through monthly breast self-examination by the patient, followed by immediate evaluation of any abnormality. The patient most often reports that she detected a painless lump or mass in her breast or that she noticed a thickening of breast tissue. Otherwise, the disease most commonly appears on a mammogram before a lesion becomes palpable. The patient's history may indicate several risk factors for breast cancer.

Inspection may reveal clear, milky, or bloody nipple discharge, nipple retraction, scaly skin around the nipple, and skin changes, such as dimpling, *peau d'orange*, or inflammation. Arm edema, also identified on inspection, may indicate advanced nodal involvement.

Palpation may identify a hard lump, mass, or thickening of breast tissue. Palpation of the cervical supraclavicular and axillary nodes may also disclose lumps or enlargement.

Complications

Disease progression and metastasis lead to site-specific complications, including infection, decreased mobility if the disease metastasizes to the bone, central nervous system effects if the tumor metastasizes to the brain, and respiratory problems if it spreads to the lung.

Diagnostic tests

Mammography, the essential test for breast cancer, can reveal a tumor that is too small to palpate. (See [Scheduling mammography.](#))

Fine-needle aspiration and excisional biopsy provide cells for histologic examination to confirm the diagnosis.

Ultrasonography can distinguish between a fluid-filled cyst and a solid mass. Chest X-rays can pinpoint metastases in the chest. Scans of the bone, brain, liver, and other organs can detect distant metastases.

Laboratory tests, such as alkaline phosphatase levels and liver function, can uncover distant metastases. Hormonal receptor assay can determine whether the tumor is estrogen or progesterone-dependent. This test guides decisions to use therapy that blocks the action of the estrogen hormone that supports tumor growth.

Treatment

The choice of treatment usually depends on the stage and type of disease, woman's age and menopausal status, and disfiguring effects of surgery. Therapy may include any combination of surgery, radiation, chemotherapy, and hormone therapy.

Surgery includes lumpectomy, partial mastectomy, simple or total mastectomy, modified radical mastectomy, and radical mastectomy.

↳ *Lumpectomy*. Through a small incision near the nipple, the surgeon removes the tumor, surrounding tissue and, possibly, nearby lymph nodes. Typically, the patient undergoes radiation therapy after lumpectomy.

Lumpectomy is used for patients with small, well-defined lesions. Lumpectomy and dissection of the axillary lymph nodes may be used to remove the tumor and axillary lymph nodes while leaving the breast intact. In some cases, the surgeon performs a lumpectomy by freezing the tumor with a cryoprobe (which chills the tumor to 292° F [180° C]), thawing the tumor, and then repeating the procedure four more times. Finally, the surgeon refreezes the tumor and then performs the surgery.

PREVENTION

Scheduling mammography

Mammography is indicated for any woman whose physical examination might suggest breast cancer. It should be done as a baseline in women ages 35 to 39; every 1 to 2 years for women ages 40 to 49; and annually for women over age 50. Women who have a history of breast cancer or have had unilateral breast cancer also should have an annual mammogram to check for new disease.

This cell-destroying technique, called *cryolumpectomy*, is recommended only for small, early, primary tumors. Radiation therapy may follow cryolumpectomy, which has few complications and may prevent local recurrence.

- ↳ *Partial mastectomy* (also known as segmental mastectomy or quadrantectomy) removes one-quarter or more of the breast.
- ↳ *Simple or total mastectomy* is the removal of the breast but not the lymph nodes or pectoral muscles.
- ↳ *Modified radical mastectomy* is the removal of the breast and some of the axillary lymph nodes.
- ↳ *Radical mastectomy* is the removal of the breast, pectoralis major and minor, and axillary lymph nodes. The use of this surgery has declined.

Before or after tumor removal, primary radiation therapy may be effective for a patient who has a small tumor in early stages without distant metastases. Radiation therapy can also prevent or treat local recurrence. Preoperative breast irradiation also helps to sterilize the field, making the tumor more manageable surgically, especially in inflammatory breast cancer.

Various cytotoxic drug combinations may be administered either as adjuvant therapy or as primary therapy. The patient may base her decision to undergo chemotherapy on several factors, including the cancer's stage and hormonal receptor assay results.

Chemotherapy commonly relies on a combination of drugs, such as cyclophosphamide, fluorouracil, methotrexate, doxorubicin, vincristine, paclitaxel, and prednisone. A typical regimen is cyclophosphamide, methotrexate, and fluorouracil; it's used in premenopausal and postmenopausal women.

Hormonal therapy lowers levels of estrogen and other hormones suspected of nourishing breast cancer cells. For example, antiestrogen therapy (specifically tamoxifen, which is most effective against tumors identified as estrogen receptor-positive) is used in postmenopausal women. Breast cancer patients may also receive estrogen, progesterone, androgen, or antiandrogen aminoglutethimide therapy. The success of these therapies provides growing evidence that breast cancer is systemic, not local, and has led to decline in ablation surgery.

HOME CARE

Managing mastectomy after discharge

Follow these guidelines when providing home care for the mastectomy patient:

- u If the patient agrees, refer her to the American Cancer Society's Reach for Recovery program.
- u Teach the patient how to examine her breasts, and observe as she performs a self-examination.
- u Encourage the patient to talk about her feelings. Discuss such issues as grief over the loss of a body part, perceived loss of femininity, breast reconstruction, and the diagnosis of cancer.
- u During each visit, look closely for signs of infection at the incision site.
- u Make sure the amount of drainage continues to decrease. Report any increases, changes in color, or foul odor.
- u Teach the patient to:
 - wash her hands before touching the incision site
 - empty the drainage device at least every 8 hours and record the amount
 - notify you if the drainage suddenly increases, changes in color, or has a foul odor
 - perform arm exercises at least four times a day, increasing them as tolerated and stopping at the point of pain
 - avoid shaving and using depilatory creams and strong deodorants in the affected area
 - avoid any constriction of the affected area (for example, from wearing tight clothing).

Nursing diagnoses

u Altered nutrition: Less than body requirements u Anxiety u Body image disturbance u Energy field disturbance u Fear u Impaired physical mobility u Impaired skin integrity u Ineffective individual coping u Pain u Risk for infection u Self-care deficit

Key outcomes

- u The patient will recognize limitations imposed by illness and will express feelings about these limitations.
- u The patient will express positive feelings about self.
- u The patient will report feeling less tension or pain.
- u The patient will express increased sense of well-being.
- u The patient will communicate feelings of comfort or satisfaction.
- u The patient will use situational supports to reduce fear.
- u The patient will remain free from signs and symptoms of infection.

Nursing interventions

- u Evaluate the patient's feelings about her illness, and determine her level of knowledge. Listen to her concerns, and stay with her during periods of severe anxiety.
- u Administer ordered analgesics as required. Monitor and record their effectiveness.
- u Perform comfort measures, such as repositioning, to promote relaxation and relieve anxiety.
- u If immobility develops late in the disease, prevent complications by frequently repositioning the patient, using a convoluted foam mattress, and providing skin care (particularly over bony prominences).
- u Watch for treatment complications, such as nausea, vomiting, anorexia, leukopenia, thrombocytopenia, GI ulceration, and bleeding. Provide comfort measures and prescribed treatments to relieve these complications.

After surgery:

- u Inspect the dressing anteriorly and posteriorly. Report excessive bleeding promptly.
- u Record the amount and color of drainage. Drainage appears bloody during the first 4 hours; then it becomes serous.
- u Monitor vital signs. If a general anesthetic was given during surgery, monitor intake and output for at least 48 hours.
- u Prevent lymphedema of the arm, which may be an early complication of lymph node dissection. Such prevention is crucial because lymphedema can't be treated effectively.
- u Use strict aseptic technique when changing dressings or I.V. tubing or performing any invasive procedure. Monitor temperature and white blood cell count closely.
- u Inspect the incision. Encourage the patient and her partner to look at her incision as soon as feasible—when the first dressing is removed, if possible.

Patient teaching

- u Clearly explain all procedures and treatments.
- u Besides the usual preoperative teaching, show the mastectomy patient how to ease postsurgical pain by lying on the affected side or by placing a hand or pillow on the incision. Point out where the incision will be. Inform the patient that after the operation, she'll receive analgesics because pain relief encourages coughing and turning and promotes well-being. Explain that a small pillow placed under the arm anteriorly may provide comfort.
- u Tell her that she may move about and get out of bed as soon as possible, usually as soon as the effects of the anesthetic subside or the first evening after surgery.
- u Explain that she may have an incisional drain or some type of suction to remove accumulated fluid, relieve tension on the suture line, and promote healing.
- u Urge the patient to avoid activities that could injure her arm and hand on the side of her surgery. Caution her not to let blood be drawn from or allow injections into that arm. She should also refuse to have blood pressure taken or I.V. therapy administered on the affected arm.
- u To help prevent lymphedema, instruct the patient to exercise her hand and arm on the affected side regularly and to avoid activities that might allow infection of this hand or arm. Tell her that infection increases the risk of lymphedema. (See [Managing mastectomy after discharge.](#))
- u Inform the patient that she may experience “phantom breast syndrome,” a tingling or pins-and-needles sensation in the area where the breast was removed.
- u Women who have had breast cancer in one breast are at higher risk for cancer in the other breast or for recurrent cancer in the chest wall. For this reason, urge the patient to continue examining the other breast and to comply with recommended follow-up treatment.

LUNG CANCER

The most common forms of lung cancer are squamous cell (epidermoid) carcinoma, small-cell (oat cell) carcinoma, adenocarcinoma, and large-cell (anaplastic) carcinoma. The most common site is the wall or epithelium of the bronchial tree.

Determining pack years

Patients who smoke cigarettes are at a higher risk for such respiratory diseases as lung cancer, emphysema, and bronchitis. Use the following formula to calculate pack years and assess a patient's risk for lung disease:
pack years = number of packs smoked daily x number of years smoked.
For example, a patient who smokes 2 packs of cigarettes daily for 42 years has accumulated 84 pack years.
Normally, the more pack years, the greater the risk for lung disease.

For most patients, the prognosis is poor, depending on the extent of the cancer when diagnosed and the cells' growth rate. Only about 13% of patients with lung cancer survive 5 years after diagnosis. Lung cancer is the most common cause of cancer death in men and is fast becoming the most common cause in women, even though it's largely preventable.

Causes

The exact cause of lung cancer remains unclear. Risk factors include tobacco smoking, exposure to carcinogenic and industrial air pollutants (asbestos, arsenic,

chromium, coal dust, iron oxides, nickel, radioactive dust, and uranium), and genetic predisposition.

Complications

Disease progression and metastasis cause various complications. When the primary tumor spreads to intrathoracic structures, complications may include tracheal obstruction; esophageal compression with dysphagia; phrenic nerve paralysis with hemidiaphragm elevation and dyspnea; sympathetic nerve paralysis with Horner's syndrome; eighth cervical and first thoracic nerve compression with ulnar and Pancoast's syndrome (shoulder pain radiating to the ulnar nerve pathways); lymphatic obstruction with pleural effusion; and hypoxemia. Other complications are anorexia and weight loss, sometimes leading to cachexia, digital clubbing, and hypertrophic osteoarthropathy. Endocrine syndromes may involve production of hormones and hormone precursors.

Assessment findings

Because early lung cancer may cause no symptoms, the disease may be advanced when it's diagnosed. While taking the patient's history, be sure to assess his exposure to carcinogens. If he's a smoker, determine pack years. (See [Determining pack years.](#))

ADVANCED PRACTICE

Additional findings in lung cancer

In addition to their obvious interference with respiratory function, lung tumors may also alter the production of hormones that regulate body function or homeostasis. Clinical conditions that result from such changes are known as hormonal paraneoplastic syndromes:

- Gynecomastia may result from oat cell carcinoma.
- Hypertrophic pulmonary osteoarthropathy — bone and joint pain from cartilage erosion — is due to abnormal production of growth hormone. It may result from large-cell carcinoma and adenocarcinoma.
- Cushing's and carcinoid syndromes may result from small-cell carcinoma. Hypercalcemia may result from epidermoid tumors. Metastatic symptoms vary greatly, depending on the effect of tumors on intrathoracic and distant structures.
- Bronchial obstruction causes hemoptysis, atelectasis, pneumonitis, and dyspnea.
- Recurrent nerve invasion leads to hoarseness and vocal cord paralysis.
- Chest wall invasion causes piercing chest pain; increasing dyspnea; severe shoulder pain radiating down the arm.
- Local lymphatic spread causes cough, hemoptysis, stridor, and pleural effusion.
- Phrenic nerve involvement leads to dyspnea, shoulder pain, and unilateral paralyzed diaphragm, with paradoxical motion.
- Esophageal compression causes dysphagia.
- Vena caval obstruction causes venous distension and edema of the neck, chest, and back.
- Pericardial involvement causes pericardial effusion, tamponade, and arrhythmias.
- Cervical thoracic sympathetic nerve involvement leads to mitosis, ptosis, exophthalmus, and reduced sweating.
- Distant metastasis may involve any part of the body, most commonly the central nervous system, liver, and bone.

Chief complaints may include coughing (induced by tumor stimulation of nerve endings), hemoptysis, dyspnea (from the tumor occluding airflow), and hoarseness (from tumor or tumor-bearing lymph nodes pressing on the laryngeal nerve).

On inspection, you may notice the patient becomes short of breath when he walks or exerts himself. You also may observe finger clubbing; edema of the face, neck, and upper torso; dilated chest and abdominal veins (superior vena cava syndrome); weight loss; and fatigue.

Palpation may reveal enlarged lymph nodes and an enlarged liver. Percussion findings may include dullness over the lung fields in a patient with pleural effusion.

Auscultation may disclose decreased breath sounds, wheezing, and pleural friction rub (with pleural effusion). (See [Additional findings in lung cancer.](#))

Diagnostic tests

Chest X-rays usually show an advanced lesion and can detect a lesion up to 2 years before signs and symptoms appear. Findings may indicate tumor size and location.

Cytologic sputum analysis, which is 75% reliable, requires a sputum specimen expectorated from the lungs and tracheobronchial tree, not from postnasal secretions or saliva.

Bronchoscopy can identify the tumor site. Bronchoscopic washings provide material for cytologic and histologic study. The flexible fiberoptic bronchoscope increases test effectiveness.

Needle biopsy of the lungs relies on biplanar fluoroscopic visual control to locate peripheral tumors before withdrawing a tissue specimen for analysis. This procedure allows a firm diagnosis in 80% of patients.

Tissue biopsy of metastatic sites (including supraclavicular and mediastinal nodes and pleura) helps to assess disease extent. Based on histologic findings, staging determines the disease's extent and prognosis and helps direct treatment.

Thoracentesis allows chemical and cytologic examination of pleural fluid.

Additional studies include chest tomography, bronchography, esophagography, and angiocardiology (contrast studies of bronchial tree, esophagus, and cardiovascular tissues). Tests to detect metastasis include a bone scan (abnormal findings may lead to a bone marrow biopsy, which is typically recommended in patients with small-cell carcinoma); a computed tomography scan of the brain; liver function studies; and gallium scans of the liver and spleen.

Treatment

Various combinations of surgery, radiation therapy, and chemotherapy improve the prognosis and prolong patient survival. Because lung cancer is usually advanced at diagnosis, most treatment is palliative.

Surgery is the primary treatment for stage I, stage II, or selected stage III squamous cell carcinoma, adenocarcinoma, and large-cell carcinoma, unless the tumor is inoperable or other conditions (such as cardiac disease) rule out surgery. Surgery may involve partial lung removal (wedge resection, segmental resection, lobectomy, radical lobectomy) or total removal (pneumonectomy, radical pneumonectomy).

Preoperative radiation therapy may reduce tumor bulk to allow for surgical resection and may also improve response rates. Radiation therapy is ordinarily recommended for stage I and stage II lesions if surgery is contraindicated, and for stage III disease confined to the involved hemithorax and the ipsilateral supraclavicular lymph nodes. Radiation therapy usually begins about 1 month after surgery (to allow the wound to heal). It's directed to the chest area most likely to develop metastasis.

Chemotherapy drug combinations of fluorouracil, vincristine, mitomycin, cisplatin, and vindesine induce a response rate of 40%, yet have minimal effect on long-term survival. Promising combinations of drugs for treating small-cell carcinomas include cyclophosphamide, doxorubicin, and vincristine; cyclophosphamide, doxorubicin,

vincristine, and etoposide; and etoposide, cisplatin, cyclophosphamide, and doxorubicin.

Immunotherapy is investigational. Nonspecific regimens using bacille Calmette-Guerin (BCG) vaccine or, possibly, *Corynebacterium parvum* offer the most promise.

In laser therapy, also largely investigational, a laser beam is directed through a bronchoscope to destroy local tumors.

Nursing diagnoses

- u Altered nutrition: Less than body requirements
- u Anxiety
- u Fatigue
- u Fluid volume deficit
- u Impaired gas exchange
- u Impaired physical mobility
- u Impaired skin integrity
- u Ineffective airway clearance
- u Ineffective breathing pattern
- u Pain
- u Risk for infection
- u Risk for injury

Key outcomes

- u The patient's fluid volume will remain within normal range.
- u The patient will carry out activities of daily living without weakness or fatigue.
- u The patient will maintain adequate ventilation.
- u The patient will maintain muscle strength and joint range of motion.
- u The patient will maintain a patent airway.
- u The patient will express feelings of comfort and decreased pain.

Nursing interventions

- u Give comprehensive supportive care and provide patient teaching to minimize complications and speed the patient's recovery from surgery, radiation therapy, and chemotherapy.
- u Urge the patient to voice his concerns and schedule time to answer his questions. Be sure to explain procedures before performing them. This will help reduce the patient's anxiety.
- u Before and after surgery give ordered analgesics as necessary.

After thoracic surgery:

- u Maintain a patent airway, and monitor chest tubes to reestablish normal intrathoracic pressure and prevent postoperative and pulmonary complications.
- u Check vital signs and watch for and report abnormal respiration and other changes.
- u Suction the patient often and encourage him to begin deep breathing and coughing as soon as possible. Check secretions often. Initially, sputum will appear thick and dark with blood, but it should become thinner and grayish yellow within 1 day.
- u Monitor and document amount and color of closed chest drainage. Keep chest tubes patent and draining effectively. Watch for fluctuation in the water seal chamber on inspiration and expiration, indicating that the chest tube remains patent. Watch for air leaks, and report them immediately. Position the patient on the surgical side to promote drainage and lung reexpansion.
- u Watch for and report any foul-smelling discharge or excessive drainage on surgical dressings. Usually, you'll remove the dressing after 24 hours, unless the wound appears infected.
- u Monitor intake and output. Maintain adequate hydration.
- u Watch for and be prepared to treat infection, shock, hemorrhage, atelectasis, dyspnea, mediastinal shift, and pulmonary embolus.
- u To help prevent pulmonary embolus, apply antiembolism stockings, and encourage the patient to perform range-of-motion exercises.

For chemotherapy:

- u Ask the dietary department to provide soft, nonirritating, protein-rich foods. Encourage the patient to eat high-calorie, between-meal snacks.
- u Give antiemetics and antidiarrheals, as needed.
- u Schedule patient care to help the patient conserve his energy.
- u Impose reverse isolation if bone marrow suppression develops during treatment.

For radiation therapy:

- u Provide meticulous skin care to minimize skin breakdown.

Patient teaching

- u Before surgery, supplement and reinforce what the doctor has told the patient about the disease and the operation.
- u Teach the patient about postoperative procedures and equipment. Discuss urinary catheterization, chest tubes, endotracheal tubes, dressing changes, and I.V. therapy. Teach him how to cough and breathe deeply from the diaphragm and how to perform range-of-motion exercises. Reassure him that analgesics and proper positioning will help to control postoperative pain.
- u Warn an outpatient to avoid tight clothing, sunburn, and harsh ointments on his chest. Teach him exercises to prevent shoulder stiffness.
- u If the patient is receiving chemotherapy or radiation therapy, explain possible adverse effects of these treatments. Teach him ways to avoid complications, such as infection. Also review reportable adverse effects.
- u Educate high-risk patients about ways to reduce their chances of developing lung cancer or recurrent cancer.
- u Refer smokers to local branches of the American Cancer Society or Smokenders. Provide information about group therapy, individual counseling, and hypnosis.
- u Urge all heavy smokers over age 40 to have a chest X-ray annually and cytologic sputum analysis every 6 months. Also encourage patients who have recurring or chronic respiratory tract infections, chronic lung disease, or a nagging or changing cough to seek prompt medical evaluation.

MESOTHELIOMAS

Mesotheliomas, which originate in the serosal lining of the pleural cavity, account for less than 10% of all cancer-related deaths. Incidence is high, however, in asbestos workers and their immediate families and among people who live along major routes used for transporting large quantities of asbestos.

Mesotheliomas have a latency period ranging from 20 to 45 years from exposure to tumor discovery, usually occur in people over age 50, and are invariably fatal. Typically, less than 2 years pass between the onset of symptoms and death.

Causes and pathophysiology

The link between this tumor and asbestos exposure is well-established. Predisposition, chronic inflammation, radiation, recurrent lung infection seldom account for a mesothelioma. Smoking alone doesn't increase the risk for developing a mesothelioma; coupled with asbestos exposure, it increases the risk by about 50%.

It's unknown whether a mesothelioma begins in the visceral or parietal pleura; in animals, tumor-causing asbestos fibers migrate to mesothelial cells, penetrating the pleura. From there, the pleural lymphatics carry them to the pleural surface. Signs and symptoms result from pleural effusion, restricted lung function, tumor mass, infection, and advanced disease.

Complications

Disease progression and metastasis can lead to severe dyspnea, infection, and complications of immobility, such as skin breakdown.

Assessment findings

The patient's history will probably reveal asbestos exposure at some time in the patient's life. His chief complaints may be chest pain and dyspnea. Other complaints

include cough, hoarseness, anorexia, weight loss, weakness, and fatigue.

Vital signs may reflect an elevated temperature. Inspection reveals shortness of breath and, in some cases, finger clubbing. You may discover dullness over lung fields on chest percussion and diminished chest sounds on auscultation.

Diagnostic tests

Open pleural biopsy is necessary to obtain a specimen. Then histologic study can confirm the diagnosis. Chest X-rays exhibit nodular, irregular, unilateral pleural thickening and varying degrees of unilateral pleural effusion. A computed tomography scan of the chest defines the tumor's extent.

Treatment

No standard treatment exists for a mesothelioma. Surgery, radiation therapy, chemotherapy, and a combination of treatments are usually tried, but they seldom control the disease in most patients.

If surgery is performed, a pleuropneumectomy is the usual procedure. Cisplatin and mitomycin are the most successful chemotherapy drug combinations. Doxorubicin and methotrexate achieve less successful results.

Nursing diagnoses

⌞ Anxiety ⌞ Fatigue ⌞ Fluid volume excess ⌞ Hopelessness ⌞ Impaired gas exchange ⌞ Impaired physical mobility ⌞ Impaired skin integrity ⌞ Ineffective breathing pattern ⌞ Risk for infection

Key outcomes

- ⌞ The patient's fluid volume will remain within normal range.
- ⌞ The patient will express feelings of increased energy.
- ⌞ The patient will carry out activities of daily living without weakness or fatigue.
- ⌞ The patient will maintain adequate ventilation.
- ⌞ The patient will maintain muscle strength and joint range of motion.
- ⌞ The patient will maintain a patent airway.
- ⌞ The patient will express feelings of comfort and decreased pain.

Nursing interventions

- ⌞ Listen to the patient's fears and concerns. Give clear, concise explanations of all procedures and actions, and remain with him during periods of severe anxiety. Encourage him to identify actions that promote comfort. Then be sure to perform them and to encourage the patient and family members to help. Include the patient in decisions related to his care whenever possible.
- ⌞ Administer ordered pain medication as required. Monitor and document the medication's effectiveness.
- ⌞ Perform comfort measures, such as repositioning and relaxation techniques.
- ⌞ Monitor respiratory status. Provide oxygen as ordered, and assist the patient to a comfortable position (Fowler's position, for example) that allows for maximal chest expansion to relieve respiratory distress.
- ⌞ If mobility decreases, turn the patient frequently. Provide skin care, particularly over bony prominences. Encourage him to be as active as possible.
- ⌞ Prevent infection. Adhere to strict aseptic technique when suctioning the patient, changing dressings or I.V. tubing, and performing any type of invasive procedure. Monitor body temperature and white blood cell count closely.
- ⌞ Monitor I.V. fluid intake to avoid circulatory overload and pulmonary congestion.
- ⌞ Watch for treatment complications by observing and listening to the patient. Also monitor laboratory studies and vital signs. Perform appropriate nursing measures to prevent or alleviate complications. Report complications.

Patient teaching

- ⌞ Show the patient how to perform relaxation techniques. Also demonstrate breathing and positioning variations to ease the dyspnea associated with progressive disease.
- ⌞ Explain all procedures and treatments. Schedule time to answer the patient's questions.
- ⌞ Teach the patient measures (such as increasing fluid intake) to minimize adverse effects of treatment.
- ⌞ When appropriate, teach the patient and family members procedures to maximize breathing and prevent the complications of immobility.
- ⌞ Explain how to practice meticulous hand-washing and aseptic techniques to avoid infection.
- ⌞ Refer the patient to the social services department, support groups, and community or professional mental health resources to help him and family members cope with terminal illness.

Abdominal and pelvic neoplasms

Cancers in the abdominal and pelvic region of the body can obstruct the affected organ or disrupt its secretory or absorptive functions and obstruct the flow of GI contents.

BLADDER CANCER

Benign or malignant tumors may develop on the bladder wall surface or grow within the wall and quickly invade underlying muscles. About 90% of bladder cancers are transitional cell carcinomas, arising from the transitional epithelium of mucous membranes. They may result from malignant transformation of benign papillomas. Less common bladder tumors include adenocarcinomas, epidermoid carcinomas, squamous cell carcinomas, sarcomas, tumors in bladder diverticula, and carcinoma in situ.

Bladder tumors are most prevalent in people over age 50, are more common in men than in women, and occur more often in densely populated industrial areas.

Causes

Certain environmental carcinogens, such as tobacco, nitrates, coffee, and 2-naphthylamine, are known to predispose a person to transitional cell tumors. This places certain industrial workers at high risk for developing such tumors, including rubber workers, weavers, aniline dye workers, hairdressers, petroleum workers, spray painters, and leather finishers. The latency period between exposure to the carcinogen and development of signs and symptoms is about 18 years.

Squamous cell carcinoma of the bladder is common in geographic areas where schistosomiasis is endemic, such as Egypt. What is more, it's also associated with chronic bladder irritation and infection in people with renal calculi, indwelling urinary catheters, chemical cystitis caused by cyclophosphamide, and pelvic irradiation.

Complications

If bladder cancer progresses, complications include bone metastases and problems resulting from tumor invasion of contiguous viscera.

Assessment findings

The patient typically reports gross, painless, intermittent hematuria (often with clots). He may complain of suprapubic pain after voiding (which suggests invasive lesions). He also may complain of bladder irritability, urinary frequency, nocturia, and dribbling. If he reports flank pain, he may have an obstructed ureter.

Diagnostic tests

To confirm a bladder cancer diagnosis, the patient typically undergoes cystoscopy and biopsy. If the test results show cancer cells, further studies will determine the cancer stage and treatment. Cystoscopy should be performed when hematuria first appears. If the patient receives an anesthetic during the procedure, he also may undergo a bimanual examination to detect whether the bladder is fixed to the pelvic wall.

Excretory urography can identify a large, early-stage tumor or an infiltrating tumor; delineate functional problems in the upper urinary tract; assess hydronephrosis; and detect rigid deformity of the bladder wall.

Urinalysis can detect blood and malignant cells in the urine.

Retrograde cystography evaluates bladder structure and integrity. Test results also help confirm a bladder cancer diagnosis. A bone scan can detect metastases. A computed tomography scan can define the thickness of the involved bladder wall and disclose enlarged retroperitoneal lymph nodes. Ultrasonography can find metastases in tissues beyond the bladder and can distinguish a bladder cyst from a bladder tumor.

Laboratory tests, such as a complete blood count and chemistry profile, may be ordered to evaluate conditions such as anemia that are associated with bladder cancer.

Treatment

The cancer's stage, the patient's lifestyle, other health problems, and mental outlook all help to determine which therapy is selected. Surgery, chemotherapy, radiation therapy, or one of several new treatments may be used. (See [New bladder cancer treatments](#).)

Superficial bladder tumors are removed cytoscopically by *transurethral resection* and electrically by *fulguration*. This usually is adequate treatment if the tumor hasn't invaded the muscle. Additional tumors may develop, and fulguration may have to be repeated every 3 months for years. When the tumors penetrate the muscle layer or recur frequently, cystoscopy with fulguration is no longer appropriate.

Intravesical chemotherapy is used for treating superficial tumors (especially tumors in many sites) and for preventing tumor recurrence. This therapy directly washes the bladder with anticancer drugs. Commonly used agents include thioteпа, doxorubicin, and mitomycin.

Intravesical administration of the live, attenuated *bacille Calmette-Guerin (BCG) vaccine* has proved successful in treating superficial bladder cancers, particularly primary and relapsed carcinoma in situ.

Tumors too large to be treated cytoscopically require *segmental bladder resection*. This surgery, which removes a full-thickness section of the bladder, is feasible only if the tumor isn't near the bladder neck or ureteral orifices. Bladder instillations of thioteпа after transurethral resection also may help.

For infiltrating bladder tumors, the treatment of choice is *radical cystectomy* with a pretreatment course of 2,000-rad external beam radiation therapy directed at the bladder. During the operation, the surgeon removes the bladder with prevesical fat, lymph nodes, urethra, and the prostate and seminal vesicles (in men) or the uterus and adnexa uteri (in women). Next, a urinary diversion is constructed, usually an ileal conduit. After surgery, the patient wears an external pouch continuously. Other diversions are *ureterostomy*, *nephrostomy*, *continent vesicostomy (Kock pouch)*, *ileal bladder*, and *ureterosigmoidostomy*. (See [Common urinary diversions](#).)

New bladder cancer treatments

New therapies offer promise for patients with bladder cancer. Treatments include photodynamic therapy, gene therapy, and immunotoxin therapy.

Photodynamic therapy
Photodynamic therapy requires I.V. injection of a photosensitizing agent called hematoporphyrin derivative (HPD). Malignant tissue appears to have an affinity for HPD, so superficial bladder cancer cells readily absorb the drug. A cystoscope is then used to introduce laser energy into the bladder; exposing the HPD-impregnated tumor cells to laser energy kills them.

However, HPD sensitizes not only tumor tissue but also normal tissue, so any patient who receives this therapy must avoid sunlight for about 30 days. Precautions involve wearing protective clothing (including gloves and a face mask), drawing heavy curtains at home during the day, scheduling outdoor travel for night, and conducting exercises inside or outdoors at night to promote circulation, joint mobility, and muscle activity. After 30 days, the patient can gradually return to normal daylight activities.

Gene therapy
Researchers have determined that mutations in tumor suppressor cells, such as p53, cause abnormal bladder cancer cell growth. Although still in the early stages of investigation, the researchers are studying methods of infecting bladder cancer cells with viruses that contain a normal p53 gene in the hope that the normal gene, when placed in a bladder cancer cell, will cause normal cell growth.

Immunotoxin therapy
Although still in early investigational stages, researchers have hope that immunotoxin therapy will someday effectively treat bladder cancer. Immunotoxins are laboratory-manufactured antibodies with powerful toxins attached to them that can recognize cancer cells. After an antibody recognizes a cancer cell, it releases the toxin, which enters the cancer cell and kills it.

Note: A male patient may become impotent after radical cystectomy and urethrectomy because the operation damages the sympathetic and the parasympathetic nerves that control erection and ejaculation. At a later date, treatment may include a penile implant to make sexual intercourse (without ejaculation) possible. Treatment for patients with advanced bladder cancer includes cystectomy to remove the tumor, radiation therapy, and combination systemic chemotherapy with cisplatin, the most active agent. Other agents include doxorubicin, cyclophosphamide, and fluorouracil. In some instances, this combined treatment successfully arrests the disease.

Nursing diagnoses

u Altered urinary elimination u Anxiety u Body image disturbance u Fear u Impaired skin integrity u Ineffective family coping: Disabling u Ineffective individual coping u Pain u Risk for infection u Sexual dysfunction

Key outcomes

- u The patient will maintain adequate intake and output.
- u The patient will express feelings of comfort and decreased pain.
- u The patient will remain free from signs and symptoms of infection.
- u The patient will exhibit adequate coping mechanisms.

u The patient will voice feelings about potential or actual changes in sexual activity.

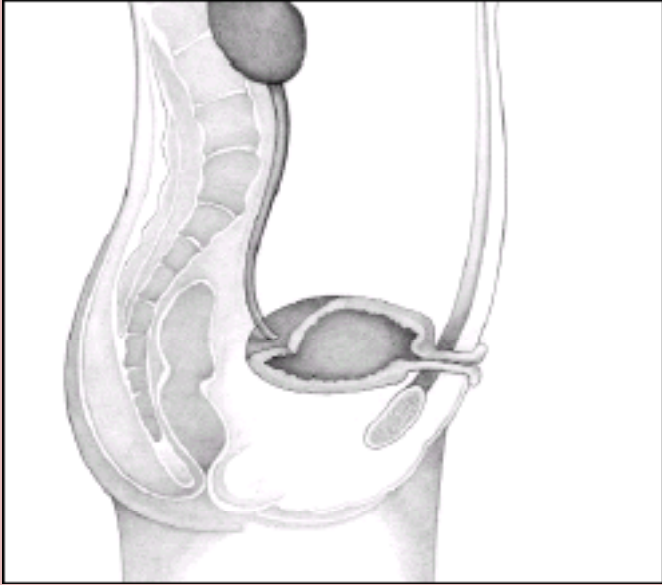

Nursing interventions

- u Listen to the patient's fears and concerns. Stay with him during periods of severe stress and anxiety, and provide psychological support. As appropriate, encourage him to express typical concerns about the cancer's extent, the surgical procedure, an altered body image (especially if he undergoes urinary diversion surgery), and sexual dysfunction.
- u To relieve discomfort, provide ordered pain medications as necessary. Implement comfort measures and distractions to help the patient relax.
- u Before surgery, offer information and support when the patient and enterostomal therapist select a stoma site. The therapist assesses the patient's abdomen in various positions. The typical site—in the rectus muscle—minimizes the risk of subsequent herniation. Advise the patient to make sure that he can easily see the selected site.

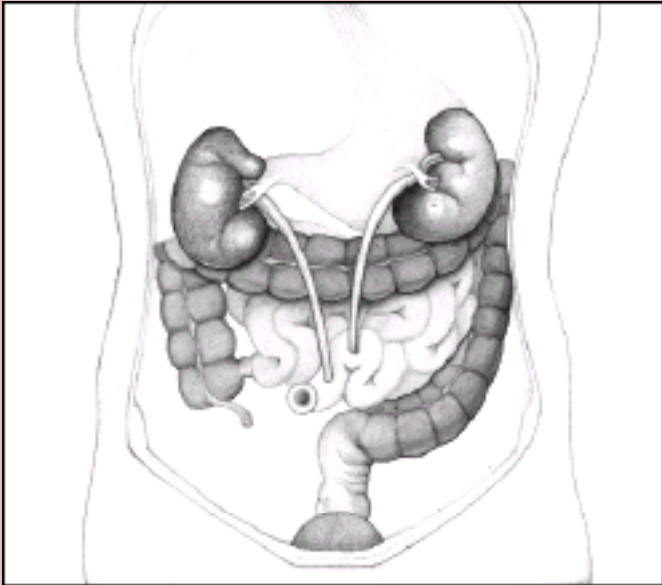

Common urinary diversions

Various urinary diversions may be done for bladder cancer patients. Two of the most commonly performed types include continent vesicostomy and ileal conduit.

Continent vesicostomy
This alternative to the ileal conduit diverts urine to a reservoir reconstructed from part of the bladder wall. The reservoir empties through a stoma on the abdomen. Accumulated urine can be drained by inserting a catheter through the stoma.

Ileal conduit
This preferred procedure diverts urine through a segment of the ileum to a stoma on the abdomen (as shown). Because urine empties continuously the patient needs to wear a collecting device (or pouch).

- u After surgery, encourage the patient to look at the stoma. If he has difficulty doing this, leave the room for a few minutes when the stoma is exposed. Offer him a mirror to make viewing easier.
- u To obtain a specimen for culture and sensitivity tests after urinary diversion surgery, catheterize the patient, using sterile technique. Insert a lubricated catheter tip into the stoma about 2" (5 cm). Many facilities use a double telescope-type catheter for ileal conduit catheterization.
- u After ileal conduit surgery, watch for these complications: wound infection, enteric fistulas, urine leaks, ureteral obstruction, bowel obstruction, and pelvic abscesses. After radical cystectomy and construction of a urine reservoir, watch for these complications: incontinence, difficult catheterization, urine reflux, obstruction, bacteriuria, and electrolyte imbalances.
- u If the patient is receiving chemotherapy, watch for complications resulting from the particular drug regimen.
- u If the patient is having radiation therapy, watch for these complications: radiation enteritis, colitis, and skin reactions. Preoperative radiation therapy may produce radiation enteritis, requiring aggressive parenteral support postoperatively. Residual damage of the bowel and the skin resembles the damage that occurs after radiation therapy for prostate cancer. As appropriate, implement measures to prevent or alleviate complications.

Patient teaching

- u Tell the patient what to expect from diagnostic tests. For example, make sure he understands that he may be anesthetized for cystoscopy. After the test results are known, explain the implications to the patient and his family.
- u Provide complete preoperative teaching. Include an explanation of the operation the patient is to undergo. Discuss equipment and procedures that the patient can expect postoperatively. Demonstrate essential coughing and deep breathing exercises. Encourage the patient to ask questions.

For the patient with a urinary stoma:

- u Teach the patient how to care for his urinary stoma. Instruction usually begins 4 to 6 days after surgery. Encourage appropriate relatives or other caregivers to attend the teaching session. Advise them beforehand that a negative reaction to the stoma can impede the patient's adjustment.
- u If the patient is to wear a urine collection pouch, teach him how to prepare and apply it. First, find out whether he will wear a reusable pouch or a disposable pouch. If he chooses a reusable pouch, he needs at least two to wear alternately.
- u Teach the patient to select the right-sized pouch by measuring the stoma and choosing a pouch with an opening that leaves a 1/8" (0.3 cm) margin of skin around the stoma.
- u Instruct the patient to remeasure the stoma after he goes home in case the size changes.
- u Advise him to be sure the pouch has a push-button or twist-type valve at the bottom to allow for drainage.
- u Tell him to empty the pouch when it's one-third full, or every 2 to 3 hours.
- u Offer the patient tips on effective skin seal. Explain that urine tends to destroy skin barriers that contain mostly karaya (a natural skin barrier). Suggest that he select a barrier made of urine-resistant synthetics with little or no karaya. Advise him to check the pouch frequently to ensure that the skin seal remains intact. Explain that a

good skin seal can last from 3 to 6 days, so he need only change the pouch that often. If desired, he can wear a loose-fitting elastic pouch belt for added security. Tell the patient that the ileal conduit stoma should reach its permanent size about 2 to 4 months after surgery.

- u Explain that the surgeon constructs the ileal conduit from the intestine, which normally produces mucus. For this reason, the patient will see mucus in the drained urine. Assure him that this is normal.
- u Teach the patient to provide stoma care. Show him how to keep the skin around the stoma clean and free of irritation. Instruct him to remove the pouch, wash the skin with water and mild soap, and rinse well with clear water to remove soapy residue. Tell him to gently pat the skin dry. Never rub.
- u Demonstrate how to place a gauze sponge soaked in vinegar water (1 part vinegar to 3 parts water) over the stoma for a few minutes to prevent a buildup of uric acid crystals. When he cares for his skin, suggest that he place a rolled-up dry sponge over the stoma to collect (or wick) draining urine.
- u Next, instruct him to coat his skin with a silicone skin protectant and then cover with the collection pouch. If skin irritation or breakdown occurs, he should apply a layer of antacid precipitate to the clean, dry skin before coating it with the silicone skin protectant.
- u To ensure a better seat and minimize skin breakdown, teach the patient how to use various products to level uneven abdominal surfaces, such as gullies, scars, and wedges.
- u If the patient with surgically induced impotence was sexually active before surgery, encourage the patient's partner to express support and understanding. Suggest alternative methods of sexual expression.
- u Postoperatively, tell the patient with a urinary stoma to avoid heavy lifting and contact sports. Encourage him to participate in his usual athletic and physical activities.
- u Refer the patient to the American Cancer Society or the United Ostomy Association, as appropriate.
- u Before discharge, arrange for follow-up home nursing care. Also refer the patient for services provided by the enterostomal therapist.

COLORECTAL CANCER

Colorectal cancer is the second most common visceral neoplasm in the United States and Europe. It's equally distributed between men and women.

Malignant tumors of the colon or rectum are almost always adenocarcinomas. About half of these are sessile lesions of the rectosigmoid area; the rest are polypoid lesions.

Colorectal cancer progresses slowly, remaining localized for a long time. With early diagnosis, the 5-year survival rate is 50%. It is potentially curable in 75% of patients if an early diagnosis allows resection before nodal involvement.

Causes

Although the exact cause of colorectal cancer is unknown, studies show a greater incidence in areas of higher economic development, suggesting a relationship to a diet that includes excess animal fat, especially from beef, and low fiber.

Other factors that magnify the risk of developing colorectal cancer include diseases of the digestive tract, a history of ulcerative colitis (cancer usually starts in 11 to 17 years), and familial polyposis (cancer almost always develops by age 50).

Complications

As the tumor grows and encroaches on the abdominal organs, abdominal distention and intestinal obstruction occur. Anemia may develop if rectal bleeding isn't treated.

Assessment findings

Signs and symptoms depend on the tumor's location. If it develops on the colon's right side, the patient probably won't have signs and symptoms in the early stages because the stool is still in liquid form in that part of the colon. He may have a history of black, tarry stools, however, and report anemia, abdominal aching, pressure, and dull cramps. As the disease progresses, he may complain of weakness, diarrhea, obstipation, anorexia, weight loss, and vomiting.

A tumor on the left side of the colon causes symptoms of obstruction even in the early disease stages because stools are more completely formed when they reach this part of the colon. The patient may report rectal bleeding (often ascribed to hemorrhoids), intermittent abdominal fullness or cramping, and rectal pressure.

As the disease progresses, obstipation, diarrhea, or ribbon- or pencil-shaped stools may develop. The patient may note that the passage of flatus or stool relieves his pain. He may also report obvious bleeding during defecation and dark or bright red blood in the feces and mucus in or on the stools.

A patient with a rectal tumor may report a change in bowel habits, often beginning with an urgent need to defecate on arising (morning diarrhea) or obstipation alternating with diarrhea. He also may notice blood or mucus in the stools and complain of a sense of incomplete evacuation. Late in the disease, he may complain of pain that begins as a feeling of rectal fullness and progresses to a dull, sometimes constant ache confined to the rectum or sacral region.

Inspection of the abdomen may reveal distention or visible masses. Abdominal veins may appear enlarged and visible from portal obstruction. The inguinal and supraclavicular nodes may also appear enlarged. You may note abnormal bowel sounds on abdominal auscultation. Palpation may reveal abdominal masses. Right side tumors usually feel bulky; tumors of the transverse portion are more easily detected.

ASSESSMENT TIP Generalized tenderness makes accurate palpation difficult. To accurately assess tenderness in such a patient, place your stethoscope on the abdomen, but instead of auscultating, press into the abdomen with the stethoscope as you would with your hands and see if the patient still complains of pain.

Diagnostic tests

Several tests support a diagnosis of colorectal cancer.

Digital rectal examination can detect almost 15% of colorectal cancers. Specifically, it can detect suspicious rectal and perianal lesions. Fecal occult blood test can detect blood in stools, a warning sign of rectal cancer.

Proctoscopy or sigmoidoscopy permits visualization of the lower GI tract. It can detect up to 66% of colorectal cancers. Colonoscopy permits visual inspection and photography of the colon up to the ileocecal valve and provides access for polypectomies and biopsies of suspected lesions.

Excretory urography verifies bilateral renal function and allows inspection for displacement of the kidneys, ureters, or bladder by a tumor pressing against these structures.

Barium enema studies, using a dual contrast of barium and air, allow the location of lesions that aren't detectable manually or visually. Barium examination shouldn't precede colonoscopy or excretory urography because barium sulfate interferes with these tests.

A computed tomography scan allows better visualization if a barium enema yields inconclusive results or if metastasis to the pelvic lymph nodes is suspected.

Carcinoembryonic antigen, although not specific or sensitive enough for early diagnosis of colorectal cancer, permits patient monitoring before and after treatment to detect metastasis or recurrence. (See [Staging colorectal cancer.](#))

Treatment

The most effective treatment for colorectal cancer is surgery to remove the malignant tumor and adjacent tissues, along with any lymph nodes that may contain cancer

cells. After surgery, treatment continues with chemotherapy, radiation therapy, or both.

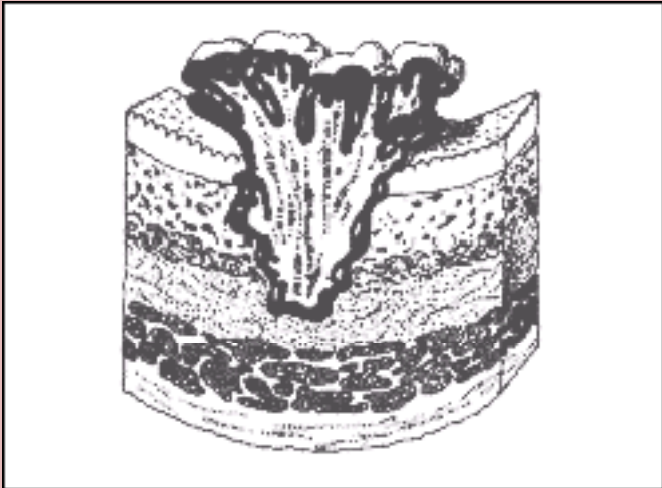

The type of surgery depends on tumor location:

u *Cecum and ascending colon.* Tumors in these areas call for right hemicolectomy (for advanced disease). Surgery may include resection of the terminal segment of the ileum, cecum, ascending colon, and right half of the transverse colon with corresponding mesentery.

Staging colorectal cancer

Named for pathologist Cuthbert Dukes, the Dukes cancer classification assigns tumors to four stages. These stages (with substages) reflect the extent of bowel mucosa and bowel wall infiltration, lymph node involvement, and metastasis. Use this summary to clarify your patient's cancer stage and prognosis.

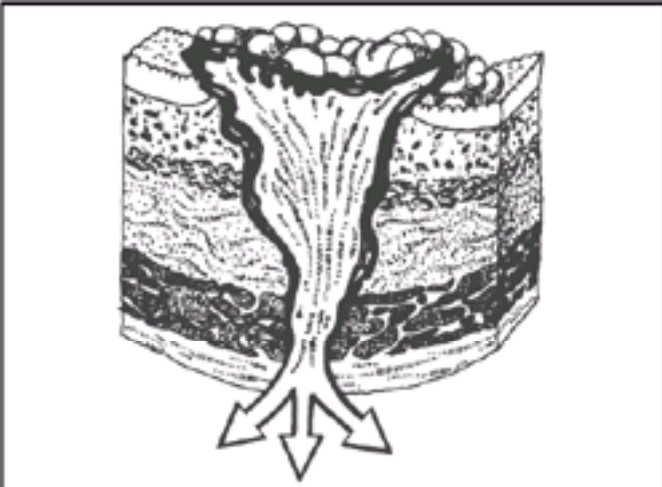

Stage A
Malignant cells are confined to the bowel mucosa, and the lymph nodes contain no cancer cells. Treated promptly, about 80% of these patients remain disease-free 5 years later.

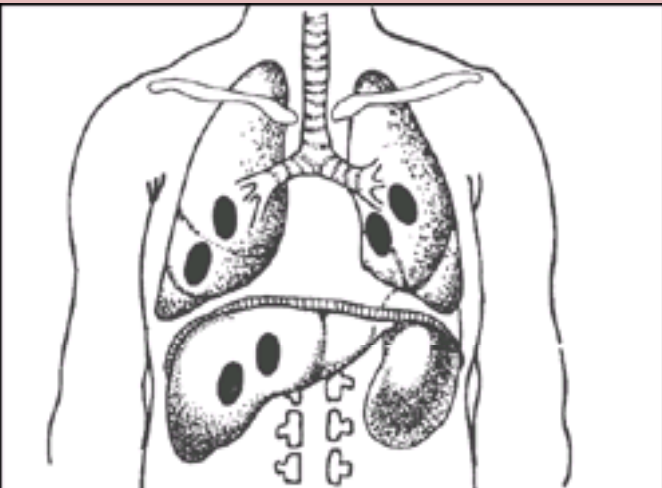

Stage B
Malignant cells extend through the bowel mucosa but remain within the bowel wall. The lymph nodes are normal. In substage B₂, all bowel wall layers and immediately adjacent structures contain malignant cells, but the lymph nodes remain normal. About 50% of patients with substage B₂ survive for 5 or more years.

Stage C
Malignant cells extend into the bowel wall and the lymph nodes. In substage C₂, malignant cells extend through the entire thickness of the bowel wall. The lymph nodes also contain malignant cells. The 5-year survival rate for patients with stage C disease reaches about 25%.

Stage D
Metastasized to distant organs by way of the lymph nodes and mesenteric vessels, malignant cells typically lodge in the lungs and liver. Only 5% of patients with stage D cancer survive 5 or more years.

u *Proximal and middle transverse colon.* Surgery consists of right colectomy that includes the transverse colon and mesentery corresponding to midcolic vessels, or segmental resection of the transverse colon and associated midcolic vessels.

u *Sigmoid colon.* Surgery usually is limited to the sigmoid colon and mesentery.

u *Upper rectum.* A tumor in this area usually requires anterior or low anterior resection. A newer method, using a stapler, allows for much lower resections than

previously possible.

- *Lower rectum.* Abdominoperineal resection and permanent sigmoid colostomy are required.

If metastasis has occurred, or if the patient has residual disease or a recurrent inoperable tumor, he needs chemotherapy. Drugs used in such treatment commonly include fluorouracil combined with levamisole or leucovorin. Researchers are evaluating the effectiveness of fluorouracil with recombinant interferon alfa-2a.

Radiation therapy, used before or after surgery, induces tumor regression.

Nursing diagnoses

▫ Altered nutrition: Less than body requirements ▫ Altered oral mucous membranes ▫ Anxiety ▫ Body image disturbance ▫ Constipation ▫ Diarrhea ▫ Fear ▫ Fluid volume deficit ▫ Impaired skin integrity ▫ Ineffective family coping: Disabling ▫ Ineffective individual coping ▫ Pain ▫ Risk for infection ▫ Sexual dysfunction

Key outcomes

- The patient won't experience further weight loss.
- The patient's fluid volume will be maintained within normal range.
- The patient's mucous membranes will remain intact.
- The patient will express positive feelings about himself.
- The patient will report feeling less tension or pain.
- The patient will express increased sense of well-being.

Nursing interventions

- Before colorectal surgery, monitor the patient's diet modifications and administer laxatives, enemas, and antibiotics, as ordered. These measures help clean the bowel and decrease abdominal and peritoneal cavity contamination during surgery.
- After surgery, monitor the patient's visual signs, intake and output, and fluid and electrolyte balance. Also monitor for complications, including anastomotic leaks, hemorrhage, irregular bowel function, phantom rectum, ruptured pelvic peritoneum, stricture, urinary dysfunction, and wound infection.
- Care for the patient's incision and, if appropriate, the stoma. To decrease discomfort, administer ordered analgesics as necessary, and perform comfort measures, such as repositioning.
- Encourage the patient to look at the stoma and to participate in caring for it as soon as possible. Teach good hygiene and skin care. Allow him to shower or bathe as soon as the incision heals.
- Consult with an enterostomal therapist, if available, for questions on setting up a postoperative regimen for the patient.
- Watch for adverse effects of radiation therapy (nausea, vomiting, hair loss, malaise) and provide comfort measures and reassurance.
- During chemotherapy, watch for complications (such as infection) and expected adverse effects. Prepare the patient for these problems. Take steps to reduce these effects; for example, by rinsing the patient's mouth with normal saline mouthwash to deter ulcers.
- To help prevent infection, use strict aseptic technique when caring for I.V. catheters and providing wound care. Change I.V. tubing and sites as directed by facility policy. Have the patient wash his hands before and after meals and after going to the bathroom.
- Listen to the patient's fears and concerns, and stay with him during periods of severe stress and anxiety.
- Encourage the patient to identify actions and care measures that will promote his comfort and relaxation. Try to perform these measures, and encourage the patient and family members to do so as well.
- Whenever possible, include the patient and family members in care decisions.

Patient teaching

- Throughout therapy, answer the patient's questions and tell him what to expect from surgery and other therapy.
- If appropriate, explain that the stoma will be red, moist, and swollen; reassure the patient that postoperative swelling eventually subsides.
- Show the patient a diagram of the intestine before and after surgery, stressing how much of the bowel remains intact. Supplement your teaching with instruction booklets (available for a fee from the United Ostomy Association and free from various companies that manufacture ostomy supplies). Arrange a postsurgical visit from a recovered ostomy patient.
- Prepare the patient for the I.V. lines, nasogastric tube, and indwelling urinary catheter he'll have postoperatively.
- Preoperatively, teach the patient the coughing and deep-breathing exercises he should use postoperatively.
- Explain to the patient's family that their positive reactions foster the patient's adjustment.
- If appropriate, instruct the patient with a sigmoid colostomy to perform his own irrigation as soon as he's able after surgery. Advise him to schedule irrigation for the time of the day when he normally evacuates. Many patients find that irrigating every 1 to 3 days is necessary for regular evacuation.
- Direct the patient to follow a high-fiber diet.
- If flatus, diarrhea, or constipation occurs, tell the patient to eliminate suspected causative foods from his diet. Explain that he may reintroduce them later. Teach him which foods may alleviate constipation, and encourage him to increase his fluid and fiber intake.
- If diarrhea is a problem, advise the patient to try eating applesauce, bananas, or rice. Caution him to take laxatives or antidiarrheal medications only as prescribed by his doctor.
- When appropriate, explain that after several months, many patients with an ostomy establish control with irrigation and no longer need to wear a pouch. A stoma cap or gauze sponge placed over the stoma protects it and absorbs mucoid secretions. Explain that before achieving such control, the patient can resume physical activities—including sports—provided he isn't at risk for injuring the stoma or surrounding abdominal muscles.
- If the patient wants to swim, he can place a pouch or stoma cap over the stoma. He should avoid heavy lifting, which can cause herniation or prolapse through weakened muscles in the abdominal wall. Suggest that he consider a structured, gradually progressive exercise program to strengthen abdominal muscles. Such a program can be instituted under a doctor's supervision.
- Emphasize the need for keeping follow-up appointments. Anyone who has had colorectal cancer runs an increased risk of developing another primary cancer. The patient should have yearly screenings (sigmoidoscopy, digital rectal examination, stool test for blood) and follow-up testing.
- If the patient is to undergo radiation therapy or chemotherapy, explain the treatment to him. Make sure he understands the adverse effects that usually occur and the measures he can take to decrease their severity or prevent their occurrence.
- Instruct the patient and family members about the American Cancer Society's guidelines for colorectal cancer screening: a digital rectal examination annually starting at age 40; periodic sigmoidoscopy and colonoscopy; and a stool test for occult blood annually starting at age 50.
- Refer the patient to a home health care agency that can check on his physical care at home.
- For male patients, suggest sexual counseling; most are impotent for a time after colostomy.

ESOPHAGEAL CANCER

Esophageal cancer is most common in men over age 60 and is nearly always fatal. The disease occurs worldwide, but incidence varies geographically. It is most commonly found in Japan, Russia, China, the Middle East, and the Transkei region of South Africa.

Esophageal tumors are usually fungating and infiltrating. In most cases, the tumor partially constricts the lumen of the esophagus. Regional metastasis occurs early by way of submucosal lymphatics, often fatally invading adjacent vital intrathoracic organs. If the patient survives primary extension, the liver and lungs are the usual sites of distant metastases. Unusual metastasis sites include the bone, kidneys, and adrenal glands.

Most cases (98%) arise in squamous cell epithelium, although a few are adenocarcinomas and fewer still, metanomas and sarcomas. About half the squamous cell cancers occur in the lower portion of the esophagus, 40% in the midportion, and the remaining 10% in the upper or cervical esophagus. Regardless of cell type, the prognosis for esophageal cancer is grim: 5-year survival rates are less than 5%, and most patients die within 6 months of diagnosis.

Causes

Although the cause of esophageal cancer is unknown, several predisposing factors have been identified. These include chronic irritation from heavy smoking or

excessive use of alcohol; stasis-induced inflammation, as in achalasia or stricture; previous head and neck tumors; and nutritional deficiency, as in untreated sprue and Plummer-Vinson syndrome.

Complications

Direct invasion of adjoining structures may lead to severe complications, such as mediastinitis, tracheoesophageal or bronchoesophageal fistula (causing an overwhelming cough when swallowing liquids), and aortic perforation with sudden exsanguination.

Other complications include an inability to control secretions, obstruction of the esophagus, and loss of lower esophageal sphincter control, which can result in aspiration pneumonia.

Assessment findings

Early in the disease, the patient may report a feeling of fullness, pressure, indigestion, or substernal burning. He may also tell you he uses antacids to relieve GI upset. Later, he may complain of dysphagia and weight loss. The degree of dysphagia varies, depending on the extent of disease. At first, the dysphagia is mild, occurring only after the patient eats solid foods, especially meat. Later, the patient has difficulty swallowing coarse foods and, in some cases, liquids.

The patient may complain of hoarseness (from laryngeal nerve involvement), chronic cough (possibly from aspiration), anorexia, vomiting, and regurgitation of food, resulting from the tumor size exceeding the limits of the esophagus. He may also complain of pain on swallowing or pain that radiates to his back.

A patient in the late stages of the disease appears very thin, cachectic, and dehydrated.

Diagnostic tests

X-rays of the esophagus, with barium swallow and motility studies, delineate structural and filling defects and reduced peristalsis. Esophagoscopy, punch and brush biopsies, and exfoliative cytologic tests confirm esophageal tumors.

Bronchoscopy (usually performed after an esophagoscopy) may reveal tumor growth in the tracheobronchial tree. Endoscopic ultrasonography of the esophagus combines endoscopy and ultrasound technology to measure the depth of tumor penetration.

A computed tomography scan may help diagnose and monitor esophageal lesions. Magnetic resonance imaging permits evaluation of the esophagus and adjacent structures.

Treatment

Esophageal cancer usually is advanced when diagnosed, so surgery and other treatments can only relieve disease effects.

Palliative therapy consists of treatment to keep the esophagus open, including dilation of the esophagus, laser therapy, radiation therapy, and installation of prosthetic tubes (such as the Celestin tube) to bridge the tumor. Radical surgery can excise the tumor and resect either the esophagus alone or the stomach and esophagus. Chemotherapy and radiation therapy can slow the growth of the tumor. Gastrostomy or jejunostomy can help provide adequate nutrition. A prosthesis can be used to seal any fistula that develops. Endoscopic laser treatment and bipolar electrocoagulation can help restore swallowing by vaporizing cancerous tissue. If the tumor is in the upper esophagus, however, the laser can't be positioned properly.

Analgesics are used for pain control.

Nursing diagnoses

u Altered nutrition: Less than body requirements u Anxiety u Fatigue u Fear u Fluid volume deficit u Impaired swallowing u Pain u Risk for aspiration u Risk for infection

Key outcomes

- u The patient will maintain weight within an acceptable range.
- u The patient will express feeling increased energy.
- u The patient will maintain fluid volumes within normal range.
- u The patient won't aspirate.
- u The patient will express feelings of comfort and decreased pain.
- u The patient will show no evidence of infection.

Nursing interventions

- u Monitor the patient's nutritional and fluid status, and provide him with high-calorie, high-protein foods. If he's having trouble swallowing solids, puree or liquefy his food, and offer a commercially available nutritional supplement. As ordered, provide tube feedings, and prepare him for supplementary parenteral nutrition.
- u To prevent food aspiration, place the patient in Fowler's position for meals and allow plenty of time to eat. If he regurgitates food after eating, provide mouth care.
- u If the patient has a gastrostomy tube, give food slowly—by gravity—in prescribed amounts (usually 200 to 500 ml). Offer him something to chew before each feeding. This promotes gastric secretions and provides some semblance of normal eating.
- u Administer ordered analgesics for pain relief as necessary. Provide comfort measures, such as repositioning and distractions.
- u After surgery, monitor the patient's vital signs, fluid and electrolyte balance, and intake and output. Immediately report any unexpected changes in the patient's condition. Monitor him for such complications as infection, fistula formation, pneumonia, empyema, and malnutrition.
- u If an anastomosis to the esophagus was performed, position the patient flat on his back to prevent tension on the suture line. Watch for signs of an anastomotic leak.
- u If the patient had a prosthetic tube inserted, make sure it doesn't become blocked or dislodged. This could cause a perforation of the mediastinum or precipitate tumor erosion.
- u After radiation therapy, monitor the patient for such complications as esophageal perforation, pneumonitis and fibrosis of the lungs, and myelitis of the spinal cord.
- u After chemotherapy, take steps to decrease adverse effects, such as providing normal saline mouthwash to help prevent mouth ulcers. Allow the patient plenty of rest, and administer medications as ordered to reduce adverse effects.
- u Protect the patient from infection.
- u Throughout therapy, answer the patient's questions and tell him what to expect from surgery and other therapies. Listen to his fears and concerns, and stay with him during periods of severe anxiety.
- u Encourage the patient to identify actions and care measures that promote his comfort and relaxation. Try to perform these measures, and encourage the patient and family members to do so as well.
- u Whenever possible, include the patient in care decisions.

Patient teaching

- u Explain the procedures the patient is to undergo after surgery—closed chest drainage, nasogastric suctioning, and placement of gastrostomy tubes.
- u If appropriate, instruct family members in gastrostomy tube care. This includes checking tube patency before each feeding, providing skin care around the tube, and keeping the patient upright during and after feeding.
- u Stress the need to maintain adequate nutrition. Ask a dietitian to instruct the patient and family members. If the patient has difficulty swallowing solids, instruct him to puree or liquefy his food and to follow a high-calorie, high-protein diet to minimize weight loss. Also, recommend that he add a commercially available, high-calorie supplement to his diet.
- u Encourage the patient to follow as normal a routine as possible after recovery from surgery and during radiation therapy and chemotherapy. Tell him that this will

- help him maintain a sense of control and reduce the complications associated with immobility.
- u Advise the patient to rest between activities and to stop any activity that tires him or causes pain.
 - u Refer the patient and family members to appropriate organizations, such as the American Cancer Society.

GALLBLADDER AND BILE DUCT CANCERS

Gallbladder and bile duct cancers are usually discovered coincidentally in patients with cholecystitis (about 90% have gallstones); these account for less than 1% of all cancer cases. The predominant type is adenocarcinoma (responsible for 85% to 95% of cases). Squamous cell carcinoma accounts for between 5% and 15%. Mixed-tissue types are rare.

Gallbladder cancer is most prevalent in women over age 60. Because it's usually discovered after cholecystectomy and at an advanced stage, the prognosis is poor. If the cancer invades gallbladder musculature, the survival rate is less than 5%—even after extensive surgery. Although some long-term survivals (4 to 5 years) have been reported, few patients survive more than 6 months after surgery. In most patients, with or without surgery, the disease progresses rapidly. Patients seldom live a year after diagnosis.

Carcinoma of the extrahepatic bile duct causes less than 3% of all cancer deaths in the United States. This disease affects men and women between ages 60 and 70. The usual site is the bifurcation in the common bile duct. About 50% of patients also have gallstones. Carcinoma at the distal end of the common duct is commonly confused with carcinoma of the pancreas. Metastasis affects local lymph nodes, the liver, the lungs, and the peritoneum. Patients typically die of hepatic failure. No staging protocol exists for this type of cancer.

Causes

Whereas tumors of the biliary system are usually related to cholelithiasis, bile duct cancer seems to accompany infestation by liver flukes or other parasites.

The cause of extrahepatic bile duct cancer isn't known; but statistics show an unexplained increase of this cancer in patients with sclerosing cholangitis, portal bacteremia, viral infections, or ulcerative colitis. Suspected causes include failure of an immune mechanism or chronic use of certain drugs by the colitis patient.

Complications

Cholangitis from obstructed bile ducts may develop as disease progresses. Typically, lymph node metastases appear in up to 70% of patients at diagnosis. Direct extension to the liver is also common (affecting up to 90% of patients). Direct extension to the cystic and the common bile ducts, stomach, colon, duodenum, and jejunum also occurs and produces obstructions. Metastases further spread by portal or hepatic veins to the peritoneum, ovaries, and lower lung lobes.

Assessment findings

The patient history may reveal pain centered in the epigastric area or in the right upper quadrant. The patient may describe the pain as sporadic rather than continuous. Like a patient with cholecystitis, she may report weight loss and fatigue resulting from anorexia, nausea, and vomiting. She also may report pruritus.

Inspection may identify scleral or gingival jaundice (usually associated with advanced disease in gallbladder cancer patients).

Palpation in the right upper quadrant reveals gallbladder enlargement.

Diagnostic tests

Liver function tests—to evaluate bilirubin, urine bile and bilirubin, and urobilinogen balances—show elevated levels in more than half of gallbladder cancer patients. Serum alkaline phosphatase levels are consistently elevated. A liver-spleen scan detects abnormalities. Cholecystography may demonstrate stones or calcification ("porcelain" gallbladder). Magnetic resonance imaging may show areas of tumor growth. Cholangiography may outline a common bile duct obstruction.

Several tests help to confirm extrahepatic bile duct carcinoma. Liver function studies indicate biliary obstruction; elevated bilirubin (5 to 30 mg/dl), alkaline phosphatase, and blood cholesterol levels; prolonged prothrombin time; and response to vitamin K. Endoscopic retrograde cholangiopancreatography identifies the tumor site and permits tissue specimen retrieval for biopsy.

Treatment

Surgery is the treatment of choice for gallbladder cancer, including cholecystectomy, common bile duct exploration, T-tube drainage, and wedge excision of hepatic tissue.

As a rule, surgery can relieve obstruction and jaundices, resulting from extrahepatic bile duct cancer. The procedure depends on the cancer site and may include cholecystoduodenostomy or T-tube drainage of the common bile duct.

Radiation therapy may be palliative, and adjuvant chemotherapy (infrequently used) may produce some good results.

Nursing diagnoses

- u Altered nutrition: Less than body requirements u Altered tissue perfusion (cardiopulmonary) u Anxiety u Fear u Impaired skin integrity u Ineffective breathing pattern u Ineffective family coping: Disabling u Ineffective individual coping u Pain u Risk for infection u Risk for injury

Key outcomes

- u The patient will show no further evidence of weight loss.
- u The patient and family members will communicate understanding of special dietary needs.
- u The patient will avoid skin breakdown or infection around the T-tube site.
- u The patient will maintain adequate cardiac output.
- u The patient will maintain adequate ventilation.
- u The patient will express feelings of comfort and decreased pain.

Nursing interventions

- u Listen to the patient's fears and concerns. Stay with her when her stress and anxiety levels increase. Encourage her to identify actions and care measures that promote comfort and relaxation.

After biliary resection:

- u Provide meticulous skin care, using strict aseptic technique when caring for the incision and surrounding tissue.
- u Give pain medications as ordered. Place the patient in low-Fowler's position to promote comfort.
- u Prevent respiratory problems by encouraging the patient to cough and breathe deeply despite the high incision, which promotes shallow breaths. Provide analgesics. Also show the patient how to splint the abdomen with a pillow or an abdominal binder. This eases discomfort and promotes greater respiratory efforts.
- u Check the patient's intake and output carefully. Watch for electrolyte imbalances. Monitor I.V. solutions to avoid overloading the cardiovascular system.
- u If the patient has an NG tube and a T-tube in place after surgery, record the amount and color of drainage at each shift. These tubes may remain for 24 to 72 hours

to relieve distention and promote drainage of blood, bile, and serosanguineous fluid.

- u Secure the T-tube and the NG tube to minimize tension and prevent them from being pulled out.
- u Encourage deep-breathing and coughing exercises.

During radiation therapy:

- u Encourage the patient to eat high-calorie, well-balanced meals.
- u Offer fluids such as ginger ale to minimize nausea and vomiting.
- u Watch for radiation's adverse effects, such as nausea, vomiting, hair loss, malaise, and diarrhea. Promote comfort measures and offer reassurance as appropriate.

During chemotherapy:

- u Watch for complications such as infection. Prepare the patient to cope with expected adverse effects.

Patient teaching

- u Offer information and support to help the patient and family members deal with their initial fears and reactions to the diagnosis.
- u Explain postoperative procedures. Prepare the patient for intubation with an NG tube, a T-tube, or I.V. tubes.
- u Preoperatively, teach coughing and deep-breathing exercises that the patient should perform postoperatively.
- u Discuss ordered treatments, such as radiation therapy and chemotherapy, with the patient and her family. Make sure the patient understands the implications of treatments. Describe potential adverse effects, and advise her to notify the doctor if they persist.
- u If appropriate, direct the patient and family members to facility and community services, such as cancer support groups and hospice care.

GASTRIC CANCER

Although gastric cancer is common throughout the world in people of all races, its incidence exhibits unexplained geographic, cultural, and gender differences. For example, mortality from this disorder is high in Japan, Iceland, Chile, and Austria. Incidence is also higher in men over age 40.

Over the past 25 years in the United States, the incidence of gastric cancer has decreased 50%, with the resulting death rate now one-third of what it was 30 years ago. This decrease has been attributed, without proof, to the improved, well-balanced diets most Americans enjoy and to refrigeration, which reduces the number of nitrate-producing bacteria.

Gastric cancer occurs more commonly in some parts of the stomach than in others; the pyloric area accounts for 50% and the lesser curvature for 25% of the incidence. This adenocarcinoma rapidly infiltrates the regional lymph nodes, omentum, liver, and lungs by way of the walls of the stomach, duodenum, and esophagus; the lymphatic system; adjacent organs; the bloodstream; and the peritoneal cavity.

The patient's prognosis depends on the stage of the disease at the time of diagnosis. Overall, the 5-year survival rate is about 15%.

Causes

Although the cause of gastric cancer is unknown, predisposing factors, such as gastritis with gastric atrophy, increase the risk. Genetic factors also have been implicated. People with type A blood have a 10% increased risk, and the disease occurs more commonly in people with a family history of such cancer.

Dietary factors also seem to have an effect. For instance, certain types of food preparation and preservation (especially smoked foods, pickled vegetables, and salted fish and meat) and physical properties of some foods increase the risk. High alcohol consumption and smoking increase the chances of developing gastric cancer.

Complications

Malnutrition occurs when the stomach can't digest protein, and GI obstruction develops as the tumor enlarges. Iron deficiency anemia results as the tumor causes ulceration and bleeding. If the patient has pernicious anemia, the tumor can interfere with the production of intrinsic factor needed for vitamin B₁₂ absorption. As the cancer metastasizes to other structures, related complications appear.

Assessment findings

In the early stages, the patient may complain of pain in the back or in the epigastric or retrosternal areas that is relieved with nonprescription medications. (He may not report this symptom because he doesn't realize its significance.) The patient typically reports a vague feeling of fullness, heaviness, and moderate abdominal distention after meals.

Depending on cancer progression, the patient may report weight loss, resulting from appetite disturbance, nausea, and vomiting. (He may report coffee-ground vomitus if the tumor is located in the cardia.) He may also complain of weakness and fatigue. If the tumor is located in the proximal area of the stomach, he may experience dysphagia.

Palpation of the abdomen may disclose a mass. You may also palpate enlarged lymph nodes, especially the supraclavicular and axillary nodes. Other assessment findings depend on the extent of the disease and location of metastasis.

Diagnostic tests

Barium X-rays of the GI tract with fluoroscopy show changes that suggest gastric cancer. Changes include a tumor or filling defect in the outline of the stomach, loss of flexibility and distensibility, and abnormal gastric mucosa with or without ulceration.

Gastroscopy with fiberoptic endoscope is used to help rule out other diffuse gastric mucosal abnormalities by allowing direct visualization. Gastroscopic biopsy permits evaluation of gastric mucosal lesions. Photography during gastroscopy provides a permanent record of gastric lesions that can later be used to judge disease progression and the effectiveness of treatment.

Gastric acid stimulation test discloses whether the stomach secretes acid properly.

Blood studies are used to monitor the course of the disease, complications, and the effectiveness of treatment. These studies include a complete blood count, chemistry profiles, arterial blood gas analysis, liver function studies, and a carcinoembryonic antigen radioimmunoassay.

Certain other studies may rule out specific organ metastases. These include computed tomography scans, chest X-rays, liver and bone scans, and liver biopsy.

Treatment

Surgery to remove the tumor often is the treatment of choice. Excision of the lesion with appropriate margins is possible in more than one-third of patients. Even in a patient whose disease isn't considered surgically curable, resection eases symptoms and improves the potential benefits of the chemotherapy and radiation therapy that usually follow surgery.

The nature and extent of the lesion determine the type of surgery. Surgical procedures include gastroduodenostomy, gastrojejunostomy, partial gastric resection, and

total gastrectomy. If metastasis has occurred, the omentum and spleen may have to be removed. (See [Understanding gastric surgery.](#))

Chemotherapy for GI tumors may help control signs and symptoms and prolong survival. Gastric adenocarcinomas respond to several agents, including fluorouracil, carmustine, doxorubicin, and mitomycin. Antiemetics can control nausea, which intensifies as the tumor grows. In the more advanced stages, the patient may need sedatives and tranquilizers to control overwhelming anxiety. Opioid analgesics can relieve severe and unremitting pain.

If the patient has a nonresectable or partially resectable tumor, radiation therapy is effective if combined with chemotherapy. The patient should receive this therapy on an empty stomach but not preoperatively because it may damage viscera and impede healing.

Treatment with antispasmodics and antacids may help relieve GI distress.

Nursing diagnoses

- u Altered nutrition: Less than body requirements
- u Altered oral mucous membrane
- u Anxiety
- u Diarrhea
- u Fatigue
- u Fear
- u Impaired gas exchange
- u Impaired skin integrity
- u Impaired swallowing
- u Pain
- u Risk for infection

Key outcomes

- u The patient won't aspirate.
- u The patient will maintain weight within an acceptable range.
- u The patient will maintain ventilation.
- u The patient will express feelings of increased energy.
- u The patient will report feeling less tension and pain.
- u The patient will maintain skin integrity.

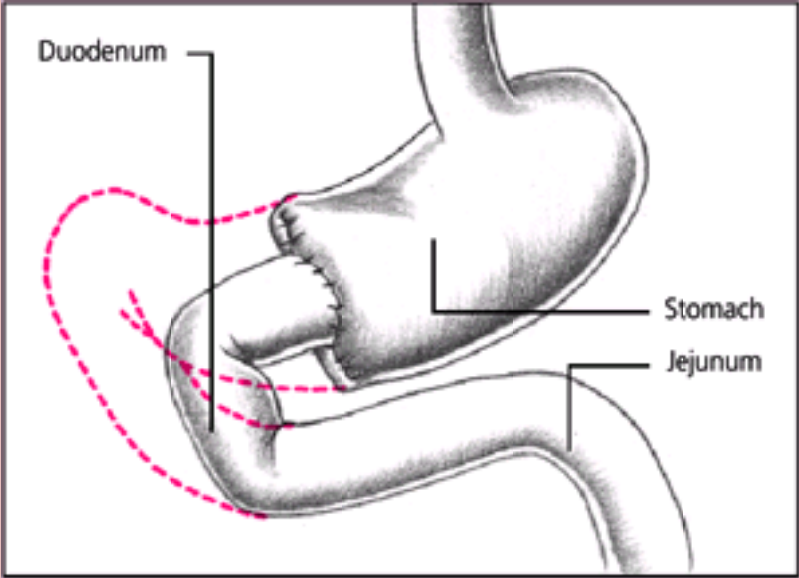

Nursing interventions

- u Provide a high-protein, high-calorie diet to help the patient avoid or recover from the weight loss, malnutrition, and anemia associated with gastric cancer. This diet also helps the patient tolerate surgery, radiotherapy, and chemotherapy; helps prevent wound dehiscence; and promotes wound healing. Plus, it provides enough protein, fluid, and potassium to aid glycogen and protein synthesis.
- u Give the patient dietary supplements, such as vitamins and iron, and provide small, frequent meals. If the patient has an iron deficiency, give him iron-rich foods, such as spinach and dried fruit.

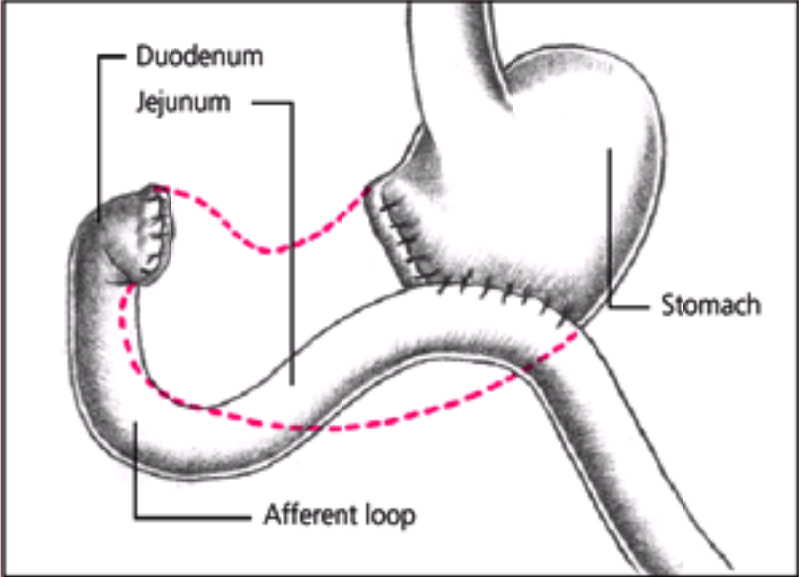

Understanding gastric surgery

The type of surgery performed depends on where the tumor occurs and how far it has spread. The dotted lines below show the areas removed.

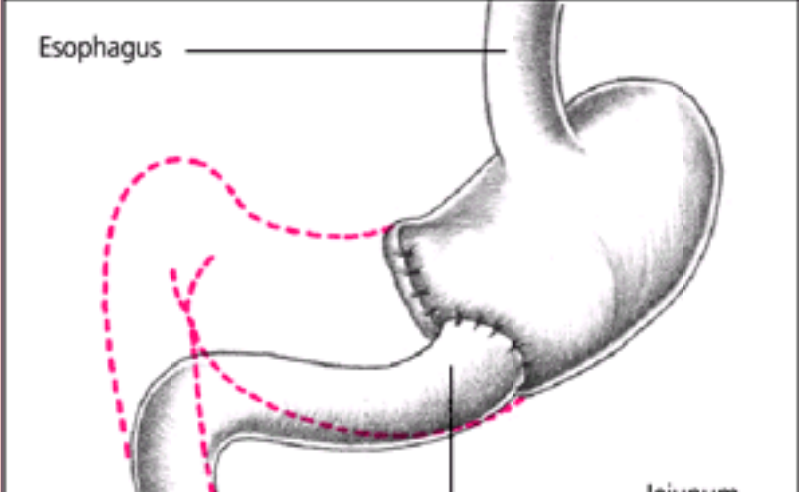

Gastroduodenostomy
Also called Billroth I, gastroduodenostomy may be performed to remove a tumor in the pyloric region. The surgeon resects the distal one-third to one-half of the stomach and anastomoses the remaining stomach portion to the duodenum.

Gastrojejunostomy
This surgery is called a Billroth II. The surgeon removes the distal portion of the antrum, anastomoses the remaining stomach to the jejunum, and then closes the duodenal stump.

Partial gastric resection
If a tumor lies in a defined area of the stomach, the surgeon performs a gastric resection by removing the diseased stomach portion and attaching the remaining stomach to the jejunum.

Total gastrectomy

If a tumor develops in the cardia or high in the fundus, the patient may require total gastrectomy. The surgeon removes the entire stomach and attaches the lower end of the esophagus to the jejunum (esophagojejunostomy) at the entrance to the small intestine.

- u To stimulate a poor appetite, administer steroids or antidepressants to the patient as ordered. Wine or brandy may also help stimulate the appetite.
- u If the patient can't tolerate oral foods, provide parenteral nutrition.
- u Administer an antacid to relieve heartburn and acid stomach and a histamine-receptor antagonist, such as cimetidine or famotidine, to decrease gastric secretions. Give opioid analgesics, as ordered, to relieve pain.
- u After surgery, provide meticulous supportive care to promote recovery and help prevent complications.
- u After any type of gastrectomy, turn the patient hourly; administer opioid analgesics (which depress respiration), as ordered; and regularly assist the patient with coughing, deep breathing, and turning to help prevent respiratory problems. If respiratory complications develop, the patient may need oxygen. If the patient can't breathe effectively on his own, use intermittent positive pressure breathing or incentive spirometry to completely expand his lungs. Also, make sure you position him properly, usually in semi-Fowler's position.
- u After total gastrectomy, support the patient during episodes of dumping syndrome, which stems from the stomach's inability to store food. Keep an emesis basin at the bedside, and provide small meals six to eight times per day when the patient is allowed food by mouth.
- u Monitor the patient's nasogastric (NG) tube for drainage. Expect little or no drainage from the tube because no secretions form after the stomach is removed.
- u Watch for signs of vitamin B₁₂ malabsorption, the result of an absence of intrinsic factor from gastric secretions.
- u If the patient has poor digestion and absorption after a gastrectomy, provide a special diet. This patient needs frequent feedings of small amounts of clear liquids, increasing to small, frequent feedings of bland food. If necessary, administer pancreatin and sodium bicarbonate after meals to prevent or control steatorrhea and dyspepsia.
- u Observe the surgical wound regularly for signs of infection (redness, swelling, warmth) and failure to heal. If needed, administer vitamin C to improve wound healing.
- u During radiation treatment offer fluids, such as orange juice, grapefruit juice, or ginger ale, to minimize nausea and vomiting. Also watch for adverse effects, such as nausea, vomiting, alopecia, malaise, and diarrhea. Provide comfort measures and reassurance as needed.
- u During chemotherapy, watch for complications such as infection, and expected adverse effects, such as nausea, vomiting, mouth ulcers, and alopecia.
- u Throughout treatment, listen to the patient's fears and concerns, and offer reassurance when appropriate. Stay with him during periods of severe anxiety.
- u Encourage the patient to identify actions and care measures that will promote comfort and relaxation. Try to perform these measures, and encourage the patient and family members to do so as well.
- u Whenever possible, include the patient and family members in decisions related to the patient's care.
- u If all treatments fail, keep the patient comfortable and free from unnecessary pain, and provide psychological support. Encourage him to express his feelings and fears and to ask questions about his illness. Answer such questions honestly; evasive answers will make the patient retreat and feel isolated.
- u Also talk with family members and answer their questions. Advise them to let the patient talk about his future; encourage them to maintain a realistic outlook.

Patient teaching

- u Before surgery, prepare the patient for its effects. Explain postsurgical procedures such as insertion of an NG tube.
- u If the patient is having a partial gastric resection, reassure him that he eventually may be able to eat normally. If he's having a total gastrectomy, prepare him for a slow recovery and only partial return to a normal diet. Explain that he has to eat small meals for the rest of his life.
- u After surgery, emphasize the importance of deep breathing and changing position every 2 hours.
- u Stress the importance of sound nutrition. Explain that the patient must take vitamins (to prevent B₁₂ deficiency) and iron for the rest of his life.
- u Teach the patient about dumping syndrome after gastric resection. Early dumping syndrome, which may be mild or severe, occurs a few minutes after eating and lasts up to 45 minutes. Onset is sudden, with nausea, weakness, sweating, palpitations, dizziness, flushing, borborygmi, explosive diarrhea, and increased blood pressure and pulse rate. Late dumping syndrome, which is less serious, occurs 2 to 3 hours after eating. The patient may experience profuse sweating, anxiety, and fine hand and leg tremors, along with vertigo, exhaustion, lassitude, palpitations, throbbing headache, faintness, sensation of hunger, glycosuria, and a marked decrease in blood pressure and glucose levels. Tell him that these symptoms may persist from a year after surgery to the rest of his life.
- u Explain the ordered treatments to the patient and his family. Describe the adverse effects the treatment may cause and tell the patient to notify the doctor if these effects persist.
- u Prepare the patient for chemotherapy's adverse effects, such as nausea and vomiting, and suggest measures such as drinking plenty of fluids that may help relieve these problems.
- u Encourage the patient to follow his normal routine as much as possible after recovering from surgery and during radiation therapy and chemotherapy. Leading a near-normal life helps foster feelings of independence and control and reduces complications of immobility.
- u Caution the patient to avoid crowds and people with known infections because chemotherapy and radiation therapy diminish the body's natural resistance to infection.
- u Encourage the patient to learn and practice relaxation and pain management techniques to help control anxiety and discomfort.
- u If appropriate, direct the patient and family members to facility and community support personnel and services. These include social workers, psychologists, cancer support groups, home health care agencies, and hospices.

KIDNEY CANCER

About 85% of kidney cancers—also called nephrocarcinoma, renal carcinoma, hypernephroma, and Grawitz's tumor—originate in the kidneys. Others are metastases from various primary-site carcinomas.

Most kidney tumors are large, firm, nodular, encapsulated, unilateral, and solitary. They may affect either kidney; occasionally they're bilateral or multifocal. (See [Unilateral kidney tumor.](#))

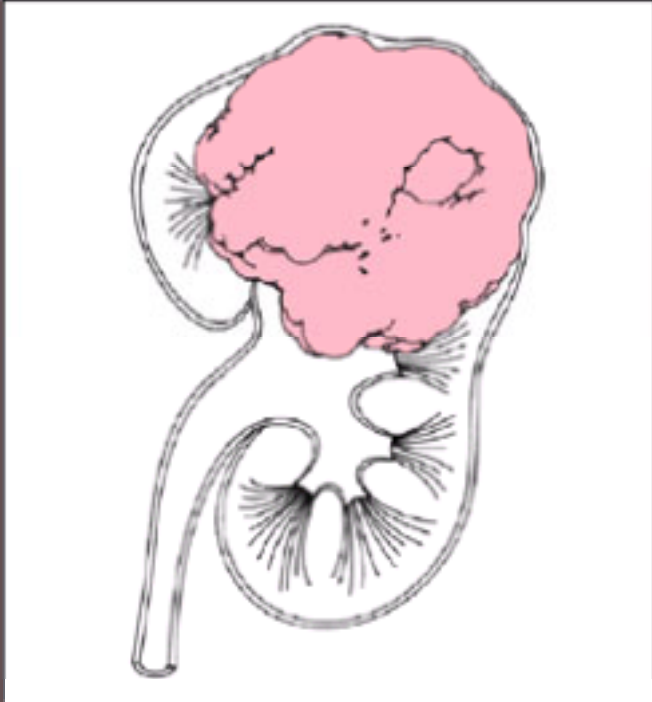

Kidney cancer is twice as common in men as in women; it typically strikes after age 40. Renal pelvic tumors and Wilms' tumor occur most commonly in children.

Kidney cancer can be separated histologically into clear cell, granular cell, and spindle cell types. Sometimes the prognosis is considered better for the clear cell type than for the other types; in general, however, the prognosis depends more on the cancer's stage than on its type.

Overall prognosis has improved considerably, with the 5-year survival rate about 50%.

Unilateral kidney tumor

In kidney cancer, tumors — such as this one in the upper kidney pole—usually occur unilaterally.

Causes

Although the cause of kidney cancer is unknown, some studies implicate particular factors, including heavy cigarette smoking. Patients who receive regular hemodialysis also may be at increased risk.

Complications

Complications include hemorrhage, respiratory problems from metastasis to the lungs, neurologic problems from brain metastasis, and GI problems from liver metastasis.

Assessment findings

The patient may complain of hematuria and often a dull, aching flank pain. He also may report weight loss, although this is uncommon. Rarely, his temperature may be elevated. Palpation may reveal a smooth, firm, nontender abdominal mass.

Diagnostic tests

Renal ultrasonography and a computed tomography scan can distinguish between simple cysts and renal cancer. In many cases, these tests eliminate the need for renal angiography. Other tests that aid diagnosis and help in staging include excretory urography, nephrotomography, and kidney-ureter-bladder radiography.

Additional relevant tests include liver function studies, which show increased alkaline phosphatase, bilirubin, and transaminase levels and prolonged prothrombin time. Such results may point to liver metastasis. If the tumor hasn't metastasized, these abnormal values reverse after tumor resection.

Treatment

Radical nephrectomy, with or without regional lymph node dissection, offers the only chance of cure. It's the treatment of choice in localized cancer or with tumor extension into the renal vein and vena cava. Nephrectomy doesn't help in disseminated disease.

Because this disease resists radiation, this treatment is used only when the cancer has spread into the perinephric region or the lymph nodes or when the primary tumor or metastatic sites can't be completely excised. In this case the patient usually needs high doses of radiation.

Chemotherapy is erratically effective against kidney cancer, and hormonal therapy has no proven results. Biotherapy with lymphokine-activated killer cells plus recombinant interleukin-2 shows promise but is expensive and causes many adverse reactions. Interferon is somewhat effective in treating advanced disease.

Nursing diagnoses

- u Altered tissue perfusion
- u Anxiety
- u Fear
- u Impaired physical mobility
- u Impaired tissue integrity
- u Ineffective breathing pattern
- u Pain
- u Risk for injury

Key outcomes

- u The patient will maintain fluid balance.
- u The patient will maintain urine-specific agents within normal range.
- u The patient's weight won't fluctuate.
- u The patient will report increased comfort.
- u The patient will communicate understanding of medical regimen, medications, diet, and activity restrictions.
- u The patient will maintain joint mobility and range of motion.
- u The patient will maintain ventilation.

Nursing interventions

- u Before surgery, assure the patient that the body will adequately adapt to the loss of a kidney.
- u Administer prescribed analgesics as necessary. Provide comfort measures, such as positioning and distractions, to help the patient cope with discomfort.
- u After surgery, encourage diaphragmatic breathing and coughing.
- u Assist the patient with leg exercises, and turn him every 2 hours to reduce the risk of phlebitis.
- u Check dressings often for excessive bleeding. Watch for signs of internal bleeding, such as restlessness, sweating, and increased pulse rate.
- u Position the patient on the operative side to allow the pressure of adjacent organs to fill the dead space at the operative site, improving dependent drainage.

- u If possible, assist the patient with walking within 24 hours of surgery.
- u Provide adequate fluid intake, and monitor intake and output.
- u Monitor laboratory test results for anemia, polycythemia, and abnormal blood chemistry values that may point to bone or hepatic involvement or may result from radiation therapy or chemotherapy.
- u Provide symptomatic treatment for adverse effects of chemotherapeutic drugs.
- u Encourage the patient to express his anxieties and fears, and remain with him during periods of severe stress and anxiety.

Patient teaching

- u Tell the patient what to expect from surgery and other treatments.
- u Before surgery, teach diaphragmatic breathing and effective coughing techniques, such as how to splint the incision.
- u Explain the possible adverse effects of radiation and drug therapy. Advise the patient how to prevent and minimize these problems.
- u When preparing the patient for discharge, stress the importance of compliance with any prescribed outpatient treatment. This includes an annual follow-up chest X-ray to rule out lung metastasis and excretory urography every 6 to 12 months to check for contralateral tumors.
- u If appropriate, refer the patient and family members to facility and community services, such as cancer support groups and hospice care.

LIVER CANCER

Primary liver cancer accounts for roughly 2% of all cancers in North America and 10% to 50% of cancers in Africa and parts of Asia. It's most prevalent in men, particularly those over age 60, and the incidence increases with age. Mortality is high.

Most primary liver tumors (90%) originate in the parenchymal cells and are hepatomas (also called hepatocellular carcinomas or primary liver cell carcinomas). Some primary tumors originate in the intrahepatic bile ducts and are known as cholangiomas (also known as cholangiocarcinomas or cholangiocellular carcinomas). Rarer tumors include a mixed-cell type, Kupffer's cell sarcoma, and hepatoblastoma, which occurs almost exclusively in children. Roughly 30% to 70% of patients with hepatomas also have cirrhosis, and a person with cirrhosis is about 40 times more likely to develop hepatomas than a person with a normal liver.

The liver is one of the most common sites of metastasis from other primary cancers, particularly melanoma and cancers of the colon, rectum, stomach, pancreas, esophagus, lung, or breast. In North America, metastatic liver cancer is about 20 times more common than primary liver cancer and, after cirrhosis, is the leading cause of fatal hepatic disease. Liver metastasis may occur as a solitary lesion, the first sign of recurrence after a remission.

No particular staging system exists for liver cancer. Although most hepatoblastomas are resectable and curable, the prognosis is almost always poor. The disease progresses rapidly, with death usually occurring within 6 months of diagnosis from GI hemorrhage, progressive cachexia, liver failure, or metastatic spread. When cirrhosis is present, the prognosis is especially grim, with death from liver failure usually occurring within 2 months of diagnosis.

Causes

The immediate cause is unknown but, in children, it's commonly attributed to congenital factors. Adult liver cancer may result from environmental exposure to carcinogens, including the chemical compound aflatoxin (a mold that grows on rice and peanuts), thorium dioxide (a contrast medium used for liver radiography in the past), *Senecio* alkaloids and, possibly, androgens and oral estrogens. Another high-risk factor is exposure to the hepatitis B virus.

Whether cirrhosis is a premalignant state or whether alcohol or malnutrition predisposes the liver to hepatomas is unclear.

Complications

Progression of this disease may cause GI hemorrhage, progressive cachexia, and liver failure.

Assessment findings

The patient's history may show weight loss resulting from anorexia, weakness, fatigue, and fever. The patient also may complain of severe pain in the epigastrium or right upper quadrant.

On inspection, you may note jaundice (including scleral icterus) and dependent edema. Peripheral edema may suggest decreased plasma albumin levels related to liver dysfunction and malnutrition. Auscultation may reveal a bruit, hum, or rubbing sound if the tumor involves a large part of the liver. Percussing the abdomen may uncover an increased span of liver dullness, indicating an enlarged liver. Dull sounds on percussion indicate ascites. Palpation may disclose a mass in the right upper quadrant and a tender, nodular liver.

Diagnostic tests

Liver biopsy by needle or open biopsy reveals cancerous cells. Liver function studies are abnormal, and alpha-fetoprotein levels rise above 500 mcg/ml.

Chest X-rays may rule out metastasis to the lungs. A liver scan may show filling defects. Arteriography may define large tumors.

Electrolyte studies may indicate increased sodium retention (resulting in functional renal failure), hypoglycemia, hypercalcemia, or hypocholesterolemia.

Treatment

Because liver cancer may reach an advanced stage before diagnosis, few hepatic tumors are resectable. A resectable tumor must be solitary and not accompanied by cirrhosis, jaundice, or ascites. Resection is performed by lobectomy or partial hepatectomy.

Radiation therapy may be used alone or with chemotherapy. Chemotherapeutic drugs include fluorouracil, doxorubicin, methotrexate, streptozocin, and lomustine I.V. or regular infusion of fluorouracil or flexuradine. Both therapies combined produce a better response rate than either therapy used alone. Liver transplantation is an alternative for some patients.

Nursing diagnoses

u Altered nutrition: Less than body requirements u Altered thought processes u Altered tissue perfusion (cardiopulmonary) u Anxiety u Fatigue u Fear u Fluid volume excess u Hyperthermia u Impaired gas exchange u Impaired skin integrity u Ineffective family coping: Disabling u Ineffective individual coping u Pain

Key outcomes

- u The patient will attain hemodynamic status.
- u The patient's skin will remain warm and dry.
- u The patient will maintain adequate cardiac output.
- u The patient will report feeling less tension or pain.
- u The patient will exhibit adequate coping behaviors.
- u The patient's fluid volume will remain within normal range.

Nursing interventions

- u Give analgesics as ordered, and encourage the patient to identify care measures that promote comfort.
- u Monitor the patient's diet throughout his illness. Most patients need a special diet that restricts sodium, fluids, and protein and prohibits alcohol. Weigh the patient daily, and note intake and output accurately.
- u Control ascites; if signs develop—peripheral edema, orthopnea, and dyspnea on exertion—measure and record the patient's abdominal girth daily.
- u To increase venous return and prevent edema, elevate the patient's legs whenever possible.
- u Monitor respiratory function. Note any shortness of breath or increase in respiratory rate. Bilateral pleural effusion (evident on chest X-ray) and metastasis to the lungs are common. Watch carefully for signs of hypoxemia from intrapulmonary arteriovenous shunting.
- u Keep the patient's fever down. Administer sponge baths and aspirin suppositories if the patient has no signs of GI bleeding. Avoid acetaminophen; the diseased liver can't metabolize it. If a high fever develops, the patient has an infection and needs antibiotics.
- u Provide meticulous skin care. Turn the patient frequently, and keep his skin clean to prevent pressure ulcers. Apply lotion to prevent chafing, and administer an antipruritic for severe itching.
- u Watch for encephalopathy. Many patients develop end-stage symptoms of ammonia intoxication, including confusion, restlessness, irritability, agitation, delirium, asterixis, lethargy, and, finally, coma. Monitor the patient's serum ammonia level, vital signs, and neurologic status.
- u As ordered, control ammonia accumulation with sorbitol (to induce osmotic diarrhea), neomycin (to reduce bacterial flora in the GI tract), lactulose (to control bacterial elaboration of ammonia), and sodium polystyrene sulfonate (to lower the potassium level).
- u If the patient has a transhepatic catheter in place to relieve obstructive jaundice, irrigate it frequently with the prescribed solution (0.9% sodium chloride or, sometimes, 5,000 units of heparin in 500 ml dextrose 5% in water). Monitor vital signs frequently for any indication of bleeding or infection.
- u After surgery, watch for intraperitoneal bleeding and sepsis, which may precipitate coma. Monitor for renal failure by checking the patient's urine output, blood urea nitrogen, and serum creatinine levels hourly.
- u Throughout therapy, provide comprehensive supportive care and emotional assistance. Remember that your primary concern throughout this intractable illness is to keep the patient as comfortable as possible.
- u At all times, listen to the concerns and fears of the patient and his family.

Patient teaching

- u Explain the treatments to the patient and family members, including adverse effects the patient may experience.
- u Explain the importance of restricting sodium and protein intake and eliminating alcohol from the diet.
- u Encourage the patient to learn and practice relaxation techniques to promote comfort and ease anxiety.
- u If appropriate, direct the patient and family members to local support groups and services.

PANCREATIC CANCER

Pancreatic cancer is the fourth most lethal of all carcinomas. It occurs most often among blacks, particularly in men between ages 35 and 70. Incidence of pancreatic cancer is highest in Israel, the United States, Sweden, and Canada and lowest in Switzerland, Belgium, and Italy. The prognosis is poor: Most patients die within 1 year of diagnosis.

Causes and pathophysiology

Evidence suggests that pancreatic cancer is linked to inhalation or absorption of carcinogens that are then excreted by the pancreas. Examples of such carcinogens include:

- u cigarette smoke (pancreatic cancer is three to four times more common among smokers)
- u excessive fat and protein (a diet high in fat and protein induces chronic hyperplasia of the pancreas, with increased turnover of cells)
- u food additives
- u industrial chemicals, such as betanaphthalene, benzdine, and urea.

Other possible predisposing factors include chronic pancreatitis, diabetes mellitus, and chronic alcohol abuse.

Tumors of the pancreas are almost always adenocarcinomas. They arise most frequently (67% of the time) in the head of the pancreas. Tumors in this location commonly obstruct the ampulla of Vater and common bile duct and metastasize directly to the duodenum. Adhesions anchor the tumor to the spine, stomach, and intestines.

Less frequently, tumors arise in the body and tail of the pancreas. When this happens, large nodular masses become fixed to retropancreatic tissues and the spine. The spleen, left kidney, suprarenal gland, and diaphragm are directly invaded, and the celiac plexus becomes involved, resulting in splenic vein thrombosis and spleen infarction. Among the rarest of pancreatic tumors are islet cell tumors. (See [Islet cell tumors](#).)

In pancreatic cancer, two main tissue types form fibrotic nodes: Cylinder cells arise in ducts and degenerate into cysts, and large, fatty, granular cells arise in parenchyma.

Complications

Related to the progression of the disease, complications may include malabsorption of nutrients, insulin-dependent diabetes, liver and GI problems, and mental status changes.

Assessment findings

A patient who seeks treatment early in the disease usually reports a dull, intermittent epigastric pain. Later, he may report continuous pain that radiates to the right upper quadrant or dorsolumbar area. He may describe it as colicky, dull, or vague and unrelated to posture or activity. Or he may state that meals seem to aggravate the epigastric pain. He may also report anorexia, nausea, vomiting, and a rapid, profound weight loss.

Inspection may reveal jaundice. On palpation you may note a palpable, well-defined, large mass in the subumbilical or left hypochondrial region—an indication that the tail of the pancreas is involved. The mass may adhere to the large vessels or the vertebral column and may produce a pulsation. If the tumor has involved or compressed the splenic artery, auscultation of the left hypochondrium may reveal an abdominal bruit.

Diagnostic tests

Several tests may be ordered to help diagnose the disease and determine its extent.

Percutaneous fine-needle aspiration biopsy of the pancreas may detect tumor cells, and laparotomy with a biopsy allows a definitive diagnosis. However, a biopsy may miss relatively small or deep-seated cancerous tissue or create a pancreatic fistula. Retroperitoneal insufflation, cholangiography, scintigraphy and, particularly, barium swallow (to locate the neoplasm and detect changes in the duodenum or stomach relating to carcinoma of the head of the pancreas) also can be performed to detect the disease.

Islet cell tumors

Islet cell tumors (insulinomas) are relatively uncommon; they may be benign or malignant. They produce symptoms in three stages and, despite treatment, the prognosis is unfavorable.

Slight hypoglycemia

Fatigue, restlessness, malaise, and excessive weight gain result from slight hypoglycemia.

Compensatory secretion of epinephrine

This stage is characterized by pallor, clamminess, perspiration, palpitations, finger tremors, hunger, decreased temperature, and increased pulse rate.

Severe hypoglycemia

Ataxia, clouded sensorium, diplopia, and episodes of violence and hysteria are the effects of severe hypoglycemia.

Therapy and prognosis

Treatment consists of enucleation of benign tumors, or chemotherapy with streptozocin or resection to include pancreatic tissue for malignant tumors. Most islet cell tumors metastasize to the liver only. Some metastasize to the bone, brain, and lungs. Death results from a combination of hypoglycemic reactions and widespread metastasis.

Ultrasonography helps identify a mass but not its histology. A computed tomography scan shows greater detail of the mass than ultrasonography. Magnetic resonance imaging discloses the tumor's location and size in great detail.

Angiography reveals the tumor's vascular supply. Endoscopic retrograde cholangiopancreatography also allows visualization, instillation of contrast medium, and specimen biopsy.

A secretin test reveals the absence of pancreatic enzymes and suggests pancreatic duct obstruction and tumors of the body and tail.

Other laboratory tests that support the diagnosis include:

- u serum bilirubin (increased)
- u serum amylase-lipase (occasionally increased)
- u prothrombin time (prolonged)
- u aspartate aminotransferase and alanine aminotransferase (elevated enzyme levels when liver cell necrosis is present)
- u alkaline phosphatase (markedly elevated with biliary obstruction)
- u plasma insulin immunoassay (shows measurable serum insulin in the presence of islet cell tumors)
- u hemoglobin and hematocrit (may show mild anemia)
- u fasting blood glucose (may indicate hypoglycemia or hyperglycemia)
- u stool studies (may show occult blood if ulceration in the GI tract or ampulla of Vater has occurred)
- u specific tumor markers for pancreatic cancer, including carcinoembryonic antigen, pancreatic oncofetal antigen, alphafetoprotein, and serum immunoreactive elastase I (all levels elevated in the presence of cancer).

Treatment

Because pancreatic cancer may metastasize widely before it's diagnosed, treatment seldom succeeds in curing the disease. Treatment consists of surgery and, possibly, chemotherapy and radiation therapy.

Some surgical procedures help increase the survival rate slightly.

- u Total pancreatectomy may increase survival time by resecting a localized tumor or by controlling postoperative gastric ulceration.
- u Cholecystojejunostomy, choledochoduodenostomy, and choledochojejunostomy have partially replaced radical resection. They bypass the obstructing common bile duct extensions, easing jaundice and pruritus.
- u If radical resection isn't indicated and duodenal obstruction is expected to develop later, a gastrojejunostomy is performed.

Whipple's operation, or radical pancreatoduodenectomy, has a high mortality rate but can obtain wide lymphatic clearance, except with tumors located near the portal vein, superior mesenteric vein and artery, and celiac axis. This seldom-used procedure removes the head of the pancreas; the duodenum; portions of the body and tail of the pancreas, stomach, jejunum, and pancreatic duct; and the distal portion of the bile duct.

Pancreatic cancer usually responds poorly to chemotherapy, but recent studies using combinations of fluorouracil, streptozocin, ifosfamide, and doxorubicin show a trend toward longer survival time.

Radiation therapy usually doesn't increase long-term survival, although it may prolong survival time from 6 to 11 months when used as an adjunct to fluorouracil chemotherapy. It also can ease the pain associated with nonresectable tumors.

Medications used in pancreatic cancer include:

- u antibiotics to prevent infection and relieve symptoms
- u anticholinergics, particularly propantheline, to decrease GI tract spasm and motility and reduce pain and secretions
- u antacids to decrease secretion of pancreatic enzymes and suppress peptic activity, thus reducing stress-induced damage to gastric mucosa
- u diuretics to mobilize extracellular fluid from ascites
- u insulin to provide an adequate exogenous insulin supply after pancreatic resection
- u opioid analgesics to relieve pain (used only after other analgesics fail because morphine, meperidine, and codeine can lead to biliary tract spasm and increase common bile duct pressure)
- u pancreatic enzymes to assist with digestion of proteins, carbohydrates, and fats when pancreatic juices are insufficient because of surgery or obstruction.

Nursing diagnoses

- u Altered nutrition: Less than body requirements
- u Anxiety
- u Constipation
- u Fluid volume deficit
- u Impaired skin integrity
- u Ineffective family coping: Disabling
- u Ineffective individual coping
- u Pain
- u Risk for injury

Key outcomes

- u The patient will maintain weight within an acceptable range.
- u The patient will experience return to normal bowel movements.
- u The patient's fluid volume status will be within normal range.
- u The patient will maintain skin integrity.
- u The patient will experience comfort and relief of pain.
- u The patient won't experience injury.

Nursing interventions

- u Monitor the patient's fluid balance, abdominal girth, metabolic state, and weight daily. If weight loss occurs, replace nutrients through an I.V. line, by mouth, or through a nasogastric (NG) tube. If the patient gains weight (from ascites), impose dietary restrictions, such as a low-sodium diet, as ordered. Maintain a 2,500-calorie diet.
- u Serve small, frequent meals. Consult the dietitian to ensure proper nutrition, and make mealtimes as pleasant as possible. Administer an oral pancreatic enzyme at mealtimes if needed. As ordered, give an antacid to prevent stress ulcers.
- u Before surgery, make sure the patient is medically stable, particularly regarding nutrition. This may take 4 to 5 days. If he can't tolerate oral feedings, provide total parenteral nutrition and I.V. fat emulsions to correct deficiencies and keep a positive nitrogen balance.

Administer blood transfusions (to combat anemia), vitamin K (to overcome prothrombin deficiency), antibiotics (to prevent postoperative complications), and gastric lavage (to maintain gastric decompression) as ordered.

CULTURAL TIP Members of some groups (such as Jehovah's Witnesses) oppose blood transfusions and may refuse this treatment. If the situation is life-threatening, a court order may be obtained to overrule family decisions if the situation warrants.

- u After surgery, watch for and report complications, such as fistula, pancreatitis, fluid and electrolyte imbalance, infection, hemorrhage, skin breakdown, nutritional deficiency, liver failure, renal insufficiency, and diabetes.
- u If the patient is receiving chemotherapy, watch for and symptomatically treat its toxic effects.
- u To prevent constipation, administer laxatives, stool softeners, and cathartics, as ordered. Also modify the patient's diet and increase his fluid intake. To increase GI motility, position him properly during and after meals, and assist him with walking.
- u Ensure adequate rest and sleep (with a sedative, if necessary). Assist with range-of-motion and isometric exercises, as appropriate.
- u Administer analgesics for pain, and antibiotics and antipyretics for fever, as ordered.
- u Watch for signs of hypoglycemia or hyperglycemia, and give the patient glucose or an antidiabetic agent (such as tolbutamide) as ordered. Monitor the patient's blood glucose, urine glucose, and acetone levels and his response to treatment.
- u Document the progression of jaundice.
- u Provide scrupulous skin care to prevent pruritus and necrosis, and keep the patient's skin clean and dry. If he develops overwhelming pruritus, you can prevent excoriation by clipping his nails and having him wear light cotton gloves.
- u Watch for signs of upper GI bleeding. Test stools and emesis for blood, and maintain a flow sheet of frequent hemoglobin and hematocrit determinations.
- u To control active bleeding, promote gastric vasoconstriction with medication and iced saline lavage through an NG or duodenal tube. Replace lost fluids.
- u Ease discomfort from pyloric obstruction with an NG tube.
- u To prevent thrombosis, apply antiembolism stockings and assist with range-of-motion exercises. If thrombosis occurs, elevate the patient's legs and apply moist heat to the thrombus site. Give an anticoagulant, such as aspirin, as ordered, to prevent further clot formation and pulmonary embolus.
- u Throughout therapy, answer questions the patient has and tell him what to expect from surgery and other therapies. Listen to his fears and concerns, and stay with him during periods of severe stress and anxiety.
- u Encourage the patient to identify actions and care measures that promote his comfort and relaxation. Try to perform these measures, and encourage the patient and family members to do so as well.
- u Whenever possible, include the patient and family members in care decisions.

Patient teaching

- u Describe expected postoperative procedures and adverse effects of radiation therapy and chemotherapy.
- u If appropriate, provide information on diabetes.
- u Help the patient and family members cope with the impending reality of death.
- u Refer the patient to resource and support services, such as the social service department, local home health care agencies, hospices, and the American Cancer Society.
- u Encourage the patient to follow as normal a routine as possible. Explain that leading a near-normal life helps foster feelings of independence and control.

Neoplasms of the male and female genitalia

Besides their impact on physiologic function, cancers of the reproductive system have profound implications for the patient's body image and self-esteem.

CERVICAL CANCER

Cervical cancer is the third most common cancer of the female reproductive system. It's classified as either preinvasive or invasive.

Preinvasive cancer ranges from minimal cervical dysplasia, in which the lower third of the epithelium contains abnormal cells, to carcinoma in situ, in which the full thickness of epithelium contains abnormally proliferating cells (also known as cervical intraepithelial neoplasia). Preinvasive cancer is curable in 75% to 90% of patients with early detection and proper treatment. If untreated, it may progress to invasive cervical cancer, depending on the form.

In invasive disease, cancer cells penetrate the basement membrane and can spread directly to contiguous pelvic structures or disseminate to distant sites by way of lymphatic routes. In 95% of cases, the histologic type is squamous cell carcinoma, which varies from well-differentiated cells to highly anaplastic spindle cells. Only 5% of cases are adenocarcinomas. Invasive cancer typically occurs between ages 30 and 50; it rarely occurs under age 20.

Causes

Although the cause is unknown, several predisposing factors have been associated with cervical cancer: frequent intercourse at a young age (under 16), multiple sexual partners, multiple pregnancies, human papillomavirus (HPV), and other bacterial or viral venereal infections.

Complications

Disease progression can cause flank pain from sciatic nerve or pelvic wall invasion and hematuria and renal failure associated with bladder involvement.

Assessment findings

Preinvasive cancer produces no symptoms or other clinical changes. In early invasive cervical cancer, the patient history includes abnormal vaginal bleeding, such as a persistent vaginal discharge that may be yellowish, blood-tinged, and foul-smelling; postcoital pain and bleeding; and bleeding between menstrual periods or unusually heavy menstrual periods. The patient history may suggest one or more of the predisposing factors for this disease.

If the cancer has advanced into the pelvic wall, the patient may report gradually increasing flank pain, which can indicate sciatic nerve involvement. Leakage of urine may point to metastasis into the bladder with formation of a fistula. Leakage of stool may indicate metastasis to the rectum with fistula development.

Inspection may disclose vaginal discharge or leakage of urine or stool.

Diagnostic tests

A Papanicolaou (Pap) test identifies abnormal cells, and colposcopy determines the source of the abnormal cells seen on the Pap test.

Cone biopsy is performed if endocervical curettage is positive.

The Vira pap test, currently under investigation, permits examination of the specimen's deoxyribonucleic acid (DNA) structure to detect HPV.

Additional studies, such as lymphangiography, cystography, and major organ and bone scans, can detect metastasis. (See [Staging cervical cancer](#).)

Treatment

Accurate clinical staging will determine the type of treatment. Preinvasive lesions may be treated with total excisional biopsy, cryosurgery, laser destruction, conization (followed by frequent Pap test follow-ups) or, rarely, hysterectomy. Therapy for invasive squamous cell carcinoma may include radical hysterectomy and radiation therapy (internal, external, or both). Rarely, pelvic exenteration may be performed for recurrent cervical cancer.

Complications of surgery include bladder dysfunction, formation of lymphocytes or seromas after lymphadenectomy, and pulmonary embolism. Complications of radiation therapy include diarrhea, abdominal cramping, dysuria, and leukopenia. Combined surgery and irradiation in the abdomen and pelvis may lead to small bowel obstruction, stricture and fibrosis of the intestine or rectosigmoid, and rectovaginal or vesicovaginal fistula.

Nursing diagnoses

u Altered sexuality patterns u Anxiety u Fear u Impaired physical mobility u Impaired skin integrity u Ineffective individual coping u Pain u Risk for infection u Sexual dysfunction

Key outcomes

- u The patient will report feeling less tension or pain.
- u The patient and partner will express feelings and perceptions about changes in sexual performance.
- u The patient will voluntarily discuss her problems.
- u The patient will maintain joint mobility and range of motion.
- u The patient will remain free from signs or symptoms of infection.

Nursing interventions

u Listen to the patient's fears and concerns, and offer reassurance when appropriate. Encourage her to use relaxation techniques to promote comfort during diagnostic procedures.

Staging cervical cancer
Treatment decisions depend on accurate staging. The International Federation of Gynecology and Obstetrics defines the following cervical cancer stages.
Stage 0 Carcinoma in situ, intraepithelial carcinoma
Stage I Cancer confined to the cervix (extension to the corpus should be disregarded)
Stage IA Preclinical malignant lesions of the cervix (diagnosed only microscopically)
Stage IA1 Minimal microscopically evident stromal invasion
Stage IA2 Lesions detected microscopically, measuring 5 mm or less from the base of the epithelium, either surface or glandular, from which it originates; lesion width shouldn't exceed 7 mm
Stage IB Lesions measuring more than 5 mm deep and 7 mm wide, whether seen clinically or not (preformed space involvement shouldn't alter the staging but should be recorded for future treatment decisions)
Stage II Extension beyond the cervix but not to the pelvic wall; the cancer involves the vagina but hasn't spread to the lower third
Stage IIA No obvious parametrial involvement
Stage IIB Obvious parametrial involvement
Stage III Extension to the pelvic wall; on rectal examination, no cancer-free space exists between the tumor and the pelvic wall; the tumor involves the lower third of the vagina; this includes all cases with hydronephrosis or nonfunctioning kidney
Stage IIIA No extension to the pelvic wall
Stage IIIB Extension to the pelvic wall and hydronephrosis, or nonfunctioning kidney, or both
Stage IV Extension beyond the true pelvis or involvement of the bladder or the rectal mucosa
Stage IVA Spread to adjacent organs
Stage IVB Spread to distant organs

u If you assist with a biopsy, drape and prepare the patient as for a routine Pap test and pelvic examination. Have a container of formaldehyde ready to preserve the specimen during transfer to the pathology laboratory. Assist the doctor as needed, and provide support for the patient throughout the procedure.

- u If you assist with cryosurgery or laser therapy, drape and prepare the patient as for a routine Pap test and pelvic examination. Assist the doctor as necessary, and provide support for the patient throughout the procedure.
- u After any surgery, monitor vital signs every 4 hours.
- u Watch for and immediately report signs of complications, such as bleeding, abdominal distention, severe pain, and wheezing or other breathing difficulties. Encourage deep breathing and coughing. Administer analgesics and prophylactic antibiotics, as ordered.

For internal radiation therapy:

- u Check to see whether the radioactive source is to be inserted while the patient is in the operating room (preloaded) or at bedside (afterloaded). If the source is preloaded, the patient returns to her room “hot,” and safety precautions begin immediately.
- u Remember that safety precautions—time, distance, and shielding—begin as soon as the radioactive source is in place. Inform the patient that she'll require a private room.
- u Encourage the patient to lie flat and to limit movement while the source is in place. If she prefers, elevate the head of the bed slightly.
- u Check the patient's vital signs every 4 hours; watch for skin reactions, vaginal bleeding, abdominal discomfort, and evidence of dehydration. Make sure the patient can reach everything she needs without stretching or straining.

HOME CARE

Guidelines for using a dilator

After undergoing intracavitary radiation, the patient may need to use a dilator to relieve vaginal narrowing, resulting from scar tissue. She should insert the dilator once or twice a day and leave it in her vagina for about 5 minutes. Also, note the following:

- u The dilator should feel smooth; if it has flaws or rough spots, the patient should use a different one.
- u The patient should wash the dilator with soap and water before and after each insertion.
- u The patient should apply a water-soluble lubricant (such as KY Jelly) to the tip of the dilator before insertion.
- u To properly insert the dilator, the patient lies on her back with her knees slightly apart. Then she inserts it into the vagina as far as possible without causing pain.
- u Dilator use may cause mild discomfort or a pink or slightly bloody discharge. Significant, menstrual-like bleeding should not occur.

- u Assist the patient with range-of-motion arm exercises.
 - u Avoid leg exercises and other body movements that could dislodge the source. If ordered, administer a tranquilizer to help the patient relax and remain still.
- Organize your time with the patient to minimize your exposure to radiation.
- u Provide diversional activities that require minimal movement.
 - u Inform visitors of safety precautions and hang a sign listing these precautions on the patient's door.
 - u Watch for treatment complications by listening to and observing the patient and monitoring laboratory studies and vital signs. When appropriate, perform measures to prevent or alleviate complications.

Patient teaching

For biopsy:

- u Explain to the patient that she may feel pressure, minor abdominal cramps, or a pinch from the punch forceps. Reassure her that the pain will be minimal because the cervix has few nerve endings.

For cryosurgery:

- u Explain to the patient that the procedure takes about 15 minutes, during which time the doctor uses refrigerant to freeze the cervix. Caution her that she may experience abdominal cramps, headache, and sweating, but reassure her that she'll feel little, if any, pain.

For laser surgery:

- u Explain that the procedure takes about 30 minutes and may cause abdominal cramps.
- u After excisional biopsy, cryosurgery, or laser therapy, tell the patient to expect a discharge or spotting for about 1 week. Advise her not to douche, use tampons, or engage in sexual intercourse during this time. Caution her to report signs of infection. Stress the need for a follow-up Pap test and a pelvic examination in 3 to 4 months and periodically thereafter. Also, tell her what to expect postoperatively if a hysterectomy is necessary.
- u Find out whether the patient is to have internal or external therapy or both. Usually, internal radiation therapy is the first procedure.

For preloaded internal radiation therapy:

- u Explain to the patient that the procedure requires a 2- to 3-day hospital stay, bowel preparation, a povidone-iodine vaginal douche, a clear liquid diet, and nothing by mouth the night before the implantation. It also requires an indwelling urinary catheter.
- u Inform the patient that the procedure is performed in the operating room under general anesthesia. She will be placed in the lithotomy position and an applicator will be inserted. A radioactive source such as radium is implanted in the applicator by the doctor.

For afterloaded internal radiation therapy:

- u Explain to the patient that a member of the radiation team implants the source after the patient returns to her room from surgery.
- u If the patient is to undergo outpatient external radiation therapy, explain that it continues for about 4 to 6 weeks. Describe the procedure and measures she can take at home to prevent complications, such as providing care around the radiation site to prevent skin breakdown.
- u Review the possible complications of radiation therapy. Remind the patient to watch for and report uncomfortable adverse effects. Because radiation therapy may increase susceptibility to infection by lowering the white blood cell count, warn the patient to avoid people with obvious infections during therapy.
- u Inform the patient that vaginal narrowing caused by scar tissue can occur after internal radiation. This condition can be managed by having regular sexual intercourse, by using a dilation procedure, or both. If appropriate, teach the patient how to use a dilator (See [Guidelines for using a dilator.](#))
- u Describe the complications that can occur even years after high-dose radiation therapy. GI problems (usually within the first 2 years after radiation therapy) include bowel obstruction, rectovaginal fistula, and small-bowel fistula. Urinary tract problems (usually 3 to 4 years after treatment) include urinary fistula and hematuria.

For all patients with cervical cancer:

- u Reassure the patient that this disease and its treatment shouldn't radically alter her lifestyle or prohibit sexual intimacy.
- u Explain the importance of complying with follow-up visits to the gynecologist and oncologist. Stress the value of follow-up visits in detecting disease progression or recurrence.

OVARIAN CANCER

After cancers of the lung, breast, and colon, primary ovarian cancer ranks as the most common cause of cancer death among American women. In women with

previously treated breast cancer, metastatic ovarian cancer is more common than cancer of any other organ.

The prognosis varies with the histologic type and staging of the disease, but it's often poor because ovarian tumors are difficult to diagnose and progress rapidly. About 40% of women with ovarian cancer survive for 5 years.

Causes and pathophysiology

Environmental and lifestyle factors seem to play a role in ovarian cancer. Women who live in industrialized nations are at greater risk, as are those whose diet is high in saturated fat. Other risk factors include infertility problems or nulliparity, celibacy, exposure to asbestos and talc, a history of breast or uterine cancer, and a family history of ovarian cancer.

Primary epithelial tumors arise in the müllerian epithelium; germ cell tumors in the ovum; and sex cord tumors in the ovarian stroma. Ovarian tumors spread rapidly intraperitoneally by local extension or surface seeding and, occasionally, through the lymphatics and the bloodstream. In most cases, extraperitoneal spread is through the diaphragm into the chest cavity, which may cause pleural effusions. Other metastasis is rare.

There are three main types of ovarian cancer:

- *Primary epithelial tumors* account for 90% of all ovarian cancers and include serous cystadenocarcinoma, mucinous cystadenocarcinoma, and endometrioid and mesonephric malignant tumors.
- *Germ cell tumors* include endodermal sinus malignant tumors, embryonal carcinoma (a rare ovarian cancer that appears in children), immature teratomas, and dysgerminoma.
- *Sex cord (stromal) tumors* include granulosa, cell tumors (which produce estrogen and may have feminizing effects), thecomas, and the rare arrhenoblastomas (which produce androgen and have virilizing effects).

Complications

Fluid and electrolyte imbalance, leg edema, ascites, and intestinal obstruction, causing nausea, malnutrition, and hunger, are common complications of progressive disease. Profound cachexia and recurrent malignant effusions, such as pleural effusions, may also occur.

Assessment findings

Because of ovarian cancer's lack of obvious signs, it's seldom diagnosed early. Usually, the cancer has metastasized before a diagnosis is made. Signs and symptoms vary with the tumor's size and the extent of metastasis.

In later stages, the history may disclose urinary frequency, constipation, pelvic discomfort, distention, and weight loss. The patient may complain of pain, possibly associated with tumor rupture, torsion, or infection. In a young patient, the pain may mimic that of appendicitis.

Inspection reveals a patient who is alert but gaunt. It often discloses a grossly distended abdomen accompanied by ascites—typically the sign that prompts the patient to seek treatment.

Palpation of the abdominal organs and peritoneum may disclose masses. On palpation, ovarian tumors may vary from a rocky hardness to a rubbery or cystlike quality. Postmenopausal women who have palpable, premenopausal—size ovaries require further evaluation for an ovarian tumor.

Diagnostic tests

Tests ordered to help assess the patient's condition may include a complete blood count, blood chemistries, and electrocardiography.

Exploratory laparotomy, including lymph node evaluation and tumor resection, is required for accurate diagnosis and staging. Abdominal ultrasonography, a computed tomography scan, or X-rays delineate tumor size. Chest X-rays can also help identify distant metastasis and pleural effusions.

Excretory urography provides information on renal function and possible urinary tract obstruction. A barium enema (especially in patients with GI symptoms) may reveal obstruction and tumor size.

Lymphangiography can show lymph node involvement, and mammography can rule out primary breast cancer.

Liver function studies or a liver scan can help identify metastasis with ascites. Aspiration of ascitic fluid can reveal atypical cells Laboratory tumor marker studies, such as ovarian carcinoma antigen, carcinoembryonic antigen, and human chorionic gonadotropin, are also evaluated. (See [Staging ovarian cancer.](#))

Treatment

Depending on the cancer's stage and the patient's age, treatment requires varying combinations of surgery, chemotherapy, and, possibly, radiation therapy.

Occasionally, in girls or young women with a unilateral encapsulated tumor who wish to maintain fertile, the following conservative approach may be appropriate:

- resection of the involved ovary
- biopsies of the omentum and the uninvolved ovary
- peritoneal washings for cytologic examination of pelvic fluid
- careful follow-up, including periodic X-rays, to rule out metastasis.

However, ovarian cancer usually requires more aggressive treatment, including total abdominal hysterectomy and bilateral salpingoophorectomy with tumor resection, omentectomy, appendectomy, lymph node palpation with probable lymphadenectomy, tissue biopsies, and peritoneal washings. Complete tumor resection is impossible if the tumor has matted around other organs or if it involves organs that can't be resected. Bilateral salpingoophorectomy in a prepubertal girl necessitates hormonal replacement therapy, beginning at puberty, to induce the development of secondary sex characteristics. Chemotherapy after surgery extends survival time in most patients but is largely palliative in advanced disease, although prolonged remissions are achieved in some patients. Drugs used include melphalan, chlorambucil, thiotepa, methotrexate, cyclophosphamide, doxorubicin, vincristine, vinblastine, dactinomycin, bleomycin, and cisplatin. These drugs are usually given in combination. Intraperitoneal administration of cisplatin or paclitaxel has slowed disease progression and increased survival.

Radiation therapy isn't commonly used because it causes myelosuppression, which limits the effectiveness of chemotherapy. Radioisotopes have been used as adjuvant therapy but cause small-bowel obstructions and stenosis.

Under investigation, immunotherapy consists of I.V. injection of *Corynebacterium parvum* or bacille Calmette-Guerin vaccine, lymphokine-activated killer cells, and interleukin-2.

Nursing diagnoses

- Altered growth and development
- Altered nutrition: Less than body requirements
- Anticipatory grieving
- Anxiety
- Fear
- Fluid volume excess
- Hopelessness
- Impaired skin integrity
- Ineffective family coping: Disabling
- Ineffective individual coping
- Pain
- Risk for infection
- Sexual dysfunction

Key outcomes

- u The patient will demonstrate age-appropriate skills and behavior.
- u The patient will maintain weight within an acceptable range.
- u The patient will express feelings about the potential loss.
- u Family members will identify their needs.
- u The patient will express feelings of comfort and decreased pain.
- u The patient will maintain or regain self-esteem.

Nursing interventions

- u Listen to the patient's concerns and fears. Answer her questions honestly. Provide support for the patient and her family. If the patient is a young woman who must undergo surgery and lose her childbearing ability, help her and her family overcome feelings of despair. If the patient is a child, find out whether her parents have told her she has cancer, and respond to her questions accordingly.
- u After surgery, frequently monitor the patient's vital signs and check I.V. fluids. Monitor intake and output while maintaining good catheter care. Check the dressing regularly for excessive drainage or bleeding, and watch for signs of infection.
- u Provide abdominal support and be alert for abdominal distention. Encourage coughing and deep breathing. Reposition the patient often, and encourage her to walk shortly after surgery.
- u If the patient has pain, make her as comfortable as possible. Give analgesics as needed, provide distractions, and have the patient perform relaxation techniques.
- u Monitor and treat adverse effects of therapy. If the patient is undergoing intraperitoneal chemotherapy, help alleviate her discomfort by infusing the fluid at a slower rate and repositioning her in an attempt to distribute the fluid evenly.

Staging ovarian cancer
<p>The International Federation of Gynecology and Obstetrics has established this staging system, which is based on findings at clinical examination, surgical exploration, or both. Histology is taken into consideration, as is cytology in effusions. Ideally, biopsies should be obtained from any suspicious areas outside of the pelvis.</p> <p>To evaluate the impact on the prognosis of the different criteria for allotting cases to stage IC or IIC, consider (1) if rupture of the capsule was (a) spontaneous or (b) caused by the surgeon, or (2) if the source of malignant cells detected was (a) peritoneal washings or (b) ascites.</p> <p>Stage I Growth limited to the ovaries</p> <p>Stage IA Growth limited to one ovary; no ascites. No tumor on the external surface; capsule intact</p> <p>Stage IB Growth limited to both ovaries; no ascites. No tumor on the external surfaces; capsules intact</p> <p>Stage IC Tumor either stage IA or IB but with tumor on surface of one or both ovaries; or with capsule ruptured; or with ascites present containing malignant cells or with positive peritoneal washings</p> <p>Stage II Growth involving one or both ovaries with pelvic extension</p> <p>Stage IIA Extension or metastasis, or both, to the uterus or both</p> <p>Stage IIB Extension to other pelvic tissues</p> <p>Stage IIC Tumor either stage IIA or IIB, but with tumor on surface of one or both ovaries; or with capsule (or capsules) ruptured; or with ascites present containing malignant cells or with positive peritoneal washings</p> <p>Stage III Tumor involving one or both ovaries with peritoneal implants outside the pelvis or positive retroperitoneal or inguinal nodes; superficial liver metastasis equals stage III</p> <p>Tumor limited to the true pelvis but with histologically proved malignant extension to small bowel or omentum</p> <p>Stage IIIA Tumor grossly limited to the true pelvis with negative nodes but with histologically confirmed microscopic seeding of abdominal peritoneal surfaces</p> <p>Stage IIIB Tumor of one or both ovaries with histologically confirmed implants of abdominal peritoneal surfaces none exceeding 2 cm in greatest dimension; nodes are negative</p> <p>Stage IIIC Abdominal implants greater than 2 cm in greatest dimension or positive retroperitoneal or inguinal nodes or both</p> <p>Stage IV Growth involving one or both ovaries with distant metastasis; if pleural effusion is present, there must be positive cytology to suggest stage IV Parenchymal liver metastasis equals stage IV</p>

- u If the patient is receiving immunotherapy, watch for flulike symptoms that may last 12 to 24 hours after drug administration. Give aspirin or acetaminophen for fever.
- u Keep the patient covered with blankets, and provide warm liquids to relieve chills. Administer an antiemetic, as needed.
- u If the patient has effusions and must undergo paracentesis and thoracentesis, assist with the procedure as necessary. Be sure to help the patient find a comfortable position during the procedure and help her maintain it, using pillows. After the procedure, encourage fluids and monitor intake and output.
- u For the malnourished patient, administer supplementary enteral or parenteral nutrition as ordered. If the GI tract is intact, offer the patient frequent, small meals. If the GI tract is obstructed, discuss the possibility of a gastrostomy tube or a jejunostomy tube with the doctor and the patient.

Patient teaching

- u Teach the patient relaxation techniques and other measures that may help ease her discomfort.

- u Stress the importance of preventing infection, emphasizing good hand-washing technique.
- u Explain measures that may help maintain adequate nutrition, such as eating small, frequent meals.
- u If the patient is to undergo drug therapy or radiation therapy, explain the adverse effects that she can expect and suggest ways to alleviate and prevent them.
- u Before surgery, thoroughly explain all preoperative tests, the expected course of treatment, and surgical and postoperative procedures.
- u In premenopausal women, explain that bilateral oophorectomy artificially induces early menopause. Such patients may experience hot flashes, headaches, palpitations, insomnia, depression, and excessive perspiration.
- u As appropriate, refer the patient and her family to the social service department, home health care agencies, hospices, and support groups, such as the American Cancer Society.

PROSTATIC CANCER

Prostatic cancer is the most common neoplasm in men over age 50; it's a leading cause of male cancer death. Adenocarcinoma is the most common form; only seldom does prostatic cancer occur as a sarcoma. Most prostatic cancers originate in the posterior prostate gland, with the rest growing near the urethra. Malignant prostatic tumors seldom result from the benign hyperplastic enlargement that commonly develops around the prostatic urethra in older men.

Slow-growing prostatic cancer seldom produces signs and symptoms until it's well advanced. Typically, when primary prostatic lesions spread beyond the prostate gland, they invade the prostatic capsule and then spread along the ejaculatory ducts in the space between the seminal vesicles or perivesicular fascia. When prostatic cancer is fatal, death usually results from widespread bone metastases.

CULTURAL TIP The incidence of prostatic cancer is highest among blacks and lowest among Asians. It appears unaffected by socioeconomic status or fertility.

Causes

Risk factors for prostatic cancer include age (the cancer seldom develops in men under age 40) and infection. Endocrine factors may also have a role, leading researchers to suspect that androgens speed tumor growth.

Complications

Progressive disease can lead to spinal cord compression, deep vein thrombosis, pulmonary emboli, and myelophthisis.

Assessment findings

The patient's history may reveal urinary problems, such as dysuria, frequency, retention, back or hip pain, and hematuria. The patient with these complaints may have advanced disease, with back or hip pain signaling bone metastasis. The patient usually has no signs or symptoms in early disease. Inspection may reveal edema of the scrotum or leg in advanced disease. During digital rectal examination (DRE), prostatic palpation may detect a nonraised, firm, nodular mass with a sharp edge (in early disease) or a hard lump (in advanced disease).

Diagnostic tests

DRE (recommended yearly by the American Cancer Society for men over age 40) is the standard screening test.

Blood tests may show elevated levels of prostate-specific antigen (PSA). Although most men with metastasized prostatic cancer have an elevated PSA level, the finding also occurs with other prostatic disease. So the PSA level should be assessed in light of DRE findings. Transrectal prostatic ultrasonography may be used for patients with abnormal DRE and PSA test findings.

Bone scan and excretory urography are used to determine the disease's extent. Magnetic resonance imaging and computed tomography scanning can help define the tumor's extent.

Treatment

Therapy varies by cancer stage and may include radiation, prostatectomy, orchiectomy (removal of the testes) to reduce androgen production, and hormonal therapy with synthetic estrogen (diethylstilbestrol). Radical prostatectomy is usually effective for localized lesions without metastasis. A transurethral resection of the prostate may be performed to relieve an obstruction.

Radiation therapy may cure locally invasive lesions in early disease and may relieve bone pain from metastatic skeletal involvement. It also may be used prophylactically for patients with tumors in regional lymph nodes. Alternatively, internal beam radiation may be recommended because it permits increased radiation to reach the prostate but minimizes the surrounding tissues' exposure to radiation.

If hormonal therapy, surgery, and radiation therapy aren't feasible or successful, chemotherapy may be tried. Chemotherapy for prostatic cancer (combinations of cyclophosphamide, doxorubicin, fluorouracil, cisplatin, etoposide, and vindesine) offers limited benefits. Researchers continue to seek the most effective chemotherapeutic regimen.

Nursing diagnoses

- u Altered urinary elimination u Anxiety u Fear u Ineffective family coping: Disabling u Ineffective individual coping u Pain u Risk for infection u Sexual dysfunction

Key outcomes

- u The patient will acknowledge a problem in sexual function.
- u The patient will maintain an adequate urine output.
- u The patient and partner will discuss their feelings and perceptions.
- u The patient will voice increased comfort.
- u The patient will avoid or minimize complications.
- u The patient will remain free from signs and symptoms of infection.

Nursing interventions

- u At all times, encourage the patient to express his fears and concerns, including those about changes in his sexual identity, owing to surgery. Offer reassurance when possible.
- u Administer ordered analgesics as necessary. Provide comfort measures to reduce pain. Encourage the patient to identify care measures that promote his comfort and relaxation.

After prostatectomy:

- u Regularly check the dressing, incision, and drainage systems for excessive blood. Also watch for signs of bleeding (pallor, restlessness, decreasing blood pressure, and increasing pulse rate).
- u Be alert for signs of infection (fever, chills, inflamed incisional area). Maintain adequate fluid intake (at least 2,000 ml daily).
- u Give antispasmodics, as ordered, to control postoperative bladder spasms. Also provide analgesics as needed.

- u Because urinary incontinence commonly follows prostatectomy, keep the patient's skin clean and dry.

After suprapubic prostatectomy:

- u Keep the skin around the suprapubic drain dry and free from drainage and urine leakage. Encourage the patient to begin perineal exercises between 24 and 48 hours after surgery.
- u Allow the patient's family to assist in his care and encourage them to provide psychological support.
- u Give meticulous catheter care. After prostatectomy, a patient usually has a three-way catheter with a continuous irrigation system. Check the tubing for kinks, mucus plugs, and clots, especially if the patient complains of pain. Warn the patient not to pull on the tubes or the catheter.

After transurethral resection:

- u Watch for signs of urethral stricture (dysuria, decreased force and caliber of urine stream, and straining to urinate). Also observe for abdominal distention (a result of urethral stricture or catheter blockage by a blood clot). Irrigate the catheter, as ordered.

After perineal prostatectomy:

- u Avoid taking the patient's temperature rectally or inserting enema or other rectal tubes. Provide pads to absorb draining urine. Assist the patient with frequent sitz baths to relieve pain and inflammation.

After perineal or retropubic prostatectomy:

- u Give reassurance that urine leakage after catheter removal is normal and subsides in time.

After radiation therapy:

- u Watch for the common adverse effects of radiation to the prostate. These include proctitis, diarrhea, bladder spasms, and urinary frequency. Internal radiation of the prostate almost always results in cystitis in the first 2 to 3 weeks of therapy. Encourage the patient to drink at least 2,000 ml of fluid daily. Administer analgesics and antispasmodics to increase comfort.

After hormonal therapy:

- u When a patient receives hormonal therapy with diethylstilbestrol, watch for adverse effects (gynecomastia, fluid retention, nausea, and vomiting). Be alert for thrombophlebitis (pain, tenderness, swelling, warmth, and redness in calf).

Patient teaching

- u Before surgery, discuss the expected results. Explain that radical surgery always produces impotence. Up to 7% of patients experience urinary incontinence.
- u To help minimize incontinence, teach the patient how to do perineal exercises while he sits or stands. To develop his perineal muscles, tell him to squeeze his buttocks together and hold this position for a few seconds; then relax. He should repeat this exercise as frequently as ordered by the doctor.
- u Prepare the patient for postoperative procedures, such as dressing changes and intubation.
- u If appropriate, discuss the adverse effects of radiation therapy. All patients who receive pelvic radiation therapy will develop such symptoms as diarrhea, urinary frequency, nocturia, bladder spasms, rectal irritation, and tenesmus.
- u Encourage the patient to maintain a lifestyle that is as nearly normal as possible during recovery.
- u When appropriate, refer the patient to the social service department, local home health care agencies, hospices, and other support organizations.

TESTICULAR CANCER

Malignant testicular tumors are the most prevalent solid tumors in men ages 20 to 40. Testicular cancer is rare in nonwhite men and accounts for less than 1% of all male cancer deaths. Rarely, testicular cancer occurs in children.

With few exceptions, testicular tumors originate from germinal cells. About 40% become *seminomas*. These tumors, which are characterized by uniform, undifferentiated cells, resemble primitive gonadal cells. Other tumors— *nonseminomas*— show various degrees of differentiation.

The prognosis depends on the cancer cell type and stage. When treated with surgery, chemotherapy, and radiation therapy, almost all patients with localized disease survive beyond 5 years. Typically, when testicular cancer extends beyond the testes, it spreads through the lymphatic system to the iliac, para-aortic, and mediastinal nodes. Metastases affect the lungs, liver, viscera, and bone.

Causes

Although researchers don't know the immediate cause of testicular cancer, they suspect that cryptorchidism (even when surgically corrected) plays a role in the developing disease. (See [Cryptorchidism and testicular cancer](#).) A history of mumps orchitis, inguinal hernia in childhood, or maternal use of diethylstilbestrol (DES) or other estrogenprogestin combinations during pregnancy also increases the risk for this disease.

Complications

Disease progression may induce back or abdominal pain from retroperitoneal adenopathy, dyspnea, cough, and hemoptysis from lung metastases, and ureteral obstruction.

Assessment findings

The patient history may disclose previous injuries to the scrotum, viral infections (such as mumps), or the use of DES or other estrogenprogestin drugs by the patient's mother during pregnancy. The patient may describe a feeling of heaviness or a dragging sensation in the scrotum. He may also report swollen testes or a painless lump found while performing testicular self-examination. In late disease stages, the patient may complain of weight loss, a cough, hemoptysis, shortness of breath, lethargy, and fatigue.

On inspection, you may notice that the patient has enlarged testes. Gynecomastia, a sign that the tumor produces chorionic gonadotropins or estrogen, may be obvious also. In later stages of testicular cancer, the patient may appear lethargic, thin, and pallid.

Palpation findings include a firm, smooth testicular mass and enlarged lymph nodes in surrounding areas. In later disease stages, palpation may disclose an abdominal mass as well.

On auscultation you may hear decreased breath sounds.

Diagnostic tests

Serum analyses may be done to evaluate betasubunit human chorionic gonadotropin (HCG) and alpha-fetoprotein (AFP) levels. Elevated levels of these proteins (tumor markers) suggest testicular cancer and can differentiate a seminoma from a nonseminoma: elevated HCG and AFP levels point to a nonseminoma; elevated

HCG and normal AFP levels indicate a seminoma.

Computed tomography scanning can detect metastases. Chest X-rays may demonstrate pulmonary metastases. Lymphangiography, ultrasonography, and magnetic resonance imaging may disclose additional metastases.

Excretory urography may detect ureteral displacement, which is caused by metastasis to a para-aortic lymph node.

Biopsy can confirm the diagnosis, help stage the disease, and plan treatment.

Treatment

In testicular cancer, treatment includes surgery, radiation therapy, and chemotherapy. Treatment intensity varies with the tumor cell type and stage.

Surgical options include orchiectomy and retroperitoneal node dissection to prevent disease extension and assess its stage. Most surgeons remove just the testis, not the scrotum. The patient may need hormonal replacement therapy after bilateral orchiectomy.

Treatment of seminomas involves postoperative radiation to the retroperitoneal and homolateral iliac nodes. Patients whose disease extends to retroperitoneal structures may be given prophylactic radiation to the mediastinal and supraclavicular nodes. Treatment of nonseminoma includes radiation directed to all cancerous lymph nodes.

Chemotherapy is most effective for late-stage seminomas and most nonseminomas when used for recurrent cancer after orchiectomy and removal of the retroperitoneal lymph nodes.

Autologous bone marrow transplantation is usually reserved for patients who don't respond to standard therapy. It involves giving high-dose chemotherapy, removing and treating the patient's bone marrow to kill remaining cancer cells, and returning the processed bone marrow to the patient.

Nursing diagnoses

u Altered oral mucous membrane u Anxiety u Body image disturbance u Fear u Ineffective family coping: Disabling u Ineffective individual coping u Pain u Risk for infection u Sexual dysfunction

Key outcomes

- u The patient will express positive feelings about himself.
- u The patient will report feeling less tension or pain.
- u The patient will continue to function in usual roles to the greatest degree possible.
- u The patient will avoid or minimize complications.
- u The patient will voice understanding of treatment.
- u The patient and partner will express feelings and perceptions about change in sexual performance.

Nursing interventions

- u Focus on responding to the psychological impact of the disease, preventing postoperative complications, and minimizing and controlling the complications of radiation therapy and chemotherapy.
- u Listen to the patient's fears and concerns. Remember that the patient with testicular cancer typically fears sexual impairment and disfigurement. (See [Sex after testicular cancer surgery](#).) When possible, provide reassurance. Stay with the patient during periods of severe anxiety and stress.

Cryptorchidism and testicular cancer

In men with cryptorchidism (the failure of a testicle to descend into the scrotum), testicular tumors are about 50 times more common than in men with normal anatomic structure. A simple surgical procedure, called orchiopexy, can bring the testicle to its normal position in the scrotum and reduce the testicular cancer risk. Nevertheless, testicular tumors occur more commonly in a surgically descended testicle than in a naturally descended one.

What happens in orchiopexy
In this procedure, the surgeon incises the groin area and separates the testicle and its blood supply from surrounding abdominal structures. Then, he creates a “tunnel” into the scrotum to accommodate the descent of the testicle.

Reducing the risk further
After orchiopexy, urge the patient to examine himself monthly to detect a tumor at its earliest stage.

- u Encourage the patient to ask questions. Base your relationship on trust so that he feels comfortable expressing his concerns.

After orchiectomy:

- u For the first day after surgery, apply an ice pack to the scrotum and provide analgesics, as ordered.
- u Check for excessive bleeding, swelling, and signs of infection, such as drainage from the incision, fever, pain, and redness.
- u Supply an athletic supporter to minimize scrotal pain during ambulation.

During chemotherapy:

- u Know what problems to expect and how to prevent or ease them.
- u Give antiemetics as ordered to prevent severe nausea and vomiting.
- u Offer the patient small, frequent meals to maintain oral intake despite anorexia. Devise a mouth care regimen, making sure to check regularly for stomatitis.
- u Be alert for signs of myelosuppression. If the patient receives vinblastine, monitor for signs and symptoms of neurotoxicity (peripheral paresthesia, jaw pain, muscle cramps). If he receives cisplatin, check for ototoxicity. To prevent renal damage, encourage increased fluid intake.

Sex after testicular cancer surgery

Patients with testicular cancer typically are anxious about their future. Besides the usual apprehensions about living with cancer, these patients fear loss of sexual function after surgery (orchiectomy). To help patients face their fear, provide support and a clear explanation of how orchiectomy affects sexual activity.

After unilateral orchiectomy

Unilateral orchiectomy doesn't cause sterility or impotence. And because most surgeons remove only the diseased testicle and leave the scrotum, later reconstructive surgery can be done. This involves implanting a gel-filled testicular prosthesis, which weighs the same as and feels like a normal testicle. The patient can resume sexual activity after the incision heals.

After bilateral orchiectomy

Bilateral testicular cancer is uncommon. However, if the patient loses both testes, sterility results. If nerve or vascular damage (or both) occur with surgery, impotence also results.

Be as positive and supportive as possible. Clearly express that a loss of fertility doesn't typically mean a loss of masculinity. Typically, the patient takes synthetic hormones to replace or supplement depleted mate hormone levels.

u To maximize hydration, give I.V. fluids as ordered with a potassium supplement. Provide diuresis as ordered by administering furosemide or mannitol.

During radiation therapy:

u Watch for and report adverse effects.
u Implement appropriate comfort and safety measures. For example, avoid rubbing the skin near radiation target sites. This helps to prevent or alleviate pain, skin breakdown, and infection.

Patient teaching

u Provide reassurance that sterility and impotence usually don't follow unilateral orchiectomy. Explain that synthetic hormones can supplement depleted hormone levels. Inform the patient that most surgeons don't remove the scrotum. Also explain that a testicular prosthetic implant can correct disfigurement.
u As suitable, review sperm-banking procedures before the patient begins treatment, especially if infertility and impotence may result from surgery.
u Explain tests and treatments that the patient is to undergo. Make sure he understands each treatment, its purpose, possible complications, and the care required during and after the treatment.
u Teach the patient how to perform testicular self-examination. Tell him that this is the best way to detect a new or recurrent tumor.
u Refer the patient to organizations such as the American Cancer Society that offer information and support during and after treatment.

UTERINE CANCER

Uterine cancer (cancer of the endometrium) is the most common gynecologic cancer. It typically afflicts postmenopausal women between ages 50 and 60. It's uncommon between ages 30 and 40 and rare before age 30. Most premenopausal women who develop uterine cancer have a history of anovulatory menstrual cycles or other hormonal imbalance. About 33,000 new cases of uterine cancer are reported annually; of these, roughly 5,500 are fatal.

Causes

Uterine cancer appears linked to several predisposing factors:

u low fertility index and anovulation
u history of infertility or failure of ovulation
u abnormal uterine bleeding
u obesity, hypertension, diabetes, or nulliparity
u familial tendency
u history of uterine polyps or endometrial hyperplasia
u prolonged estrogen therapy with exposure unopposed by progesterone.

In most patients, uterine cancer is an adenocarcinoma that metastasizes late, usually from the endometrium to the cervix, ovaries, fallopian tubes, and other peritoneal structures. It may spread to distant organs, such as the lungs and the brain, by way of the blood or the lymphatic system. Lymph node involvement can also occur. Less common uterine tumors include adenoacanthoma, endometrial stromal sarcoma, lymphosarcoma, mixed mesodermal tumors (including carcinosarcoma), and leiomyosarcoma.

Complications

Intestinal obstruction, ascites, increasing pain, and hemorrhage are complications related to disease progression.

Assessment findings

The patient history may reflect one or more predisposing factors. In a younger patient, it may also reveal spotting and protracted, heavy menstrual periods. A postmenopausal woman may report that bleeding began 12 or more months after menses had stopped. In either case, the patient may describe the discharge as watery at first, then blood-streaked, and gradually becoming bloodier.

In more advanced stages, palpation may disclose an enlarged uterus.

Diagnostic tests

Endometrial, cervical, or endocervical biopsy confirms cancer cells. Fractional dilatation and curettage is used to identify the problem when the disease is suspected but the endometrial biopsy is negative.

Positive diagnosis requires these tests to provide baseline data and permit staging: multiple cervical biopsies and endocervical curettage to pinpoint cervical involvement; Schiller's test staining of the cervix and vagina with an iodine solution that turns healthy tissues brown (cancerous tissues resist the stain); computed tomography scans or magnetic resonance imaging to detect metastasis to the myometrium, cervix, lymph nodes, and other organs; and excretory urography and, possibly, cystoscopy to evaluate the urinary system.

Proctoscopy or barium enema studies may be performed if bladder and rectal involvement are suspected.

Blood studies, urinalysis, and electrocardiography may also help in staging the disease. (See [Staging uterine cancer.](#))

Treatment

Depending on the extent of the disease, the treatment may include one or more of the following:

u *Surgery* usually involves total abdominal hysterectomy, bilateral salpingoophorectomy or, possibly, omentectomy with or without pelvic or paraaortic

lymphadenectomy. Total pelvic exenteration removes all pelvic organs, including the rectum, bladder, and vagina, and is only performed when the disease is sufficiently contained to allow surgical removal of diseased parts. This surgery seldom is curative, especially in nodal involvement.

- u *Radiation therapy* is used when the tumor isn't well differentiated. Intracavitary radiation, external radiation, or both may be given 6 weeks before surgery to inhibit recurrence and lengthen survival time.
- u *Hormonal therapy*, using tamoxifen, shows a response rate of 20% to 40%.
- u *Chemotherapy*, including both cisplatin and doxorubicin, is usually tried when other treatments have failed.

Nursing diagnoses

u Altered urinary elimination u Anxiety u Body image disturbance u Fear u Impaired tissue integrity u Ineffective individual coping u Pain u Risk for infection u Sexual dysfunction

Key outcomes

- u The patient will express positive feelings about self.
- u The patient will report feeling less tension or pain.
- u The patient and partner will express feelings and perceptions about change in sexual performance.
- u The patient will voluntarily express problems.
- u The patient will remain free from signs or symptoms of infection.

Nursing interventions

- u Listen to the patient's fears and concerns. She may be fearful for her survival and concerned that treatment will alter her lifestyle or prevent sexual intimacy. Remain with the patient during periods of severe stress and anxiety.
- u Administer ordered pain medications as necessary. Patients who require pain medications for this disease are often in the later stages. Encourage the patient to identify actions that promote comfort and then be sure to perform them as often as possible. Provide distractions and help her perform relaxation techniques that may ease discomfort.

After surgery:

- u Measure fluid contents of the blood drainage system every shift. Notify the doctor immediately if drainage exceeds 400 ml.
- u If the patient has received subcutaneous heparin, continue administration, as ordered, until she is fully ambulatory. Give prophylactic antibiotics, as ordered, and provide good indwelling urinary catheter care.
- u Check the patient's vital signs every 4 hours. Watch for and immediately report any sign of complications, such as bleeding, abdominal distention, severe pain, and wheezing or other breathing difficulties. Provide analgesics as ordered.
- u Regularly encourage the patient to breathe deeply and cough. Promote the use of an incentive spirometer once every waking hour to help keep lungs expanded.

Staging uterine cancer
<p>The following are the International Federation of Gynecology and Obstetrics uterine (endometrial) cancer stages.</p> <p>Stage 0 Carcinoma in situ</p> <p>Stage I Carcinoma confined to the corpus</p> <p>Stage IA Length of the uterine cavity 8 cm or less</p> <p>Stage IB Length of the uterine cavity more than 8 cm</p> <p>Stage I cases are subgrouped by the following histologic grades of the adenocarcinoma:</p> <p>G1— Highly differentiated adenomatous carcinoma G2— Moderately differentiated adenomatous carcinoma with partly solid areas G3— Predominantly solid or entirely undifferentiated carcinoma</p> <p>Stage II Carcinoma has involved the corpus and the cervix but has not extended outside the uterus</p> <p>Stage III Carcinoma has extended outside the uterus but not outside the true pelvis</p> <p>Stage IV Carcinoma has extended outside the true pelvis or has obviously involved the mucosa of the bladder or rectum</p> <p>Stage IVA Spread of the growth to adjacent organs</p> <p>Stage IVB Spread to distant organs</p>

- u Find out whether the patient is to have internal or external radiation or both. Usually, internal radiation therapy is used first.

For internal radiation therapy:

- u Check to see whether the radioactive source is to be inserted while the patient is in the operating room (preloaded) or at the bedside (afterloaded). If the source is preloaded, the patient returns to her room “hot,” and safety precautions begin immediately.
- u Remember that safety precautions—time, distance, and shielding—must be imposed as soon as the radioactive source is in place. Inform the patient that she'll require a private room.
- u Encourage the patient to limit movement while the source is in place. If she prefers, slightly elevate the head of the bed. Make sure the patient can reach everything she needs (the call bell, telephone, water) without stretching or straining. Assist her in range-of-motion arm exercises; leg exercises and other body movements could dislodge the source.
- u If ordered, administer a tranquilizer to help the patient relax and remain still.
- u Provide diversional activities that require minimal movement.

- u Check the patient's vital signs every 4 hours; watch for skin reaction, vaginal bleeding, abdominal discomfort, and evidence of dehydration.
- u Inform visitors of safety precautions, and hang a sign listing these precautions on the patient's door.

For internal and external radiation therapy:

- u Be alert for the possible adverse effects of radiation. Perform measures that help prevent them.
- u Organize the time you spend with the patient to minimize your exposure to radiation.

Patient teaching

- u Emphasize that prompt treatment significantly improves a patient's likelihood of survival. Discuss tests to diagnose and stage the disease, and explain treatments, which may include radiation therapy, surgery, hormonal therapy, or chemotherapy, or a combination of these.

For surgery:

- u Reinforce what the doctor told the patient about the surgery, and explain the routine tests (such as repeated blood tests the morning after surgery) and postoperative care. If the patient is to have a lymphadenectomy and a total hysterectomy, explain that she'll probably have a blood drainage system for about 5 days after surgery. Also explain indwelling catheter care. Fit the patient with antiembolism stockings for use during and after surgery. Make sure the patient's blood has been typed and crossmatched. If the patient is premenopausal, inform her that removal of her ovaries will induce menopause.
- u As appropriate, explain that except in total pelvic exenteration, the vagina remains intact and that when she recovers, sexual intercourse is possible.

For internal radiation therapy:

- u Describe the procedure for radiation therapy to the patient. Answer the patient's questions and counsel her about radiation's adverse effects. Advise her to rest frequently and to maintain a well-balanced diet.
- u Explain that the preloaded internal radiation procedure requires a 2- to 3-day hospital stay, bowel preparation, a povidone-iodine vaginal douche, a clear liquid diet, and nothing taken by mouth the night before the implantation, as well as an indwelling catheter. Inform the patient that the procedure is performed in the operating room under general anesthesia. She is placed in a dorsal position, with knees and hips flexed and heels resting in footrests. The doctor implants the radiation source in the vagina.
- u Explain that in *afterloaded internal* radiation therapy, a member of the radiation team implants the source while the patient is in her room.

For external radiation therapy:

- u Teach the patient and her family about the therapy before it begins. Tell the patient that treatment is usually given 5 days per week for 6 weeks. Warn her not to scrub body areas marked with indelible ink because these markings direct treatment to exactly the same area each time.
- u Instruct the patient to maintain a high-protein, high-carbohydrate, low-residue diet to reduce bulk and yet maintain calories. Administer diphenoxylate with atropine as ordered to minimize diarrhea, a possible adverse effect of pelvic radiation.
- u To minimize skin breakdown and reduce the risk of skin infection, tell the patient to keep the treatment area dry, avoid wearing clothes that rub against the area, and avoid using heating pads, alcohol rubs, or irritating skin creams. Because radiation therapy increases susceptibility to infection (possibly by lowering the white blood cell [WBC] count), instruct the patient to avoid people with colds or other infections.

For chemotherapy or immunotherapy:

- u Explain the therapy and be sure the patient understands what adverse effects to expect and how to alleviate them. If the patient is receiving a synthetic form of progesterone, such as hydroxyprogesterone (Delalutin), medroxyprogesterone (Provera), or megestrol (Megace), tell her to watch for depression, dizziness, backache, swelling, breast tenderness, irritability, and abdominal cramps. Instruct her to report signs of thrombophlebitis, such as pain in the calves, numbness, tingling, or loss of leg function.
- u Advise the patient receiving chemotherapy that WBC counts must be checked weekly, and reinforce the importance of preventing infection. Assure her that hair loss is temporary.
- u If the patient works and is undergoing chemotherapy, point out that continuing to work during this period may offer an important diversion. Advise her to talk with her employer about a flexible work schedule.
- u Refer the patient to the social service department and to community services that offer psychological support and information, such as the American Cancer Society.

VAGINAL CANCER

Vaginal cancer is the rarest gynecologic cancer. It usually appears as squamous cell carcinoma, but occasionally as melanoma, sarcoma, or adenocarcinoma. Vaginal cancer usually occurs in women in their early to middle 50s, but some rarer types do appear in younger women, and rhabdomyosarcoma appears in children.

Causes and pathophysiology

Although the relation is unclear, certain factors predispose the patient to the development of squamous cell carcinoma of the vagina. These include trauma, chronic pessary use, and the use of chemical carcinogens, such as those in some sprays and douches.

The likeliest risk factor appears to be advanced age combined with any of the above. Cancer in this area may also be an extension of a previous cancer of the endometrium, vulva, or cervix. In addition, vaginal adenocarcinoma has been associated with the use of diethylstilbestrol (DES) by the patient's mother during pregnancy.

Because the vagina is a thin-walled structure with rich lymphatic drainage, cancer here varies in severity, depending on its exact location and effect on lymphatic drainage. Vaginal cancer resembles cervical cancer in that it may progress from an intraepithelial tumor to an invasive cancer. It spreads more slowly than cervical cancer, however.

A lesion in the upper third of the vagina, the most common site, usually metastasizes to the groin nodes; a lesion in the lower third, the second most common site, usually metastasizes to the hypogastric and iliac nodes. A lesion in the middle third metastasizes erratically. A posterior lesion displaces and distends the vaginal posterior wall before spreading to deep layers. By contrast, an anterior lesion spreads more rapidly into other structures and deep layers because, unlike the posterior wall, the anterior vaginal wall isn't flexible.

Staging vaginal cancer

The International Federation of Gynecology and Obstetrics has established this staging system as a guide to the treatment and the prognosis of vaginal cancer.

Stage 0

Carcinoma in situ, intraepithelial carcinoma

Stage I

Carcinoma limited to the vaginal wall

Stage II

Carcinoma involves the subvaginal tissue but has not extended to the pelvic wall

Stage III

Carcinoma extends to the pelvic wall

Stage IV

Carcinoma extends beyond the true pelvis or involves the mucosa of the bladder or rectum

Complications

Metastasis may affect the cervix, uterus, and rectum.

Assessment findings

The history may reveal one or more risk factors and the most frequent presenting signs—bloody vaginal discharge and irregular or postmenopausal bleeding. The patient may also complain of urine retention or urinary frequency if the lesion is close to the neck of the bladder. Vaginal examination may reveal a small or large ulcerated lesion in any area of the vagina.

Diagnostic tests

Several tests are used to help identify and stage vaginal cancer. A Papanicolaou test shows abnormal cells. Biopsy of the lesion is performed to identify cancerous cells. Biopsy of the cervix and vulva may also be performed to rule out these areas as primary cancer sites. Colposcopy may be used to locate lesions that may have been missed during the pelvic examination. Lugol's solution painted on the suspected area helps identify malignant areas by staining glycogen-containing normal tissue; abnormal tissue resists staining. Barium enema is performed to rule out rectal metastasis. (See [Staging vaginal cancer.](#))

Treatment

Early-stage treatment aims to treat the malignant area and preserve the vagina. Topical chemotherapy with fluorouracil and laser surgery can be used for stages 0 and 1. Recommendations for radiation therapy and surgery vary with the size, depth, and location of the lesion and the patient's desire to preserve a functional vagina. Such preservation is possible only in the early stages. Survival rates are the same for patients treated with radiation as for those who undergo surgery.

Surgery may be recommended only when the tumor is so extensive that exenteration is needed because the vagina's close proximity to the bladder and rectum allows only minimal tissue margins around resected vaginal tissue.

Radiation therapy is the preferred treatment for all stages of vaginal cancer. Most patients need preliminary external radiation treatment to shrink the tumor before internal radiation can begin. If the tumor is localized to the vault and the cervix is present, radiation (radium or cesium) can be given with an intrauterine tandem and colpostat (avoids); if the cervix is absent, a specially designed vaginal applicator is used instead. To minimize complications, radioactive sources and filters are carefully placed away from radiosensitive tissues, such as the bladder and rectum. Such treatment lasts 48 to 72 hours, depending on the dosage.

Nursing diagnoses

u Altered sexuality patterns u Anxiety u Fear u Impaired physical mobility u Impaired tissue integrity u Ineffective individual coping u Pain u Risk for infection

Key outcomes

u The patient will express positive feelings about self.
u The patient will experience feelings of comfort and decreased pain.
u The patient and partner will express feelings and perceptions about change in sexual performance.
u The patient will voluntarily express problems.
u The patient will remain free from signs and symptoms of infection.

Nursing interventions

u Listen to the patient's fears and concerns and offer psychological support. The patient may fear both the disease and its impact on her sexual behavior.
u When appropriate, administer ordered analgesics and provide comfort measures and distractions that help minimize pain.

For internal radiation therapy:

u Before treatment, find out if the radiation source is to be inserted in the operating room or the patient's room so that you can minimize your radiation exposure.
u Because radiation effects are cumulative, wear a radiosensitive badge and a lead shield when you enter the patient's room. Check with the radiation therapist concerning the maximum recommended time that you can safely spend providing direct care. Organize care to minimize your exposure.
u While the radiation source is in place, the patient must lie flat on her back and limit movement. The head of the bed can be slightly elevated. Insert an indwelling urinary catheter if this wasn't done in the operating room, and don't change the patient's linens unless they are soiled. Give only partial bed baths, and make sure the patient has a call bell, telephone, water, and anything else she needs within easy reach. The doctor orders a clear liquid or low-residue diet and an antidiarrheal drug to prevent bowel movements.
u Provide diversional activities that require minimal movement.
u Inform visitors of safety precautions, and hang a sign listing these precautions on the patient's door.
u To compensate for immobility, encourage the patient to do active range-of-motion exercises with both arms.
u Watch for the complications of prescribed treatments. Perform measures that help prevent or alleviate complications of radiation therapy and chemotherapy.

Patient teaching

u Explain all treatments to the patient and, as appropriate, family members.
u Before external radiation therapy, stress the importance of providing good skin care to the target site after treatment to maintain skin integrity. Tell the patient to avoid constrictive clothing over the area, extremes of hot or cold, and vigorously rubbing the area. Also stress the need to take measures to prevent infection, such as avoiding crowds and washing her hands.
u Before internal radiation therapy, explain the necessity of immobilization during therapy, and tell the patient what this therapy entails (such as no linen changes and the use of an indwelling catheter).
u After internal radiation therapy, instruct the patient to use a stent or prescribed dilator exercises to prevent vaginal stenosis. Coitus also helps prevent such stenosis.

u Refer the patient for psychological counseling, if necessary, or to the social service department and support groups, such as the American Cancer Society.

Bone, skin, and soft-tissue neoplasms

Cancer in bone, skin, and soft tissue can be just as serious as cancer in some major organs. Both primary malignant tumors and metastatic lesions may afflict these structures.

BASAL CELL EPITHELIOMA

Basal cell epithelioma, a slow-growing, destructive skin tumor, usually occurs in people over age 40. Basal cell epithelioma is most prevalent in blond, fair-skinned men, and it's the most common malignant tumor that affects whites. The two major types of basal cell epithelioma are noduloulcerative and superficial.

Causes and pathophysiology

Prolonged sun exposure is the most common cause of basal cell epithelioma—90% of tumors occur on sun-exposed areas of the body. Arsenic ingestion, radiation exposure, burns, immunosuppression and, rarely, vaccinations are other possible causes.

Although the pathogenesis is uncertain, some experts hypothesize that basal cell epithelioma originates when undifferentiated basal cells become carcinomatous instead of differentiating into sweat glands, sebum, and hair.

Complications

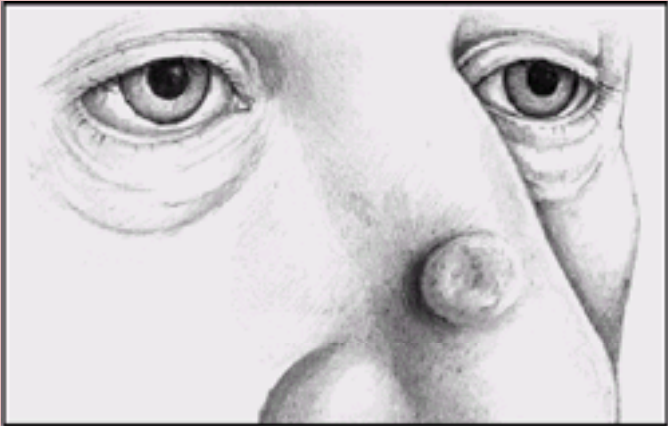

Disease progression can lead to disfiguring lesions of the eyes, nose, and cheeks.

Assessment findings

The patient history may reveal that the patient became aware of an odd-looking skin lesion, which prompted him to seek medical examination. The history may also disclose prolonged exposure to the sun sometime in the patient's life or other risk factors for this disease.

Identifying basal cell carcinoma

The figure below shows an enlarged nasal nodule in basal cell carcinoma. Note its depressed center and firm, elevated border.

Inspection of the face—particularly the forehead, eyelid margins, and nasolabial folds —may reveal lesions characterized as small, smooth, pinkish, and translucent papules (early-stage noduloulcerative). Telangiectatic vessels cross the surface, and the lesions may be pigmented. As the lesions enlarge, their centers become depressed and their borders become firm and elevated. These ulcerated tumors are called rodent ulcers.

Inspection of the chest and back may disclose multiple oval or irregularly shaped, lightly pigmented plaques. These may have sharply defined, slightly elevated, threadlike borders (superficial basal cell epitheliomas).

Inspection of the head and neck may show waxy, sclerotic, yellow to white plaques without distinct borders. These plaques may resemble small patches of scleroderma and may suggest sclerosing basal cell epitheliomas (morphea-like epitheliomas). (See [Identifying basal cell carcinoma.](#))

Diagnostic tests

All types of basal cell epitheliomas are diagnosed by clinical appearance. Incisional or excisional biopsy and histologic study may help to determine the tumor type and histologic subtype.

Treatment

Depending on the size, location, and depth of the lesion, treatment may include curettage and electrodesiccation, chemotherapy, surgical excision, irradiation, or chemosurgery:

- u *Curettage and electrodesiccation* offer good cosmetic results for small lesions.
- u *Topical fluorouracil* is often used for superficial lesions. This medication produces marked local irritation or inflammation in the involved tissue but no systemic effects.
- u Microscopically controlled *surgical excision* carefully removes recurrent lesions until a tumor-free plane is achieved. After removal of large lesions, skin grafting may be required.
- u *Irradiation* is used if the tumor location requires it. It's also preferred for elderly or debilitated patients who might not tolerate surgery.
- u *Chemosurgery* may be necessary for persistent or recurrent lesions. It consists of periodic applications of a fixative paste (such as zinc chloride) and subsequent removal of fixed pathologic tissue. Treatment continues until tumor removal is complete.
- u *Cryotherapy* , using liquid nitrogen, freezes the cells and kills them.

Nursing diagnoses

u Altered nutrition: Less than body requirements u Anxiety u Body image disturbance u Fear u Impaired skin integrity u Ineffective family coping: Disabling u Ineffective individual coping u Risk for infection u Self-esteem disturbance

Key outcomes

- u The patient will maintain weight within an acceptable range.
- u The patient will express positive feelings about self.
- u The patient will express feelings of increased comfort.
- u The patient will sustain adequate food and fluid intake.

- u The patient will exhibit improved or healed lesions or wounds.
- u The patient and family members will demonstrate effective coping mechanisms.

Nursing interventions

- u Listen to the patient's fears and concerns. Offer reassurance when appropriate. Remain with the patient during periods of severe stress and anxiety. Provide positive reinforcement for the patient's efforts to adapt.
- u Arrange for the patient to interact with others who have a similar problem.
- u Assess the patient's readiness for decision making; then involve him and family members in decisions related to his care whenever possible.
- u Watch for complications of treatment, including local skin irritation from chemotherapeutic agents applied topically and infection.
- u Watch for radiation's adverse effects, such as nausea, vomiting, hair loss, malaise, and diarrhea. Provide reassurance and comfort measures when appropriate.

Patient teaching

- u Instruct the patient to eat frequent, small, high-protein meals. Advise him to include eggnog, blender-processed foods, and liquid protein supplements if the lesion has invaded the oral cavity and is causing eating difficulty.
- u To prevent disease recurrence, tell the patient to avoid excessive sun exposure and to use a strong sunscreen or sunshade to protect his skin from damage by ultraviolet rays. If he must be out in the sun, tell him to avoid the hours of strongest sunlight and cover up with protective clothing.
- u Advise the patient to relieve local inflammation from topical fluorouracil with cool compresses or with corticosteroid ointment.
- u Instruct the patient with noduloulcerative basal cell epithelioma to wash his face gently when ulcerations and crusting occur; scrubbing too vigorously may cause bleeding.
- u As appropriate, direct the patient and family members to facility and community support services such as social workers, psychologists, and cancer support groups.

MALIGNANT MELANOMA

Malignant melanoma is a neoplasm that arises from melanocytes. It's potentially the most lethal of the skin cancers. It's also relatively rare, accounting for only 1% to 2% of all malignant tumors. Melanoma is slightly more common in women than in men and is unusual in children. Peak incidence occurs between ages 50 and 70, although the incidence in younger age groups is increasing.

Melanoma spreads through the lymphatic and vascular systems and metastasizes to the regional lymph nodes, skin, liver, lungs, and central nervous system. Its course is unpredictable and recurrence and metastases may not appear for more than 5 years after resection of the primary lesion. The prognosis varies with the tumor thickness. In most patients, superficial lesions are curable, whereas deeper lesions tend to metastasize.

Common sites for melanoma are the head and neck in men, the legs in women, and the backs of people exposed to excessive sunlight. Up to 70% of malignant melanomas arise from a preexisting nevus. (See [Recognizing potentially malignant nev.](#)) It seldom appears in the conjunctiva, choroid, pharynx, mouth, vagina, or anus.

The four types of melanomas are as follows:

- u *Superficial spreading melanoma*, the most common type, usually develops between ages 40 and 50.
- u *Nodular melanoma* usually develops between ages 40 and 50. It grows vertically, invades the dermis, and metastasizes early.
- u *Acrallentiginous melanoma* is the most common melanoma among Hispanics, Asians, and Blacks. It occurs on the palms and soles and in sublingual locations.
- u *Lentigo maligna melanoma* is relatively rare. This is the most benign, slowest growing, and least aggressive of the four types. It most commonly occurs in areas heavily exposed to the sun. It arises from a lentigo maligna, on an exposed skin surface, and usually occurs between ages 60 and 70.

Causes

Several factors may influence the development of melanoma:

- u *Excessive exposure to sunlight.* Melanoma occurs most commonly in persons in sunny, warm areas and often develops on body parts that are exposed to the sun.
- u *Skin type.* Most people who develop melanoma have blond or red hair, fair skin, and blue eyes; are prone to sunburn; and are of Celtic or Scandinavian ancestry. Melanoma is rare among Blacks; when it does develop, it usually arises in lightly pigmented areas (the palms, plantar surface of the feet, or mucous membranes).
- u *Hormonal factors.* Pregnancy may increase the risk of melanoma and exacerbate growth.
- u *Family history.* Melanoma occurs slightly more often within families.
- u *Past history of melanoma.* A person who has had one melanoma is at greater risk of developing a second.

Recognizing potentially malignant nevi

Nevi (moles) are skin lesions that may be hereditary. They're commonly pigmented, begin to grow in childhood (occasionally they're congenital), and become more numerous in young adulthood. Up to 70% of patients with melanoma have a history of a preexisting nevus at the tumor site. Of these, about one-third are reported to be congenital; the remainder develop later in life.

Changes in nevi (color, size, shape, texture, ulceration, bleeding, or itching) suggest possible malignant transformation. The presence or absence of hair within a nevus has no significance.

Types of nevi

Junctional nevi are flat or slightly raised and light to dark brown, with melanocytes confined to the epidermis. Usually they appear before age 40. These nevi may change into compound nevi if junctional nevus cells proliferate and penetrate into the dermis.

Compound nevi are usually tan to dark brown and slightly raised, although size and color vary. They contain melanocytes in both the dermis and epidermis and seldom undergo malignant transformation. Excision is necessary only to rule out malignant transformation or for cosmetic reasons.

Dermal nevi are elevated lesions from 2 to 10 mm in diameter. They vary in color from flesh to brown. They usually develop in people over age 40, typically on the upper body. Excision is necessary only to rule out malignant transformation.

Blue nevi are flat or slightly elevated lesions from 0.5 to 1 cm in diameter. They appear on the head, neck, arms, and dorsa of the hands, and are twice as common in women as in men. The blue color results from pigment and collagen in the dermis, which reflect blue light but absorb other wavelengths. Excision is necessary to rule out pigmented basal cell epithelioma or melanoma, or for cosmetic reasons.

Dysplastic nev. are generally greater than 5 mm in diameter, with irregularly notched or indistinct borders. Coloration is a mixture of tan and brown, sometimes with red, pink, and black pigmentation. No two lesions are alike. They occur in great numbers (typically more than 100 at a time), never singly, usually appearing on the back, scalp, chest, and buttocks. Dysplastic nevi are potentially malignant, especially in patients with a personal or family history of melanoma. Skin biopsy confirms diagnosis; treatment is by surgical excision, followed by regular physical examinations (every 6 months) to detect any new lesions or changes in existing lesions.

Complications

This cancer has a strong tendency to metastasize. Complications result from disease progression to the lungs, liver, or brain.

Assessment findings

A sore that doesn't heal, a persistent lump or swelling, and changes in preexisting skin markings, such as moles, birthmarks, scars, freckles, or warts, may be part of the patient history. Suspect melanoma when any preexisting skin lesion or nevus enlarges, changes color, becomes inflamed or sore, itches, ulcerates, bleeds, changes texture, or shows signs of surrounding pigment regression.

In superficial spreading melanoma, inspection may reveal lesions on the ankles or the inside surfaces of the knees. These lesions may appear red, white, or blue over a brown or black background. They may have an irregular, notched margin. Palpation may reveal small, elevated tumor nodules that may ulcerate and bleed. These tumors may grow horizontally for years, but when vertical growth occurs, the prognosis worsens.

In nodular malignant melanoma, inspection of the knees and ankles may reveal a uniformly discolored nodule. It may appear grayish and resemble a blackberry. Occasionally, this melanoma is flesh-colored with flecks of pigment around its base, which may be inflamed. Palpation may disclose polypoid nodules that resemble the surface of a blackberry.

In acral lentiginous melanoma, inspection may show pigmented lesions on the palms and soles and under the nails. The color may resemble a mosaic of rich browns, tans, and black. Inspection of the nail beds may reveal a streak in the nail associated with an irregular tan or brown stain that diffuses from the nail bed.

In lentigo maligna melanoma, the patient history may reveal a longstanding lesion that has now ulcerated. Inspection may disclose a large lesion (3 to 6 cm) that appears as a freckle of tan, brown, black, whitish, or slate color on the face, back of the hand, or under the fingernails. There may be irregular scattered black nodules on the surface. Palpation may reveal a flat nodule with smaller nodules scattered over the surface.

Diagnostic tests

Excisional biopsy and full-depth punch biopsy with histologic examination can distinguish malignant melanoma from a benign nevus, seborrheic keratosis, or pigmented basal cell epithelioma and can also determine tumor thickness and disease stage.

Baseline laboratory studies may include complete blood count with differential, erythrocyte sedimentation rate, platelet count, and liver function studies, in addition to urinalysis.

Depending on the depth of tumor invasion and any metastatic spread, baseline diagnostic studies may also include such tests as chest X-rays, computed tomography (CT) scans of the chest and abdomen, and a gallium scan. Signs of bone metastasis may require a bone scan; central nervous system metastasis may require a CT scan of the brain. Magnetic resonance imaging may be used to assess metastasis.

Treatment

A patient with malignant melanoma always requires surgical resection to remove the tumor (a 3- to 5-cm margin is desired). The extent of resection depends on the size and location of the primary lesion. Closure of a wide resection may necessitate a skin graft. If so, plastic surgery techniques provide excellent cosmetic repair. Surgical treatment may also include regional lymphadenectomy.

Deep primary lesions may merit adjuvant chemotherapy. The most consistently used drugs have been dacarbazine and carmustine. After surgical removal of a mass, intra-arterial isolation perfusions are performed to prevent recurrence and metastatic spread.

Although still experimental, biotherapy, consisting of treatment with bacille Calmette-Guerin (BCG) vaccine, offers hope to patients with advanced melanoma. In theory, immunotherapy combats cancer by boosting the body's disease-fighting systems.

Chemotherapy is useful only in metastatic disease. Dacarbazine and the nitrosoureas have generated some response. Similarly, radiation therapy is usually reserved for metastatic disease. It doesn't prolong survival but may reduce tumor size and relieve pain.

Regardless of treatment, melanomas require close long-term follow-up care to detect metastases and recurrences. Statistics show that about 13% of recurrences develop more than 5 years after primary surgery.

Nursing diagnoses

u Altered nutrition: Less than body requirements u Anticipatory grieving u Anxiety u Body image disturbance u Fear u Impaired skin integrity u Ineffective family coping: Disabling u Ineffective individual coping u Pain u Risk for infection

Key outcomes

- u The patient will maintain weight within an acceptable range.
- u The patient will express positive feelings about self.
- u The patient and family members will demonstrate effective coping mechanisms.
- u The patient will experience healing of wound without signs of infection.
- u The patient will express feelings of increased comfort.

Nursing interventions

- u Listen to the patient's fears and concerns. Stay with him during episodes of stress and anxiety. Include the patient and family members in care decisions.
- u Provide positive reinforcement as the patient attempts to adapt to his disease.
- u Watch for complications associated with chemotherapy, such as mouth sores, hair loss, weakness, fatigue, and anorexia. Offer orange and grapefruit juices and ginger ale to help with nausea and vomiting.
- u Provide an adequate diet for the patient, one that is high in protein and calories. If the patient is anorexic, provide small, frequent meals. Consult with the dietitian to incorporate foods that the patient enjoys into his diet.
- u After surgery, take precautions to prevent infection. Check dressings often for excessive drainage, foul odor, redness, and swelling. If surgery included lymphadenectomy, apply a compression stocking, and instruct the patient to keep the extremity elevated to minimize lymphedema.

In advanced metastatic disease:

- u Control and prevent pain with regularly scheduled administration of analgesics.
- u If the patient is dying, identify the needs of patient, family, and friends, and provide appropriate support and care.

Patient teaching

- u Make sure the patient understands the procedures and treatments associated with his diagnosis. Review the doctor's explanation of treatment alternatives. Honestly answer any questions he has about surgery, chemotherapy, and radiation therapy.
- u Tell the patient what to expect before and after surgery, what the wound will look like, and what type of dressing he'll have. Warn him that the donor site for a skin graft may be as painful, if not more so, than the tumor excision site.
- u Teach the patient and family members relaxation techniques to help relieve anxiety. Encourage the patient to continue these after he is discharged.

- u Emphasize the need for close follow-up care to detect recurrences early. Explain that recurrences and metastases, if they occur, are often delayed, so follow-up must continue for years. Teach the patient how to recognize the signs of recurrence.
- u To help prevent malignant melanoma, stress the detrimental effects of overexposure to solar radiation, especially to fair-skinned, blue-eyed patients. Recommend that they use a sunblock or a sunscreen.
- u When appropriate, refer the patient and family members to community support services, such as the American Cancer Society or a hospice.

MULTIPLE MYELOMA

Multiple myeloma is a disseminated neoplasm of marrow plasma cells. It's also called malignant plasmacytoma, plasma cell myeloma, and myelomatosis. The disease infiltrates bone to produce osteolytic lesions throughout the skeleton (flat bones, vertebrae, skull, pelvis, and ribs). In late stages, it infiltrates the body organs as well (liver, spleen, lymph nodes, lungs, adrenal glands, kidneys, skin, and GI tract).

Multiple myeloma strikes mostly men over age 40. It usually carries a poor prognosis because by the time it's diagnosed, it has already infiltrated the vertebrae, pelvis, skull, ribs, clavicles, and sternum. By then, skeletal destruction is widespread and, without treatment, leads to vertebral collapse. Within 3 months of diagnosis, 52% of patients die; within 2 years, 90% die. If the disease is diagnosed early, treatment can often prolong life by 3 to 5 years.

Causes

Although the cause of multiple myeloma isn't known, genetic factors and occupational exposure to radiation have been linked to the disease.

Complications

Multiple myeloma can cause infections, such as pneumonia, pyelonephritis (caused by tubular damage from large amounts of Bence Jones protein, hypercalcemia, and hyperuricemia), renal calculi, renal failure, hematologic imbalance, fractures, hypercalcemia, hyperuricemia, and dehydration. Patients may also develop a predisposition toward bleeding; the result of M protein coating the platelets. Such bleeding usually occurs in the GI tract or the nose.

Assessment findings

The patient may have a history of neoplastic fractures. He usually complains of severe, constant back pain, which may increase with exercise. He may also report other symptoms similar to those of arthritis, such as aches, joint swelling, and tenderness, probably from vertebral compression. Other complaints include numbness, prickling, and tingling of the extremities (peripheral paresthesia).

Inspection may reveal that the patient has pain on movement or weight bearing, especially in the thoracic and lumbar vertebrae.

As the disease advances, the patient becomes progressively weaker because of vertebral compression, anemia, and weight loss. As the nerves associated with respiratory function are affected, he may develop pneumonia as well as noticeable thoracic deformities and a reduction in body height of 5" (13 cm) or more as vertebral collapse occurs.

Diagnostic tests

Complete blood count shows moderate or severe anemia. The differential may show 40% to 50% lymphocytes but seldom more than 3% plasma cells. Rouleau formation, often the first clue, is seen on differential smear and results from elevation of the erythrocyte sedimentation rate.

Urine studies may show protein urea, Bence Jones protein, and hypercalciuria. Absence of Bence Jones protein doesn't rule out multiple myeloma, but its presence almost invariably confirms the disease. (See [Bence Jones protein.](#))

Bone marrow aspiration reveals myelomatous cells (abnormal number of immature plasma cells); 10% to 95% instead of the normal 3% to 5%.

Serum electrophoresis shows an elevated globulin spike that is electrophoretically and immunologically abnormal.

X-rays during the early stages may reveal only diffuse osteoporosis. Eventually, they show multiple, sharply circumscribed osteolytic (punched out) lesions, particularly on the skull, pelvis, and spine—the characteristic lesions of multiple myeloma.

Excretory urography can assess renal involvement. To avoid precipitation of Bence Jones protein, iothalamate or diatrizoate is used instead of the usual contrast medium.

Treatment

Long-term treatment of multiple myeloma consists mainly of chemotherapy to suppress plasma cell growth and control pain. Combinations of melphalan and prednisone or of cyclophosphamide and prednisone are used. Adjuvant local radiation reduces acute lesions and relieves the pain of collapsed vertebrae.

Other treatment usually includes administration of analgesics for pain. If the patient develops vertebral compression, he may require a laminectomy; if he has renal complications, he may need dialysis. Maintenance therapy with interferon may prolong the plateau phase when the initial chemotherapy is complete.

Because the patient may have bone demineralization and may lose large amounts of calcium into blood and urine, he's a prime candidate for renal calculi, nephrocalcinosis, and, eventually, renal failure from hypercalcemia. Hydration, diuretics, corticosteroids, oral phosphate, and gallium I.V. to decrease serum calcium levels control the hypercalcemia. Plasmapheresis removes the M protein from the blood and returns the cells to the patient, although this effect is only temporary.

Nursing diagnoses

u Altered nutrition: Less than body requirements u Altered protection u Anxiety u Energy field disturbance u Fear u Hopelessness u Impaired physical mobility u Ineffective breathing pattern u Ineffective family coping: Disabling u Ineffective individual coping u Pain u Sensory or perceptual alterations

Key outcomes

- u Family members will identify their needs.
- u The patient will express feelings of increased energy.
- u The patient will maintain adequate ventilation.
- u The patient will express feelings of comfort and decreased pain.
- u The patient will recognize limitations imposed by illness and will express feelings about these limitations.
- u The patient will demonstrate use of protective measures, including conserving energy, maintaining a balanced diet, and getting adequate rest.
- u The patient will demonstrate effective coping skills.

Nursing interventions

- u Encourage the patient to drink 3,000 to 4,000 ml of fluids daily, particularly before excretory urography. Monitor fluid intake and output, which shouldn't fall below 1,500 ml.
- u Administer ordered analgesics for pain as necessary. Provide comfort measures, such as repositioning and relaxation techniques.
- u During chemotherapy, watch for complications, such as fever and malaise, which may signal the onset of infection. Also watch for signs of other problems, such as

severe anemia and fractures.

Bence Jones protein

The Bence Jones protein is the hallmark of multiple myeloma. This protein — a light chain of gamma globulin — was named for Henry Bence Jones, an English doctor. In 1848, he noticed that patients with a certain bone disease excreted a unique protein, unique in that it coagulated at 113° to 131° F (45° to 55° C), then redissolved when heated to boiling.

Otto Kahler, an Austrian, demonstrated in 1889 that Bence Jones protein was related to myeloma. Bence Jones protein isn't found in the urine of all multiple myeloma patients, but it's almost never found in patients without this disease.

- u If the patient is taking melphalan, a phenylalanine derivative of nitrogen mustard that depresses bone marrow, obtain a platelet and white blood cell count before each treatment. If he's taking prednisone, closely watch for signs of infection, which this drug masks.
- u After laminectomy, try to get the patient out of bed within 24 hours, if possible, and encourage him to walk. This helps prevent pneumonia and diminish the bone demineralization that immobilization can cause. Never allow the patient to walk unaccompanied, and make sure he uses a walker or other supportive aid to prevent falls. Reassure him if he's fearful, and allow him to move at his own pace; these patients are particularly vulnerable to pathologic fractures.
- u If the patient is bedridden, change his position every 2 hours. Provide passive range-of-motion and deep-breathing exercises; promote active exercises when he can tolerate them.
- u Check for hemorrhage, motor or sensory deficits, and loss of bowel or bladder function. Position the patient as ordered, maintain alignment, and logroll him when turning.
- u Throughout therapy, listen to the patient's fears and concerns. Offer reassurance when appropriate, and stay with him if he experiences periods of severe stress and anxiety.
- u Encourage the patient to identify actions and measures that promote comfort and relaxation. Try to perform these measures, and encourage the patient and family members to do so as well.
- u Involve the patient and family members in decisions about his care whenever possible.
- u Help relieve the patient's and family members' anxiety by answering their questions.

Patient teaching

- u Reinforce the doctor's explanation of the disease, diagnostic tests, treatment options, and prognosis. Make sure the patient understands what to expect from the treatment and diagnostic tests (including painful procedures, such as bone marrow aspiration and biopsy). Tell him to notify the doctor if the adverse effects of treatment persist.
- u Prepare the patient for the effects of surgery.
- u Explain the procedures the patient will undergo, such as insertion of an I.V. line and an indwelling urinary catheter.
- u Emphasize the importance of deep breathing and changing position every 2 hours after surgery.
- u Tell the patient to dress appropriately because multiple myeloma may make him particularly sensitive to cold.
- u Caution the patient to avoid crowds and people with known infections because chemotherapy diminishes the body's natural resistance to infection.
- u If appropriate, direct the patient and family members to community resources such as the American Cancer Society for support.

PRIMARY MALIGNANT BONE TUMORS

Primary malignant bone tumors (sarcomas of the bone) are rare, constituting less than 1% of all malignant tumors. Most bone tumors result from metastasis from another malignant tumor.

Primary bone tumors occur more commonly in males than in females, especially in children and adolescents, although some types occur in people between ages 35 and 60.

Causes

Although the cause of primary malignant bone tumors remains unknown, some researchers hypothesize that primary malignant bone tumors arise in centers of rapid skeletal growth because children and young adults with these tumors seem to be much taller than average. Other theories point to heredity factors, trauma, and excessive radiotherapy as causes.

Prior exposure to carcinogens, an underlying condition such as Paget's disease, or radiation exposure has been linked with the development of osteogenic sarcomas, chondrosarcomas, and fibrosarcomas.

Primary malignant bone tumors may originate in osseous or nonosseous tissue. Osseous tumors arise from the bony structure as well as from cartilage, fibrous tissue, and bone marrow. They include osteogenic sarcoma (the most common), parosteal osteogenic sarcoma, chondrosarcoma (malignant cartilage tumor), and malignant giant cell tumor. Together, these make up about 60% of all malignant bone tumors.

Nonosseous tumors arise from hematopoietic, vascular, and neural tissues. They include Ewing's sarcoma, fibrosarcoma, and chordoma. Osteogenic and Ewing's sarcomas are the most common bone tumors of children. (See [Types of primary malignant bone tumors.](#))

Complications

Hypercalcemia is a life-threatening complication that commonly occurs from excessive calcium release associated with tumor destruction of bone. When the calcium reaches a level that exceeds the renal and GI capacity to excrete it, the calcium blood level rises above normal. (See [Counteracting hypercalcemia.](#))

Assessment findings

The patient may complain of bone pain and describe it as a dull ache. The pain is usually localized, although it may be referred from the hip or spine. The patient may describe the pain as more intense at night and note that movement doesn't aggravate the pain.

Inspection may reveal weakness in the affected limb; you may also note that the patient walks with a limp. In late stages, the patient may appear cachectic, with fever and impaired mobility.

Palpation may disclose a mass or tumor, possibly accompanied by swelling. You may also find a pathologic fracture.

Diagnostic tests

A biopsy (by incision or aspiration) confirms primary malignant bone tumors. Bone X-rays and radioisotope bone and computed tomography scans delineate the tumor size. A patient with sarcoma usually has elevated serum alkaline phosphatase levels.

Treatment

Treatment focuses on preserving the limb as well as controlling the cancer. Surgical resection of the tumor (often with preoperative radiation and postoperative

chemotherapy) saves many limbs from amputation. Some facilities may perform both preoperative and postoperative radiation therapy and chemotherapy, or various other combinations.

Types of primary malignant bone tumors		
TYPE	CLINICAL FEATURES	TREATMENT

Osseous origin

Osteogenic sarcoma	u Osteoid tumor present in specimen	u Surgery (wide resection or amputation)
	u Arises from bone-forming osteoblast	u Chemotherapy, preoperative and postoperative
	u Occurs most commonly in femur, but also in tibia humerus; occurs occasionally in fibula, ileum, vertebra, or mandible	
	u Usually develops in males ages 10 to 30	
Parosteal osteogenic sarcoma	u Develops on surface of bone instead of interior	u Surgery (tumor resection, possible amputation, interscapular thoracic surgery, hemipelvectomy)
	u Progresses slowly	
	u Occurs most commonly in distal femur, but also intibia, humerus, and ulna	
	u Usually develops in women ages 30 to 40	
Chandrosarcoma	u Develops from cartilage	u Wide surgical resection, if possible; amputation, if necessary
	u Painless; grows slowly, but is locally recurrent and invasive	
	u Occurs most commonly in pelvis, proximal femur, ribs, and shoulder girdle	
	u Usually develops in men ages 30 to 50	
Malignant giant cell tumor	u Arises from benign giant cell tumor	u Total excision
	u Found most commonly in long bones, especially in knee area	u Radiation therapy (for recurrent disease)
		u Chemotherapy
	u Usually develops in women ages 18 to 50	

Nonosseous origin

Ewing's sarcoma	u Originates in bone marrow and invades shafts of long and flat bones	u High-voltage radiation therapy (tumor is very radiosensitive)
	u Usually affects lower extremities, most commonly in femur, innominate bones, ribs, tibia, humerus, vertebra, and fibula; may metastasize to lungs	u Chemotherapy to slow growth
		u Amputation (only if no evidence of metastases)
	u Causes increasingly severe and persistent pain	
	u Usually develops in males ages 10 to 20	
Fibrosarcoma	u Prognosis has improved dramatically with effective chemotherapy	
	u Occurs relatively rarely	u Amputation
	u Originates in fibrous tissue of bone	u Radiation therapy
	u Invades long or flat bones (femur, tibia, mandible) but also involves periosteum and overlying muscle	u Chemotherapy
		u Bone grafts (with low-grade fibrosarcoma)
Chordona	u Usually develops in men ages 30 to 40	
	u Derived from embryonic remnants of notochord	u Surgical resection (often resulting in neural defects)
	u Progresses slowly	
	u Usually found at end of vertebral column and in sphenoccipital, sacrococcygeal, and vertebral areas	u Radiation therapy (palliative, or when surgery not applicable, as in occipital area)
	u Characterized by constipation and visual disturbances	
	u Usually develops in men ages 50 to 60	

WARNING

Counteracting hypercalcemia

When hypercalcemia first develops, it causes lethargy, anorexia, nausea, vomiting, constipation, and dehydration. The patient may also develop pathologic fractures from weakening of involved bone and kidney stones from excessive glomerular filtration of calcium. If the condition continues uninterrupted, the patient's serum calcium levels become markedly elevated (greater than 15 mg/dl) and interfere with normal conduction and muscle contraction. This can result in life-threatening cardiac arrhythmias, coma and, eventually, cardiac arrest.

If the patient develops any of these signs, take the following steps:

- To reduce the risk of renal damage and help decrease the patient's serum calcium level, immediately start a 1,000-ml infusion of 0.9% sodium chloride solution. Repeat this infusion every 4 to 6 hours to promote diuresis. Monitor the patient's urine output and adjust the infusion accordingly.
- If the sodium chloride solution doesn't promote adequate diuresis, give furosemide as ordered. *Don't* give thiazide diuretics, which inhibit calcium excretion.
- Administer drugs, such as calcitonin, mithramycin, corticosteroids and, possibly, sodium bicarbonate, as ordered to decrease serum calcium levels. Watch for adverse drug effects and for rebound hypocalcemic tetany. If the patient isn't responsive to conventional drug therapy, give gallium nitrate (Ganite) I.V. as ordered.
- Obtain an electrocardiogram (ECG) to check for cardiac arrhythmias. Carefully monitor the patient's vital signs and watch for signs of impending cardiac arrest.
- Repeat the ECG and serum calcium determination as ordered, and continue to monitor the patient.

Sometimes treatment calls for radical surgery, such as hemipelvectomy. When any type of surgical amputation is indicated, a 3" to 4" (8- to 10-cm) margin of healthy tissue should be left.

Intensive chemotherapy combines cyclophosphamide, cisplatin, vincristine, doxorubicin, and dacarbazine. Chemotherapy may be performed intra-arterially into the long bones of the legs.

Nursing diagnoses

▫ Altered nutrition: Less than body requirements ▫ Altered tissue perfusion ▫ Anxiety ▫ Body image disturbance ▫ Fear ▫ Impaired physical mobility ▫ Impaired tissue integrity ▫ Ineffective family coping ▫ Ineffective individual coping ▫ Pain ▫ Risk for infection

Key outcomes

- The patient will maintain weight within an acceptable range.
- The patient will express positive feelings about self.
- The patient will maintain joint mobility and range of motion.
- The patient will express feelings of comfort and decreased pain.
- The patient and family members will express feelings and fears.

Nursing interventions

- Before surgery, start I.V. infusions to maintain the patient's fluid and electrolyte balance and to keep a vein open if blood or plasma is needed during surgery.
- Administer analgesics as necessary.
- After surgery, check the patient's vital signs every hour for the first 4 hours, every 2 hours for the next 4 hours, and then every 4 hours if the patient is stable.
- Check the dressing for oozing often, and tape a tourniquet to the bed in case of hemorrhage. Elevate the foot of the bed or the stump on a pillow for the first 24 hours (but not more than 48 hours; contractures are possible).
- Make sure the patient has received his analgesic before morning care. If necessary, brace him with pillows, keeping the affected part at rest.
- Provide foods high in protein, vitamins, and folic acid. Administer laxatives, if necessary. Encourage fluids to prevent dehydration, and record intake and output.
- An NG tube and an indwelling urinary catheter usually are inserted during hemipelvectomy surgery to prevent abdominal distention. Continue low gastric suction for 2 days after surgery or until the patient can tolerate a soft diet. Administer antibiotics as ordered to prevent infection. Give transfusions if necessary. Keep drains in place to facilitate wound drainage and prevent infection. Keep the indwelling urinary catheter in place until the patient can void voluntarily.
- Because the patient may have thrombocytopenia, make sure he uses a soft toothbrush and an electric razor to avoid bleeding. Don't give I.M. injections or take rectal temperatures. Be careful not to bump the patient's arms or legs; low platelet count causes bruising.
- To encourage rehabilitation, start physical therapy 24 hours postoperatively.
- The patient usually doesn't have severe pain after amputation. If he does, check for such wound complications as hematoma, excessive stump edema, and infection.
- Wash the stump, massage it gently, and keep it dry until it heals. Make sure the bandage is firm and always stays on. When you reapply the bandage, make sure you wrap the stump so it's shaped for a prosthesis.
- During radiation therapy, watch for adverse effects (nausea, vomiting, and dry skin with excoriation).
- During chemotherapy, watch for such complications as infection and for expected adverse effects, including nausea, vomiting, mouth ulcers, and alopecia. Take measures to reduce these effects, such as providing the patient with plenty of fluids to drink and normal saline mouthwash for gargling.
- Throughout treatment, be sensitive to the enormous emotional strain of amputation. Encourage communication, and help the patient set realistic goals.
- Listen to the patient's fears and concerns, and offer reassurance when appropriate. Stay with the patient during periods of severe stress and anxiety.
- Whenever possible, include the patient and the family in care decisions.

Patient teaching

- Help the patient and family members understand the disease. Reinforce the doctor's explanations and provide information that will help the patient and family members make informed decisions about treatment.
- Prepare the patient for the effects of surgery.
- Explain the procedures the patient will undergo, such as insertion of I.V. lines, NG tubes, and indwelling urinary catheters.
- If amputation is inevitable, teach the patient how to readjust his body weight so that he can get in and out of his bed and wheelchair. Teach exercises that will help him do this even before surgery. If appropriate, have an amputee visit the patient.
- Emphasize the importance of deep breathing and turning every 2 hours immediately after surgery.
- Stress the importance of getting plenty of rest and sleep to promote recovery, but encourage some physical exercise.
- Teach the patient about phantom limb syndrome. Explain that he may sense an itch or tingling in the amputated extremity. Reassure him this sensation is normal after amputation and usually subsides within several hours. Explain, however, that the sensation may recur off and on for years.
- To avoid contractures and ensure the best conditions for wound healing, teach the patient *not* to hang the stump over the edge of the bed; sit in a wheelchair with the stump flexed; place a pillow under his hip, knee, or back, or between his thighs; lie with knees flexed; rest an above-the-knee stump on the crutch handle; or abduct an above-the-knee stump.
- Help the patient select a prosthesis. Explain the needs he must consider and the types of prostheses available. The rehabilitation staff makes the final decision, but most patients know nothing about choosing a prosthesis and appreciate some basic guidelines.
- When discussing prostheses, keep in mind the patient's age. Children need relatively simple devices, whereas elderly patients may require prostheses that provide more stability. Consider personal and family finances as well. Children outgrow prostheses, so parents may need to select inexpensive ones.
- Teach the patient and a family member how to care for the stump. Stress the need for following aseptic technique to prevent infection.
- Emphasize the importance of sound nutrition. Ask the dietitian to provide instruction for the patient.
- Teach the patient and family members about the complications of any postoperative treatments. Explain actions that he can take to alleviate and prevent them.
- Refer the patient and family members to the social service department, home health care agencies, and support groups such as the American Cancer Society as appropriate.
- Try to help the patient develop a positive attitude toward recovery, and urge him to resume an independent lifestyle. If he's elderly, refer him to community health services as necessary. Suggest tutoring for a child to help him keep up with his schoolwork.

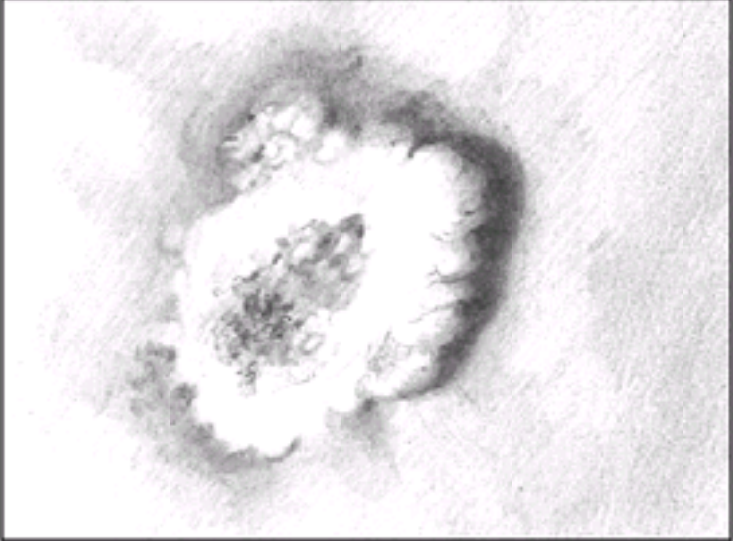

SQUAMOUS CELL CARCINOMA

Squamous cell carcinoma of the skin is an invasive tumor arising from keratinizing epidermal cells; it has the potential for metastasis. Squamous cell carcinoma occurs most commonly in fair-skinned white men over age 60. Outdoor employment and residence in a sunny, warm climate (southern United States and Australia, for example) greatly increase the risk for squamous cell carcinoma.

Lesions on sun-damaged skin tend to be less invasive with less tendency to metastasize than lesions on unexposed skin. (See [Squamous cell carcinoma nodule.](#)) Notable exceptions are squamous cell lesions on the lower lip and the ears; almost invariably, these are markedly invasive metastatic lesions with a poor prognosis.

Squamous cell carcinoma nodule

This ulcerated nodule with an indurated base and a raised, irregular border is a typical lesion in squamous cell carcinoma.

Causes and pathophysiology

Predisposing factors associated with squamous cell carcinoma include overexposure to the sun's ultraviolet rays, radiation therapy, ingestion of herbicides containing arsenic, chronic skin irritation and inflammation, exposure to local carcinogens (such as tar and oil), hereditary diseases (such as xeroderma pigmentosum and albinism), and the presence of premalignant lesions (such as actinic keratosis or Bowen's disease). (See [Comparing premalignant skin lesions.](#))

Rarely, squamous cell carcinoma may develop on the site of smallpox vaccination, psoriasis, or chronic discoid hipus erythematosus.

Transformation from a premalignant lesion to squamous cell carcinoma may begin with induration and inflammation of the preexisting lesion. When squamous cell carcinoma arises from normal skin, the nodule grows slowly on a firm, indurated base. If untreated, this nodule eventually ulcerates and invades underlying tissues.

Complications

Lymph node involvement and visceral metastasis, resulting in respiratory problems, are possible complications from disease progression.

Assessment findings

The patient history may disclose areas of chronic ulceration, especially on sun-damaged skin.

Inspection may reveal lesions on the face, ears, and dorsa of the hands and forearms and on other sun-damaged skin areas. The lesions may appear scaly and keratotic with raised, irregular borders. In late disease, the lesions grow outward (exophytic), are friable, and tend toward chronic crusting.

As the disease progresses and metastasizes to the regional lymph nodes, the patient may complain of pain and malaise. He may also complain of anorexia and resulting fatigue and weakness.

Diagnostic tests

An excisional biopsy provides a definitive diagnosis of squamous cell carcinoma. Appropriate laboratory tests depend on systemic symptoms.

Treatment

The size, shape, location, and invasiveness of a squamous cell tumor and the condition of the underlying tissue determine the treatment method; a deeply invasive tumor may require a combination of techniques. All the major treatment methods have excellent cure rates. In most cases, the prognosis is better with a well-differentiated lesion than with a poorly differentiated one in an unusual location.

Depending on the lesion, treatment may consist of wide surgical excision; curettage and electrodesiccation, which offer good cosmetic results for smaller lesions; radiation therapy, which is generally for older or debilitated patients; chemotherapy; and chemosurgery, which is reserved for resistant or recurrent lesions.

The chemotherapeutic agent fluorouracil is available in various strengths (1%, 2%, and 5%) as a cream or solution. Local application causes immediate stinging and burning. Later effects include erythema, vesiculation, erosion, superficial ulceration, necrosis, and reepithelialization. The 5% solution induces the most severe inflammatory response but provides complete involution of the lesions with little recurrence.

Fluorouracil treatment is continued until the lesions reach the ulcerative and necrotic stages (usually 2 to 4 weeks). Then a corticosteroid preparation such as an anti-inflammatory agent may be applied. Complete healing occurs within 1 to 2 months.

Nursing diagnoses

⌘ Altered nutrition: Less than body requirements ⌘ Anxiety ⌘ Body image disturbance ⌘ Fatigue ⌘ Fear ⌘ Impaired skin integrity ⌘ Ineffective family coping: Disabling ⌘ Ineffective individual coping

ADVANCED PRACTICE

Comparing premalignant skin lesions

Review the chart below to help you differentiate among diseases associated with premalignant skin lesions, including their causes, the people at risk, lesion descriptions, and treatment.				
DISEASE	CAUSE	PEOPLE AT RISK	LESION DESCRIPTION	TREATMENT
<i>Actinic keratosis</i>	Solar radiation	White men with fair skin (middle-aged to elderly)	Reddish brown lesions 1 mm to 1 cm in size (may enlarge if untreated) on face, ears, lower lip, bald scalp, dorsa of hands and forearms	Topical fluorouracil, cryosurgery using liquid nitrogen, or curettage and electrodesiccation
<i>Bowen's disease</i>	Unknown	Men (middle-aged to elderly)	Brown to reddish brown lesions, with scaly surface on exposed and unexposed areas	Surgical excision, topical fluorouracil
<i>Erythroplasia of Queyrat</i>	Bowen's disease of the mucous membranes	Men (middle-aged to elderly)	Red lesions with a glistening or granular appearance on mucous membranes, particularly the glans penis in uncircumcised men	Surgical excision
<i>Leukoplakia</i>	Smoking, alcohol, chronic cheek-biting, ill-fitting dentures, misaligned teeth	Men (middle-aged to elderly)	Lesions on oral, anal, and genital mucous membranes, varying in appearance from smooth and white to rough and gray	Elimination of irritating factors, surgical excision, or curettage and electrodesiccation (if lesion is still premalignant)

Key outcomes

- u The patient will maintain weight within an acceptable range.
- u The patient will express positive feelings about self.
- u The patient will experience feelings of increased energy.
- u The patient will exhibit improved or healed lesions or wounds.
- u The patient will express feelings of increased comfort.

Nursing interventions

- u Although disfiguring lesions are distressing, try to accept the patient as he is to increase his self-esteem and to strengthen a caring relationship.
- u Listen to the patient's fears and concerns. Offer reassurance when appropriate. Remain with the patient during periods of severe stress and anxiety.
- u Accept the patient's perception of himself. Help the patient and family members set realistic goals and expectations.
- u Assess the patient's readiness for decision making; then involve him in making choices and decisions related to his care. Provide positive reinforcement for the patient's efforts to adapt.
- u Coordinate a consistent care plan for changing the patient's dressings. A standard routine helps the patient and family members learn how to care for the wound.
- u To promote healing and prevent infection, keep the wound dry and clean.
- u Try to control odor with balsam of Peru, yogurt flakes, oil of cloves, or other odor-masking substances, even though they may be ineffective for long-term use. Topical or systemic antibiotics also temporarily control odor and eventually alter the lesion's bacterial flora.
- u Provide periods of rest between procedures if the patient fatigues easily.
- u Be prepared for the adverse effects of radiation therapy, such as nausea, vomiting, hair loss, malaise, and diarrhea.
- u Provide small, frequent meals of a high-protein, high-calorie diet if the patient is anorexic. Consult with the dietitian to incorporate foods that the patient enjoys into his diet.

Patient teaching

- u Explain all procedures and treatments to the patient and his family. Encourage the patient to ask questions, and answer them honestly.
- u Instruct the patient to avoid excessive sun exposure to prevent recurrence. Direct him to wear protective clothing (hats, long sleeves) whenever he is outdoors.
- u Urge the use of a strong sunscreen or sunshade to protect the skin from ultraviolet rays. Those agents containing para-aminobenzoic acid, benzophenone, and zinc oxide are most effective. Apply these agents 30 to 60 minutes before sun exposure, as well as lipscreens to protect the lips from sun damage.
- u Advise the patient to relieve local inflammation from topical fluorouracil with cool compresses or with corticosteroid ointment.
- u Teach the patient to periodically examine the skin for precancerous lesions and to have any removed promptly.
- u If appropriate, direct the patient and family members to facility and community support services, such as social workers, psychologists, and cancer support groups.
- u Be careful to keep fluorouracil away from the eyes, scrotum, or mucous membranes. Warn the patient to avoid excessive exposure to the sun during the course of treatment because it intensifies the inflammatory reaction. Possible adverse effects of treatment include postinflammatory hyperpigmentation.

Blood and lymph neoplasms

When cancer affects the circulatory systems, the entire body may become rapidly involved in the disease.

ACUTE LEUKEMIA
<p>Acute leukemia begins as a malignant proliferation of white blood cell (WBC) precursors, or blasts, in bone marrow or lymph tissue. It results in an accumulation of these cells in peripheral blood, bone marrow, and body tissues.</p> <p>The most common forms of acute leukemia include acute lymphoblastic (lymphocytic) leukemia (ALL), characterized by abnormal growth of lymphocyte precursors (lymphoblasts); acute myeloblastic (myelogenous) leukemia (AML), which causes rapid accumulation of myeloid precursors (myeloblasts); and acute monoblastic (monocytic) leukemia, or Schilling's type, which results in a marked increase in monocyte precursors (monoblasts). Other variants include acute myelomonocytic leukemia and acute erythroleukemia.</p> <p>The disease is more common in males than in females, in whites (especially those of Jewish ancestry), in children between ages 2 and 5 (80% of all leukemias in this age-group are ALL), and in those who live in urban and industrialized areas. Among children, acute leukemia is the most common form of cancer.</p> <p>Untreated, acute leukemia is invariably fatal, usually because of complications resulting from leukemic cell infiltration of bone marrow or vital organs. With treatment, the prognosis varies. In ALL, treatment induces remissions in 90% of children (average survival time: 5 years) and in 65% of adults (average survival time: 1 to 2 years). Children between ages 2 and 8 have the best survival rate—about 50%—with intensive therapy.</p> <p>In AML, the average survival time is only 1 year after diagnosis, even with aggressive treatment. Remissions lasting 2 to 10 months occur in 50% of children; adults survive only about 1 year after diagnosis, even with treatment.</p>
<p>Causes and pathophysiology</p>

The exact cause of acute leukemia is unknown; however, radiation (especially prolonged exposure), certain chemicals and drugs, viruses, genetic abnormalities, and chronic exposure to benzene are likely contributing factors.

In children, Down syndrome, ataxia, and telangiectasia may increase the risk, as may such congenital disorders as albinism and congenital immunodeficiency syndrome.

Although the pathogenesis isn't clearly understood, immature, nonfunctioning WBCs appear to accumulate first in the tissue where they originate (lymphocytes in lymph tissue, granulocytes in bone marrow). These immature WBCs then spill into the bloodstream. They then overwhelm the red blood cells and the platelets. From there, they infiltrate other tissues.

Complications

Acute leukemia increases the risk of infection and, eventually, organ malfunction through encroachment or hemorrhage.

Assessment findings

The patient's history usually shows a sudden onset of high fever and abnormal bleeding, such as bruising after minor trauma, nosebleeds, gingival bleeding, purpura, ecchymoses, petechiae, and prolonged menses. He may also report fatigue and night sweats. More insidious symptoms include weakness, lassitude, recurrent infections, and chills.

The patient with ALL, AML, or acute monoblastic leukemia may also complain of abdominal or bone pain. When assessing this patient, you may note tachycardia and, during auscultation, decreased ventilation, palpitations, and a systolic ejection murmur.

Inspection of any patient with acute leukemia may reveal pallor. On palpation you may note lymph node enlargement as well as liver or spleen enlargement.

Diagnostic tests

Bone marrow aspiration showing a proliferation of immature WBCs confirms acute leukemia. If the aspirate is dry or free of leukemic cells but the patient has other typical signs of leukemia, a bone marrow biopsy—usually of the posterior superior iliac spine—must be performed.

Blood counts show thrombocytopenia and neutropenia, and a WBC differential determines the cell type. Lumbar puncture detects meningeal involvement. A computed tomography scan shows the affected organs, and cerebrospinal fluid analysis detects abnormal WBC invasion of the central nervous system.

Treatment

Systemic chemotherapy aims to eradicate leukemic cells and induce remission. It's used when fewer than 5% of blast cells in the marrow and peripheral blood are normal. The specific chemotherapeutic and radiation treatment varies with the diagnosis:

- u For meningeal infiltration, the patient receives an intrathecal instillation of methotrexate or cytarabine with cranial radiation.
- u For ALL, the treatment is vincristine, prednisone, high-dose cytarabine, and daunorubicin. Because ALL carries a 40% risk of meningeal infiltration, the patient also receives intrathecal methotrexate or cytarabine. If brain or testicular infiltration has occurred, the patient also needs radiation therapy.
- u For AML, treatment consists of a combination of I.V. daunorubicin and cytarabine. If these fail to induce remission, treatment involves some or all of the following: a combination of cyclophosphamide, vincristine, prednisone, or methotrexate; high-dose cytarabine alone or with other drugs; amsacrine; etoposide; and 5-azacytidine and mitoxantrone.
- u For acute monoblastic leukemia, the patient receives cytarabine and thioguanine with daunorubicin or doxorubicin.

Treatment may also include antibiotic, antifungal, and antiviral drugs and granulocyte injections to control infection, as well as transfusions of platelets to prevent bleeding and of red blood cells to prevent anemia. Bone marrow transplantation is performed in some patients.

Nursing diagnoses

u Altered nutrition: Less than body requirements u Altered oral mucous membrane u Altered protection u Anticipatory grieving u Anxiety u Fatigue u Fear u Impaired tissue integrity u Ineffective family coping: Disabling u Ineffective individual coping u Pain u Risk for altered body temperature u Risk for infection u Risk for injury

Key outcomes

- u The patient will maintain weight within an acceptable range.
- u The patient will exhibit intact mucous membranes.
- u The patient won't experience chills, fever, or other signs and symptoms of illness.
- u The patient will demonstrate use of protective measures, including conserving energy, maintaining a balanced diet, and getting adequate rest.
- u The patient and family members will express feelings.
- u The patient will express feelings of increased energy.

Nursing interventions

- u Develop a plan of care for the leukemic patient that emphasizes comfort, minimizes the adverse effects of chemotherapy, promotes preservation of veins, manages complications, and provides teaching and psychological support. Because so many of these patients are children, be especially sensitive to their emotional needs and to those of their families when developing your plan.
- u Before treatment begins, help establish an appropriate rehabilitation program for the patient during remission.
- u Watch for signs of meningeal infiltration (confusion, lethargy, and headache). If it develops, the patient will need intrathecal chemotherapy.
- u After drug instillation, place the patient in Trendelenburg position for 30 minutes. Make sure he receives enough fluids, and keep him supine for 4 to 6 hours.
- u Check the lumbar puncture site often for bleeding.
- u Take steps to prevent hyperuricemia, a possible result of rapid, chemotherapy-induced leukemic cell lysis. Make sure the patient receives about 2 L of fluid daily, and give acetazolamide, sodium bicarbonate tablets, and allopurinol, as ordered. Check the patient's urine pH often; it should be above 7.5. Watch for a rash or other hypersensitivity reactions to allopurinol.
- u If the patient receives daunorubicin or doxorubicin, watch for early indications of cardiotoxicity, such as arrhythmias and signs of heart failure.
- u To control infection, place the patient in a private room and impose reverse isolation if necessary (although the benefits of reverse isolation are controversial). Coordinate care so that the patient doesn't come into contact with staff members who also care for patients with infections or infectious diseases. Screen staff members and visitors for contagious diseases, and watch for and report any signs of infection. Don't use an indwelling urinary catheter or give I.M. injections; they provide an avenue for infection.
- u Keep the patient's skin and perianal area clean, apply mild lotions or creams to keep the skin from drying and cracking, and thoroughly clean the skin before all invasive skin procedures. Change I.V. tubing according to facility policy. Use strict aseptic technique and a metal scalp vein needle (metal butterfly needle) when starting an I.V. line. If the patient is receiving total parenteral nutrition, provide scrupulous subclavian catheter care.
- u Monitor the patient's temperature every 4 hours. If his temperature rises over 101° F (38.3° C) and his WBC count decreases, he needs prompt antibiotic therapy.
- u Watch for bleeding. If it occurs, apply ice compresses and pressure, and elevate the extremity. Avoid giving the patient aspirin or aspirin-containing drugs or rectal suppositories, taking a rectal temperature, or performing a digital rectal examination.
- u After bone marrow transplantation, keep the patient in a sterile room, administer antibiotics, and transfuse packed red blood cells as necessary.
- u Administer prescribed pain medications as needed, and monitor their effectiveness. Provide comfort measures, such as position changes and distractions, to alleviate the patient's discomfort.

- u Control mouth ulceration by checking often for obvious ulcers and gum swelling and by providing frequent mouth care and saline rinses.
- u Check the rectal area daily for induration, swelling, erythema, skin discoloration, and drainage.
- u Minimize stress by providing a calm, quiet atmosphere that is conducive to rest and relaxation. If the patient is a child, be flexible with patient care and visiting hours so that he has time to be with family members and friends and to play and do schoolwork.
- u Establish a trusting relationship to promote communication. Allow the patient and family members to express their anger, anxiety, and depression.
- u Let the patient and family members participate in his care as much as possible.
- u If the patient doesn't respond to treatment and has reached the terminal phase of the disease, he'll need supportive nursing care. Take steps to manage pain, fever, and bleeding; make sure the patient is comfortable; and provide emotional support for him and his family. If the patient wishes, provide for religious counseling. Discuss the option of home or hospice care.

Patient teaching

- u Explain the course of the disease to the patient.
- u Teach the patient and family members how to recognize signs and symptoms of infection (fever, chills, cough, sore throat). Tell them to report an infection to the doctor.
- u Explain to the patient that his blood may not have enough platelets for proper clotting, and teach him the signs of abnormal bleeding (bruising, petechiae). Explain that he can apply pressure and ice to the area to stop such bleeding. Teach him steps he can take to prevent bleeding. Urge him to report excessive bleeding or bruising to the doctor.
- u Inform the patient that drug therapy is tailored to his type of leukemia. Explain that he'll probably need a combination of drugs; teach him about the ones he'll receive. Make sure he understands their adverse effects and the measures he can take to prevent or alleviate them.
- u Explain that if the chemotherapy causes weight loss and anorexia, the patient will need to eat and drink high-calorie, high-protein foods and beverages. If he loses his appetite, advise him to eat small, frequent meals. If the chemotherapy and adjunctive prednisone cause weight gain, he'll need dietary counseling.
- u Instruct the patient to use a soft toothbrush and to avoid hot, spicy foods and commercial mouth-washes, which can irritate the mouth ulcers that result from chemotherapy.
- u If the patient receives cranial radiation, explain what the treatment is and how it will help him. Be sure to discuss potential adverse effects and the steps he can take to minimize them.
- u If the patient needs a bone marrow transplant, reinforce the doctor's explanation of the treatment, its possible benefits, and the potential adverse effects. Teach him about total-body irradiation and the chemotherapy that he'll undergo before transplantation. Tell the patient what to expect after the transplantation.
- u Advise the patient to limit his activities and to plan rest periods during the day.
- u Refer the patient to the social service department, home health care agencies, and support groups such as the American Cancer Society.

CHRONIC GRANULOCYTIC LEUKEMIA

Chronic granulocytic leukemia is characterized by the abnormal overgrowth of granulocytic precursors (myeloblasts, promyelocytes, metamyelocytes, and myelocytes) in bone marrow, peripheral blood, and body tissues. It's also called chronic myelogenous (or myelocytic) leukemia.

The disease is most common in young and middle-aged adults, slightly more common in men than in women, and rare in children. In the United States, between 3,000 and 4,000 cases of chronic granulocytic leukemia develop annually, accounting for about 20% of all leukemias.

The clinical course of chronic granulocytic leukemia proceeds in two distinct phases: the insidious *chronic phase*, characterized by anemia and bleeding abnormalities, and eventually the *acute phase (bast crisis)*, in which myeloblasts, the most primitive granulocytic precursors, proliferate rapidly.

The disease is always deadly. Average survival time is 3 to 4 years after onset of the chronic phase and 3 to 6 months after onset of the acute phase.

Causes

Although the exact causes remain unknown, almost 90% of patients with this leukemia have the Philadelphia chromosome, an abnormality in which the long arm of chromosome 22 translocates to chromosome 9. Radiation and carcinogenic chemicals may induce this abnormality.

Myeloproliferative diseases also may increase the incidence of chronic granulocytic leukemia. Some researchers suspect that an unidentified virus causes this leukemia.

Complications

Complications include infection, hemorrhage, and pain.

Assessment findings

The patient history may reveal renal calculi or gouty arthritis (from increased uric acid excretion). The patient may relate symptoms of anemia: fatigue, weakness, dyspnea, decreased exercise tolerance, and headache. Evidence of bleeding and clotting disorders may include bleeding gums, nosebleeds, easy bruising, and hematuria. Additionally, the patient may report recent weight loss and anorexia.

The patient's vital signs may include a low-grade fever and tachycardia. Inspection may reveal pallor and difficulty breathing, and ophthalmoscopic examination may disclose retinal hemorrhage.

Palpation may uncover hepatosplenomegaly with abdominal discomfort and pain (in splenic infarction from leukemic cell infiltration) and sternal and rib tenderness (from leukemic infiltration of the periosteum).

Auscultation may disclose hypoventilation, especially if the patient has dyspnea.

Diagnostic tests

Chromosomal studies of peripheral blood or bone marrow showing the Philadelphia chromosome and low leukocyte alkaline phosphatase levels confirm chronic granulocytic leukemia.

Serum analysis shows white blood cell (WBC) abnormalities: leukocytosis (WBC count over 50,000/mm³, rising as high as 250,000/mm³); occasionally leukopenia (WBC count under 5,000/mm³); neutropenia (neutrophil count under 1,500/mm³) despite high WBC count; and increased circulating myeloblasts.

Additional findings may include a decreased hemoglobin level (below 10 g/dl), low hematocrit (less than 30%), and thrombocytosis (more than 1 million thrombocytes/mm³). The serum uric acid level may exceed 8 mg/dl.

Bone marrow aspirate—or biopsy (performed only if the aspirate is dry)—may be hypercellular, characteristically showing bone marrow infiltration by a significantly increased number of myeloid elements; in the acute phase, myeloblasts predominate.

A computed tomography scan may identify the organs affected by this leukemia.

Treatment

In the chronic phase, treatment strives to control leukocytosis and thrombocytosis. Commonly used drugs include busulfan and hydroxyurea. Aspirin may be given to

prevent a cerebrovascular accident if the patient's platelet count exceeds 1 million/mm ³.

Bone marrow transplantation may be tried. During the chronic phase, more than 60% of patients who receive a transplant achieve remission.

Ancillary treatments may include the following:

- local splenic radiation or splenectomy to increase the platelet count and to decrease adverse effects associated with splenomegaly
- leukapheresis (selective leukocyte removal) to reduce the WBC count
- allopurinol to prevent secondary hyperuricemia or colchicine to relieve gouty attacks caused by elevated serum levels of uric acid
- prompt antibiotic treatment of infections that may result from chemotherapy-induced bone marrow suppression.

During the acute phase of this leukemia, either lymphoblastic or myeloblastic disease may develop. Treatment is similar to that for acute lymphoblastic leukemia. Remission, if achieved, is commonly short-lived.

Despite vigorous treatment, chronic granulocytic leukemia rapidly advances after onset of the acute phase.

Nursing diagnoses

- Altered nutrition: Less than body requirements
- Altered oral mucous membrane
- Altered protection
- Anticipatory grieving
- Anxiety
- Constipation
- Fatigue
- Fear
- Impaired tissue integrity
- Ineffective family coping: Disabling
- Ineffective individual coping
- Pain
- Risk for altered body temperature
- Risk for infection
- Risk for injury

Key outcomes

- The patient will maintain weight within an acceptable range.
- The patient will exhibit intact mucous membranes.
- The patient won't experience chills, fever, or other signs and symptoms of illness.
- The patient will demonstrate use of protective measures, including conserving energy, maintaining a balanced diet, and getting adequate rest.
- The patient and family members will express their feelings.
- The patient will express feelings of increased energy.

Nursing interventions

Take the following steps during the chronic phase of chronic granulocytic leukemia when the patient is hospitalized:

- If the patient has persistent anemia, plan your care to minimize his fatigue. Schedule laboratory tests and physical care with frequent rest periods in between. Assist the patient with walking if necessary. Regularly check the patient's skin and mucous membranes for pallor, petechiae, and bruising.
- To minimize bleeding and infection risks, provide the patient with a soft-bristled toothbrush, an electric razor, and other safety devices.
- To minimize the abdominal discomfort of spleno-megaly, provide small, frequent meals. For the same reason, prevent constipation with a stool softener or laxative, as needed. Maintain adequate fluid intake, and ask the dietary department to provide a high-bulk diet.
- To prevent atelectasis, help the patient perform coughing and deep-breathing exercises.
- Listen to the patient's fears and concerns, and provide emotional support. Stay with the patient during periods of severe stress and answer his questions honestly. Encourage his participation in care decisions whenever possible.
- Administer ordered pain medications as necessary, and monitor their effectiveness. Provide comfort measures and distractions to help the patient cope with his discomfort. Instruct the patient in appropriate relaxation techniques.
- Watch for adverse effects of treatment, and take measures that will reduce or prevent them. For example, the patient who is undergoing chemotherapy should rinse his mouth with normal saline mouthwash to reduce the severity of ulcers.
- After bone marrow transplantation keep the patient in a sterile room, and administer antibiotics and packed red blood cells as ordered. Watch for signs of infection.

For more information about nursing interventions during the acute phase, see “ [Acute Leukemia](#)”.

Patient teaching

- At the time of diagnosis, repeat and reinforce the doctor's explanation of the disease and its treatment to the patient and his family.
- Take extra care to provide sound patient teaching because the patient with chronic granulocytic leukemia typically receives outpatient chemotherapy throughout the chronic phase.
- Explain diagnostic test procedures to the patient. Be sure he understands why the tests are necessary.
- Explain expected adverse effects of chemotherapy, especially bone marrow suppression (bleeding, infection). Inform the patient that he'll receive a combination of drugs tailored to his leukemia type.
- Teach the patient the signs and symptoms of infection to watch for and report any temperature over 100° F (37.8° C), chills, redness or swelling anywhere on the skin, sore throat, or cough.
- Instruct the patient to watch for signs of thrombocytopenia and to apply ice and pressure immediately to any external bleeding site. Unless his doctor tells him to do otherwise, advise him to avoid using aspirin and aspirin-containing compounds, which may increase his bleeding risk.
- Urge the patient to obtain adequate rest to minimize fatigue from anemia.
- To minimize the toxic effects of chemotherapy, encourage the patient to eat foods high in calories and protein. Explain that these foods will help him maintain his strength and prevent body tissues from breaking down. Suggest that he eat small, frequent meals throughout the day, especially if he has little appetite.
- If the patient will undergo bone marrow transplantation, reinforce the doctor's explanation of the procedure, its possible outcome, and potential adverse effects. Be sure the patient fully understands the therapy. Teach him about total body irradiation, which usually takes place before the procedure, and discuss any chemotherapy that he will undergo.
- As appropriate, refer the patient and family members to the social service department, home health care agencies, hospices, and support groups such as the American Cancer Society.

CHRONIC LYMPHOCYTIC LEUKEMIA

Chronic lymphocytic leukemia is a generalized, progressive disease marked by an uncontrollable spread of abnormal, small lymphocytes in lymphoid tissue, blood, and bone marrow. When these cells infiltrate bone marrow, lymphoid tissue, and organ systems, clinical signs begin to appear.

This disease occurs most commonly in elderly people; nearly all those afflicted are men over age 50. According to the American Cancer Society, chronic lymphocytic leukemia accounts for almost one-third of new leukemia cases annually.

Chronic lymphocytic leukemia is the most benign and the most slowly progressive form of leukemia. However, the prognosis is poor if anemia, thrombocytopenia, neutropenia, bulky lymphadenopathy, and severe lymphocytosis develop. Gross bone marrow replacement by abnormal lymphocytes is the most common cause of death, usually within 4 to 5 years of diagnosis.

Causes

Although the cause of the disease is unknown, researchers suspect hereditary factors because a higher incidence has been recorded within families. Undefined chromosomal abnormalities and certain immunologic defects, such as ataxia telangiectasia or acquired agammaglobulinemia, are also suspected. The disease doesn't seem to result from radiation exposure.

Complications

The most common complication is infection, which can be fatal. In the end stage of the disease, possible complications include anemia, progressive splenomegaly, leukemic cell replacement of the bone marrow, and profound hypogammaglobulinemia, which usually terminates with fatal septicemia.

Assessment findings

In the early stages of the disease the patient usually complains of fatigue, malaise, fever, weight loss, and frequent infections.

Inspection may reveal macular or nodular eruptions, evidence of skin infiltration. On palpation, you may note enlarged lymph nodes, liver, and spleen, along with bone tenderness and edema from lymph node obstruction.

As the disease progresses, you may note anemia, pallor, weakness, dyspnea, tachycardia, palpitations, bleeding, and infection from bone marrow involvement. You may also see signs of opportunistic fungal, viral, or bacterial infections, which commonly occur in late stages.

Diagnostic tests

Typically, chronic lymphocytic leukemia is an incidental finding during a routine blood test that reveals numerous abnormal lymphocytes. In the early stages, the patient has a mildly but persistently elevated white blood cell (WBC) count. Granulocytopenia is the rule, although the WBC count climbs as the disease progresses.

Blood studies also reveal a hemoglobin count under 11g/dl, hypogammaglobulinemia, and depressed serum globulin levels. Other common developments include neutropenia (less than 1,500/mm³), lymphocytosis (more than 10,000/mm³), and thrombocytopenia (less than 150,000/mm³).

Bone marrow aspiration and biopsy show lymphocytic invasion. A computed tomography scan identifies affected organs.

Treatment

Systemic chemotherapy includes alkylating agents, usually chlorambucil or cyclophosphamide, and sometimes corticosteroids (prednisone) when autoimmune hemolytic anemia or thrombocytopenia occurs.

When chronic lymphocytic leukemia causes obstruction or organ impairment or enlargement, local radiation therapy can reduce organ size, and splenectomy can help relieve the symptoms. Allopurinol can prevent hyperuricemia, a relatively uncommon finding.

Radiation therapy can help relieve symptoms. It's generally used to treat enlarged lymph nodes, painful bony lesions, or massive splenomegaly.

Nursing diagnoses

u Altered nutrition: Less than body requirements u Altered protection u Anticipatory grieving u Anxiety u Fatigue u Fear u Impaired tissue integrity u Ineffective family coping: Disabling u Ineffective individual coping u Pain u Risk for infection u Risk for injury

Key outcomes

- u The patient will maintain weight within an acceptable range.
- u The patient will exhibit intact mucous membranes.
- u The patient won't experience chills, fever, or other signs and symptoms of illness.
- u The patient will demonstrate use of protective measures, including conserving energy, maintaining a balanced diet, and getting adequate rest.
- u The patient and family members will express feelings.
- u The patient will express feelings of increased energy.

Nursing interventions

- u Help establish an appropriate rehabilitation program for the patient during remission.
- u To control infection, place the patient in a private room and impose reverse isolation if necessary (although the benefits of reverse isolation are controversial). Coordinate care so that the patient doesn't come into contact with staff members who also care for patients with infections or infectious diseases. Screen staff members and visitors for contagious diseases. Don't use an indwelling urinary catheter or give I.M. injections; they provide an avenue for infection. If the patient does develop signs of infection—a temperature over 100° F (37.8° C), chills, or redness or swelling of any body part—report them at once.
- u Clean the patient's skin daily with mild soap and water, and provide frequent soaks if ordered. Keep the patient's perianal area clean, apply mild lotions or creams to keep the skin from drying and cracking, and thoroughly clean the skin before all invasive skin procedures. Change I.V. tubing according to facility policy. Use strict aseptic technique and a metal scalp vein needle (metal butterfly needle) when starting an I.V. line. If the patient is receiving total parenteral nutrition, provide scrupulous subclavian catheter care.
- u Watch for bleeding. If it occurs, apply ice compresses and pressure, and elevate the extremity. Don't give the patient aspirin or aspirin-containing drugs, and don't administer rectal suppositories, take a rectal temperature, or perform a digital rectal examination.
- u Watch for signs of thrombocytopenia (easy bruising and nosebleeds, bleeding gums, black, tarry stools) and anemia (pale skin, weakness, fatigue, dizziness, palpitations).
- u Be alert for adverse effects of treatment, and take measures to prevent or alleviate them. For instance, you can control mouth ulceration by checking often for obvious ulcers and gum swelling and by providing frequent mouth care and saline rinses.
- u Check the rectal area daily for induration, swelling, erythema, skin discoloration, and drainage.
- u Administer blood component therapy as necessary.
- u Establish a trusting relationship to promote communication. Allow the patient and family members to express their anger, anxiety, and depression. Let the family participate in the patient's care as much as possible.
- u The patient with chronic lymphocytic leukemia is likely to be elderly and may feel frightened, so take time to listen to his fears. Try to keep his spirits up by concentrating on little things, such as improving his personal appearance, providing a pleasant environment, and asking questions about his family. If possible, provide opportunities for his favorite activities.
- u Minimize stress by maintaining a calm, quiet atmosphere that is conducive to rest and relaxation.
- u Administer prescribed pain medications as appropriate, and monitor their effectiveness. Provide comfort measures, such as position changes and distractions, to help alleviate the patient's discomfort.
- u If the patient doesn't respond to treatment and has reached the terminal phase of the disease, he'll need supportive nursing care. Take steps to manage pain, fever, and bleeding; make sure the patient is comfortable; and provide emotional support for him and his family. If the patient wishes, provide for religious counseling. Discuss the option of home or hospice care.

Patient teaching

- u Describe the disease course, diagnostic tests, and treatments and their adverse effects.
- u Teach the patient and family members how to recognize signs and symptoms of infection (fever, chills, cough, sore throat).
- u Warn the patient about to be discharged to avoid coming into contact with obviously ill people, especially children with common contagious childhood diseases.
- u Explain that if the chemotherapy causes weight loss and anorexia, the patient will need to eat and drink high-calorie, high-protein foods and beverages. If he loses his appetite, advise him to eat small, frequent meals. If the chemotherapy and adjunctive prednisone cause weight gain, he'll need dietary counseling.
- u Instruct the patient to use a soft toothbrush and to avoid hot, spicy foods and commercial mouth-washes to prevent irritating the mouth ulcers that result from chemotherapy.

- ⌞ Warn the patient to take care to prevent bleeding because his blood may not have enough platelets for proper clotting. Tell him to avoid aspirin and aspirin-containing drugs, and teach him how to recognize drugs that contain aspirin. Teach him the signs of abnormal bleeding (bruising, petechiae) and how to apply pressure and ice to the area to stop such bleeding. Urge him to report excessive bleeding or bruising to his doctor.
- ⌞ Advise the patient to limit his activities and to plan rest periods during the day.
- ⌞ Stress the importance of follow-up care, frequent blood tests, and taking all medications exactly as prescribed. Teach the patient the signs of recurrence (swollen lymph nodes in the neck, axilla, and groin; increased abdominal size or discomfort), and tell him to notify his doctor immediately if these signs occur.
- ⌞ As appropriate, refer the patient and family members to the social service department, home health care agencies, hospices, and support groups such as the American Cancer Society.

HODGKIN'S DISEASE

A neoplastic disorder, Hodgkin's disease is characterized by painless, progressive enlargement of the lymph nodes, spleen, and other lymphoid tissue. This enlargement results from proliferation of lymphocytes, histiocytes, eosinophils, and Reed-Sternberg cells. The latter cells are the special histologic feature of Hodgkin's disease.

Hodgkin's disease occurs in all races but is slightly more common in whites. Its incidence peaks in two age-groups—15 to 38 and after age 50. It occurs most commonly in young adults, except in Japan, where it occurs exclusively among people over age 50. It has a higher incidence in men than in women. A family history of Hodgkin's disease increases the likelihood of acquiring the disorder.

Untreated, Hodgkin's disease follows a variable but relentlessly progressive and ultimately fatal course. However, recent advances in therapy make Hodgkin's disease potentially curable, even in advanced stages. Appropriate treatment yields a 5-year survival rate of about 90%.

Causes

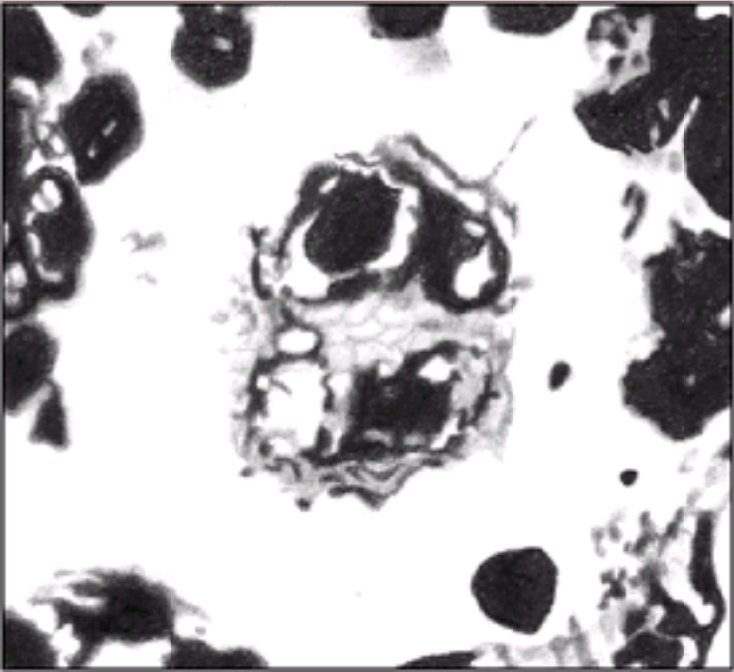

Although the cause of Hodgkin's disease is unknown, some studies point to genetic, viral, or environmental factors.

Complications

Hodgkin's disease can cause multiple organ failure.

Spotting Reed-Sternberg cells

The illustration below shows Reed-Sternberg cells. Note the large, distinct nucleoli.

Assessment findings

Most commonly, the patient's history reveals painless swelling of one of the cervical lymph nodes or sometimes the axillary or inguinal lymph nodes. The history may also reveal a persistent fever and night sweats. The patient may complain of weight loss despite an adequate diet, with resulting fatigue and malaise. As the disease advances, the patient may become increasingly susceptible to infection.

Inspection during the advanced stages of the disease may reveal edema of the face and neck and jaundice.

Palpation may identify enlarged, rubbery lymph nodes in the neck. These nodes enlarge during periods of fever and then revert to normal size.

Diagnostic tests

Tests must first rule out other disorders that enlarge the lymph nodes.

Lymph node biopsy confirms the presence of Reed-Sternberg cells, abnormal histiocyte proliferation, and nodular fibrosis and necrosis. (See [Spotting Reed-Sternberg cells](#).)

Lymph node biopsy also helps determine lymph node and organ involvement, as do bone marrow, liver, mediastinal, and spleen biopsies; routine chest X-rays; abdominal computed tomography scan and lung and bone scans; lymphangiography; and laparoscopy.

Hematologic tests show mild to severe normocytic anemia; normochromic anemia (in 50% of patients); and elevated, normal, or reduced white blood cell count and differential, showing any combination of neutrophilia, lymphocytopenia, monocytosis, and eosinophilia. Elevated serum alkaline phosphatase levels indicate liver or bone involvement.

A staging laparotomy is necessary for patients under age 55 and for those without obvious stage III or stage IV disease, lymphocyte predominance subtype histology, or medical contraindications. (See [Staging Hodgkin's disease](#).)

Treatment

Depending on the stage of the disease, the patient may receive chemotherapy, radiation therapy, or both. Correct treatment allows longer survival and may even induce a cure in many patients.

A patient with stage I or stage II disease receives radiation therapy alone; a patient with stage III disease receives radiation therapy and chemotherapy. For stage IV, the patient receives chemotherapy alone, sometimes inducing a complete remission. As an alternative, he may receive chemotherapy and radiation therapy to

involved sites.

Chemotherapy consists of various combinations of drugs. The well-known MOPP protocol (mechlorethamine, vincristine [Oncovin], procarbazine, and prednisone) was the first to provide significant cures for generalized Hodgkin's disease. Another useful combination is ABVD (doxorubicin [Adriamycin], bleomycin, vinblastine, and dacarbazine). Treatment with these drugs may require concomitant administration of antiemetics, sedatives, and antidiarrheals to combat GI adverse effects.

Other treatments include autologous bone marrow transplantation or autologous peripheral blood sternal transfusions and immunotherapy, which by itself hasn't proved effective.

Nursing diagnoses

u Altered nutrition: Less than body requirements u Altered oral mucous membrane u Anxiety u Fatigue u Fear u Impaired skin integrity u Ineffective family coping: Disabling u Ineffective individual coping u Pain u Risk for infection

Key outcomes

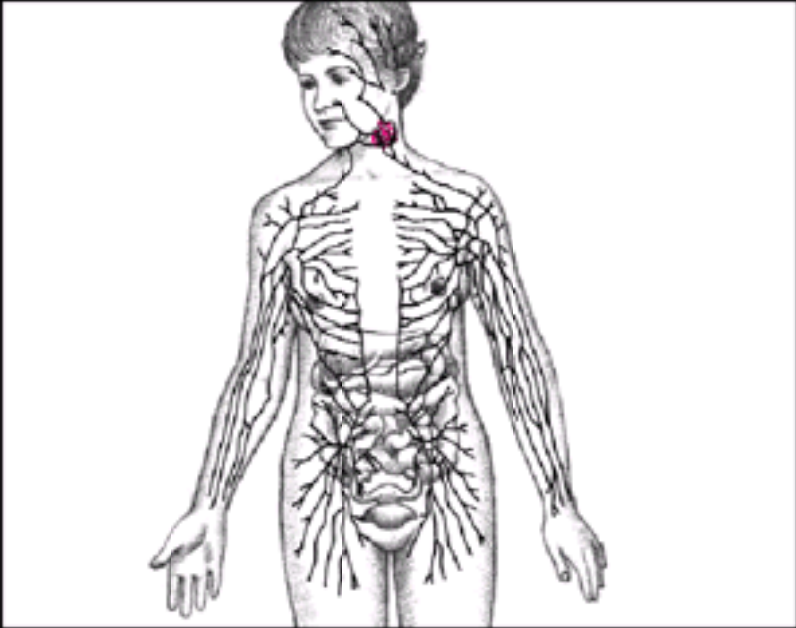

u The patient will maintain weight within an acceptable range.

Staging Hodgkin's disease

Treatment of Hodgkin's disease depends on the stage it has reached; that is, the number, location, and degree of involved lymph nodes. The Ann Arbor classification system, adopted in 1971, divides Hodgkin's disease into four stages, as shown below. Doctors subdivide each stage into categories. Category A includes patients without defined signs and symptoms, and category B includes patients who experience such defined signs as recent unexplained weight loss, fever, and night sweats.

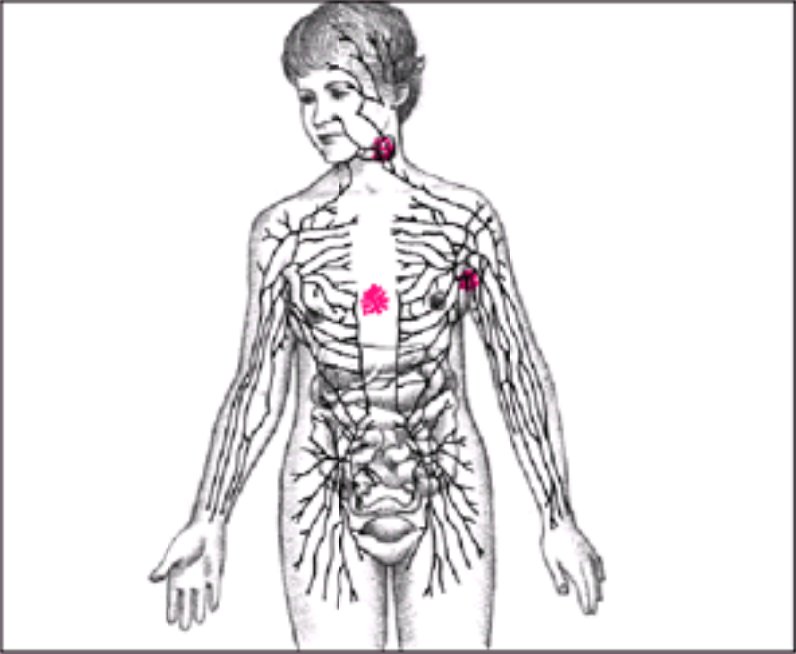

Stage I

Hodgkin's disease appears in a single lymph node region (I) or a single extralymphatic organ (IE).

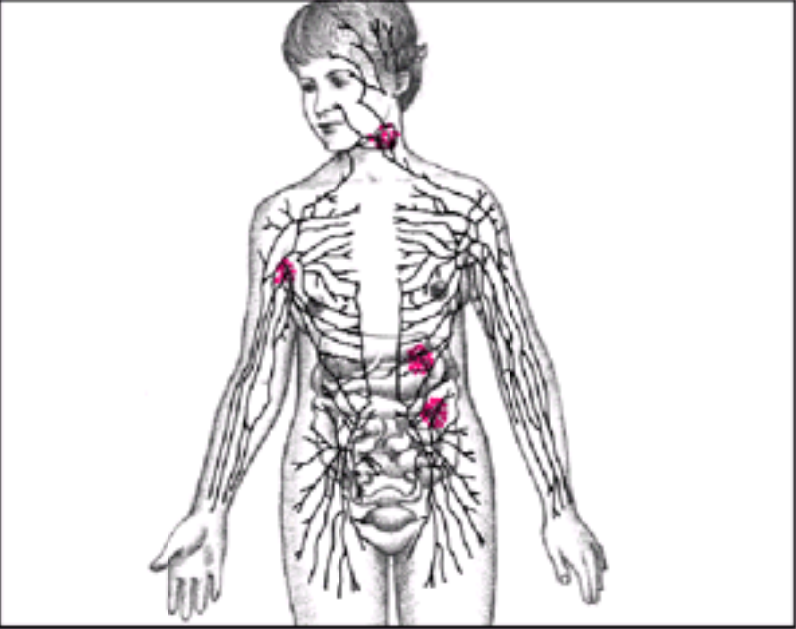

Stage II

The disease appears in two or more nodes on the same side of the diaphragm (II) and in an extralymphatic organ (IIE).

Stage III

Hodgkin's disease spreads to both sides of the diaphragm (III) and perhaps to an extralymphatic organ (IIIE), the spleen (IIIS), or both (IIIES).

Stage IV

Stage IV

The disease disseminates, involving one or more extralymphatic organs or tissues, with or without lymph node involvement.

- u The patient will exhibit intact mucous membranes.
- u The patient will express feelings of increased energy.
- u The patient will demonstrate adequate skin integrity.
- u The patient and family members will demonstrate effective coping mechanisms.
- u The patient will express feelings of comfort and decreased pain.

Nursing interventions

- u Watch for complications during chemotherapy, including anorexia, nausea, vomiting, alopecia, and mouth ulcers.
- u Provide a well-balanced, high-calorie, high-protein diet. If the patient is anorexic, provide frequent, small meals. Consult with the dietitian to incorporate foods the patient enjoys into his diet.
- u Be alert for adverse effects of radiation therapy, such as hair loss, nausea, vomiting, and anorexia.
- u Offer the patient grapefruit juice, orange juice, or ginger ale to alleviate nausea and vomiting.
- u Perform comfort measures that promote relaxation. Provide for periods of rest if the patient tires easily. Administer pain medication as ordered, and monitor its effectiveness.
- u Watch for the development of hypothyroidism, sterility, and a second neoplastic disease, including late-onset leukemia and non-Hodgkin's lymphoma. Although these are complications of the treatments, they also indicate the success of treatment.
- u Throughout therapy, listen to the patient's fears and concerns. Encourage him to express his feelings, and stay with him during periods of extreme stress and anxiety. Provide emotional support to the patient and family members.
- u Involve the patient and family members in all aspects of his care.

Patient teaching

- u Explain all procedures and treatments associated with the plan of care.
- u Because sudden withdrawal of prednisone is life-threatening, advise the patient taking this medication not to change his drug dosage or discontinue the drug without contacting his doctor.
- u If the patient is a woman of childbearing age, advise her to delay pregnancy until long-term remission occurs. Radiation therapy and chemotherapy can cause genetic mutations and spontaneous abortions.
- u Stress the importance of maintaining good nutrition (aided by eating small, frequent meals of the patient's favorite foods) and drinking plenty of fluids.
- u Instruct the patient to pace his activities to counteract therapy-induced fatigue. Teach him how to use relaxation techniques to promote comfort and reduce anxiety.
- u Stress the importance of good oral hygiene to prevent stomatitis. To control pain and bleeding, teach the patient to use a soft toothbrush, a cotton swab, or an anesthetic mouthwash such as viscous lidocaine (as prescribed); to apply petroleum jelly to his lips; and to avoid astringent mouthwashes.
- u Advise the patient to avoid crowds and any person with a known infection. Emphasize that he should notify the doctor if he develops any infections.
- u Because enlarged lymph nodes may indicate disease recurrence, teach the patient the importance of checking his lymph nodes.
- u Make sure the patient understands the possible adverse effects of his treatments. Tell him to notify the doctor if these signs and symptoms persist.
- u When appropriate, refer the patient and family members to community organizations, such as psychological counseling services, support groups, and hospices.
- u Advise the patient to seek follow-up care after he has completed the initial treatment.

KAPOSI'S SARCOMA

Initially, Kaposi's sarcoma of the lymphatic cell wall was described as a rare blood vessel sarcoma, occurring mostly in elderly Italian and Jewish men. In recent years, the incidence of Kaposi's sarcoma has risen dramatically along with the incidence of acquired immunodeficiency syndrome (AIDS). Currently, it's the most common AIDS-related cancer.

Characterized by obvious, colorful lesions, Kaposi's sarcoma causes structural and functional damage. When associated with AIDS, it progresses aggressively, involving the lymph nodes, the viscera, and possibly GI structures.

Causes

The exact cause of Kaposi's sarcoma is unknown, but the disease may be related to immunosuppression. Genetic or hereditary predisposition is also suspected.

Complications

Disease progression can cause severe pulmonary involvement, resulting in respiratory distress, and GI involvement, leading to digestive problems.

Assessment findings

The health history typically reveals that the patient has AIDS. If the sarcoma advances beyond the early stages or if a lesion breaks down, the patient may report pain. Usually, however, the lesions remain pain-free unless they impinge on nerves or organs.

On inspection, you may observe several lesions of various shapes, sizes, and colors (ranging from red-brown to dark purple) on the skin, buccal mucosa, hard and soft palates, lips, gums, tongue, tonsils, conjunctiva, and sclera (the most common sites). In advanced disease, the lesions may join, becoming one large plaque. Untreated lesions may appear as large, ulcerative masses. You may notice that the patient has dyspnea, especially if pulmonary involvement occurs.

Palpation and inspection may also disclose edema from lymphatic obstruction.

Auscultation may uncover wheezing and hypoventilation. Respiratory distress usually results from bronchial blockage. The most common extracutaneous sites are the lungs and GI tract (esophagus, oropharynx, and epiglottis).

Diagnostic tests

Usually, the patient undergoes a tissue biopsy to determine the lesion's type and stage. A computed tomography scan may be performed to evaluate metastasis. (See [Laubenstein's stages in Kaposi's sarcoma.](#))

Treatment

Radiation therapy, chemotherapy, and drug therapy with biological response modifiers are treatment options. Radiation therapy offers palliation of symptoms, including pain from obstructing lesions in the oral cavity or extremities and edema caused by lymphatic blockage. It may also be used for cosmetic improvement.

Chemotherapy includes combinations of doxorubicin, vinblastine, vincristine, and etoposide (VP16). The biological response modifier interferon alfa-2b may be prescribed in AIDS-related Kaposi's sarcoma. It reduces the number of skin lesions but is ineffective in advanced disease.

Nursing diagnoses

- u Altered nutrition: Less than body requirements
- u Anticipatory grieving
- u Anxiety
- u Body image disturbance
- u Fatigue
- u Fear
- u Impaired gas exchange
- u Impaired skin integrity
- u Ineffective breathing pattern
- u Ineffective family coping: Disabling
- u Ineffective individual coping
- u Pain
- u Risk for infection

Laubenstein's stages in Kaposi's sarcoma

The following staging system was proposed by L.J. Laubenstein for use in evaluating and treating patients who have acquired immunodeficiency virus and Kaposi's sarcoma:

- u *Stage I*—locally indolent cutaneous lesions
- u *Stage II*— locally aggressive cutaneous lesions
- u *Stage III* —mucocutaneous and lymph node involvement
- u *Stage IV* —visceral involvement.

Within each stage, a patient may have different symptoms classified as a stage subtype A or B, as follows:

- u *Subtype A*— no systemic signs or symptoms
- u *Subtype B*— one or more systemic signs and symptoms, including 10% weight loss, fever of unknown origin that exceeds 100° F (37.8° C) for more than 2 weeks, chills, lethargy, night sweats, anorexia, and diarrhea.

Key outcomes

- u The patient will maintain weight within an acceptable range.
- u The patient will express positive feelings about self.
- u The patient will demonstrate adequate ventilation.
- u The patient will maintain a patent airway.
- u The patient will remain free from signs and symptoms of infection.

Nursing interventions

- u Listen to the patient's fears and concerns and answer his questions honestly. Stay with him during periods of severe stress and anxiety. Allow him to participate in care decisions whenever possible, and encourage him to participate in self-care measures as much as he can.
- u Inspect the patient's skin every shift. Look for new lesions and skin breakdown. If the patient has painful lesions, help him into a more comfortable position.
- u Administer pain medications. Suggest distractions, and help the patient with relaxation techniques.
- u To help the patient adjust to changes in his appearance, urge him to share his feelings. Give encouragement.
- u Supply the patient with high-calorie, high-protein meals. If he can't tolerate regular meals, provide him with frequent, smaller meals. Consult with the dietitian, and plan meals around the patient's treatment. If the patient can't take food by mouth, administer I.V. fluids. Give antiemetics and sedatives as ordered.
- u Provide rest periods if the patient tires easily.
- u Be alert for adverse effects of radiation therapy or chemotherapy—such as anorexia, nausea, vomiting, and diarrhea—and take steps to prevent or alleviate them.

Patient teaching

- u Offer emotional support to help the patient and family cope with the diagnosis and prognosis. Provide opportunities for them to discuss their concerns.
- u Reinforce the doctor's explanation of treatments. Be sure the patient understands which adverse effects to expect and how to manage them. For example, during radiation therapy, instruct the patient to keep irradiated skin dry to avoid possible breakdown and subsequent infection.
- u Explain infection prevention techniques and, if necessary, demonstrate basic hygiene measures to prevent infection. These measures are especially important if the patient has AIDS.
- u Stress the need for ongoing treatment and care.
- u As appropriate, refer the patient to the social service department support groups.

MALIGNANT LYMPHOMAS

Also called non-Hodgkin's lymphomas and lympho-sarcomas, malignant lymphomas are a heterogeneous group of malignant diseases that originate in lymph glands and other lymphoid tissue. A chronic form of T-cell lymphoma originates in the skin. (See [Mycosis fungoides.](#))

Lymphomas are usually classified according to histologic, anatomic, and immunomorphic characteristics developed by the National Cancer Institute. However, the Rappaport histologic and Lukes classifications also are used in some settings. (See [Classifying malignant lymphomas.](#))

Malignant lymphomas occur three times more commonly than Hodgkin's disease, and the incidence is increasing, especially in patients with autoimmune disorders and those receiving immunosuppressant treatment. Nodular lymphomas yield a better prognosis than the diffuse form of the disease, but in both, the prognosis is less hopeful than in Hodgkin's disease.

Causes

Although some theories point to a viral source, the cause of malignant lymphomas is unknown.

Complications

Malignant lymphomas can lead to hypercalcemia, hyperuricemia, lymphomatosis, meningitis, and anemia from bone marrow involvement. As tumors grow, they may produce liver, kidney, and lung problems. Central nervous system involvement can lead to increased intracranial pressure.

Assessment findings

The symptoms of malignant lymphomas may mimic those of Hodgkin's disease. Most commonly, the patient history reveals painless, swollen lymph glands. The swelling may have appeared and disappeared over several months.

As the lymphoma progresses, the patient may complain of fatigue, malaise, weight loss, and night sweats. If the patient is a child, he may have trouble breathing and have a cough, probably the result of enlarged lymph nodes.

Inspection may reveal enlarged tonsils and adenoids, and palpation may disclose rubbery nodes in the cervical and supraclavicular areas.

Diagnostic tests

Biopsies—of lymph nodes; of tonsils, bone marrow, liver, bowel, or skin; or, as needed, of tissue removed during exploratory laparotomy—differentiate a malignant lymphoma from Hodgkin's disease. Chest X-rays; lymphangiography; liver, bone, and spleen scans; a computed tomography scan of the abdomen; and excretory urography indicate disease progression.

A complete blood count may show anemia. The patient may have a normal or elevated uric acid level and an elevated serum calcium level, resulting from bone lesions.

The same staging system used for Hodgkin's disease is used for malignant lymphomas.

Treatment

Radiation and chemotherapy are the main treatments for lymphomas. Radiation therapy is used mainly during the localized stage of the disease. Total nodal irradiation often effectively treats both nodular and diffuse lymphomas.

Chemotherapy is most effective with combinations of antineoplastic agents. For example, the CHOP protocol (cyclophosphamide, doxorubicin, vincristine [Oncovin], and prednisone) can induce a complete remission in 70% to 80% of those with nodular lymphoma and in 20% to 55% of those with diffuse lymphoma. Other combinations such as MACOPB (methotrexate, leucovorin, doxorubicin [Adriamycin], cyclophosphamide, vincristine [Oncovin], prednisone, and bleomycin) can induce a prolonged remission and possibly a cure for diffuse lymphoma.

Because perforation commonly occurs in patients with gastric lymphomas, these patients usually undergo a debulking procedure before chemotherapy, such as a subtotal or, in some cases, a total gastrectomy.

Nursing diagnoses

u Altered nutrition: Less than body requirements u Altered protection u Anxiety u Fatigue u Fear u Ineffective family coping: Disabling u Ineffective individual coping u Pain u Risk for infection

Key outcomes

- u The patient will maintain weight within an acceptable range.
- u The patient will demonstrate use of protective measures, including conserving energy, maintaining a balanced diet, and getting adequate rest.
- u The patient will express feelings of increased energy.
- u The patient and family members will demonstrate effective coping mechanisms.
- u The patient will express feelings of comfort and decreased pain.

Nursing interventions

- u Administer ordered pain medication and monitor its effectiveness.
- u Provide for rest periods if patient tires easily.
- u Watch for complications of chemotherapy, such as nausea and vomiting, anorexia, hair loss, mouth ulcers, and infection.
- u Offer the patient fluids, such as grapefruit juice, orange juice, or ginger ale, to counteract nausea.
- u Because this disease causes large numbers of tumors, provide the patient with lots of fluids to help flush out the cells that are destroyed during treatment. This helps prevent tumor lysis syndrome.
- u Provide a well-balanced, high-calorie, high-protein diet. Consult with the dietitian and plan small, frequent meals that include the patient's favorite foods. Schedule meals around the patient's treatment.

Mycosis fungoides
<p>Mycosis fungoides, a rare, chronic form of T-cell lymphoma, originates in the skin and eventually affects lymph nodes and internal organs. The cause is unknown, but it's associated with exposure to certain chemicals, family history of Hodgkin's disease or lymphoma, and defects in host immunosurveillance. Most patients are 40 to 60 years old.</p> <p>In the early, premycotic stage, mycosis fungoides is commonly mistaken for psoriasis or dermatitis, with itching and superficial skin eruptions that appear and disappear spontaneously.</p> <p>Later, in the plaque stage, great discomfort and itching accompany raised, irregularly shaped plaques. Alopecia and painful lesions on the palms and soles can occur.</p> <p>In the tumor stage, mass lesions appear, most commonly on the face and body folds. The lymph nodes may be palpable.</p> <p>Diagnosis and staging involves complete blood count and differential, fingerstick smear for abnormal lymphocytes, blood chemistry studies, X-rays, isotopic scanning, lymphangiography, and biopsy.</p> <p>Early treatment can produce long-term remission and may include phototherapy, photochemotherapy, radiation, or topical, intralesional, or systemic corticosteroids or mechlorethamine. Systemic chemotherapy can help patients with advanced, tumor-stage disease. After the tumor stage, progression to disability and death is rapid.</p>

- u If the patient can't tolerate oral feedings, administer I.V. fluids. If necessary, give antiemetics and sedatives as ordered.
- u Throughout therapy, listen to the patient's fears and concerns. Stay with him during periods of severe stress or anxiety. Encourage him to express his anger and concerns, and offer reassurance when appropriate.
- u Involve the patient and family members in his care whenever possible.

Patient teaching

- u Make sure the patient receives thorough explanations about all forms of his treatment.
- u Instruct the patient to keep irradiated skin dry.
- u Before surgery, explain preoperative and postoperative procedures thoroughly to the patient. Tell him that he may have an NG tube or an indwelling urinary catheter inserted postoperatively.
- u After chemotherapy and radiation therapy, advise the patient to avoid crowds and anyone who has an infection.

Classifying malignant lymphomas		
Several classification and staging systems are in current use for evaluating the extent of malignant lymphoma. Among the most common are the National Cancer Institute's (NCI) system (named the "Working formulation for classification of nonHodgkin's lymphomas for clinical usage"), the Rappaport histologic classification, and Lukes classification. The three systems appear below.		
NCI WORKING FORMULATION	RAPPAPORT HISTOLOGIC CLASSIFICATION	LUKES CLASSIFICATION
Low grade		
u Small lymphocytic	u Diffuse well-differentiated lymphocytic	u Small lymphocytic and plasmacytoid lymphocytic
u Follicular, predominantly small cleaved cell	u Nodular poorly differentiated lymphocytic	u Small cleaved follicular center cell, follicular only, or follicular and diffuse
u Follicular mixed, small and large cell	u Nodular mixed lymphoma	u Small, cleaved follicular center cell, follicular; large cleaved follicular center cell, follicular
Intermediate grade		
u Follicular, predominantly large cell	u Nodular histiocytic lymphoma	u Large cleaved or noncleaved follicular center cell, or both, follicular
u Diffuse, small cleaved cell	u Diffuse poorly differentiated lymphoma	u Small cleaved follicular center cell, diffuse
u Diffuse mixed, small and large cell	u Diffuse mixed lymphocythistiocytic	u Small cleaved, large cleaved, or large noncleaved follicular center cell, diffuse
u Diffuse large cell, cleaved or noncleaved	u Diffuse histiocytic lymphoma	u Large cleaved or noncleaved follicular center cell, diffuse
High grade		
u Diffuse large cell immunoblastic	u Diffuse histiocytic lymphoma	u Immunoblastic sarcoma, T-cell or B-cell, type
u Large cell, lymphoblastic	u Lymphoblastic, convoluted or non-convoluted	u Convoluted T-cell
u Small noncleaved cell	u Undifferentiated, Burkitt's and nonBurkitt's diffuse undifferentiated lymphoma	u Small noncleaved follicular center cell
Miscellaneous		
u Composite		
u Mycosis fungoides		
u Histiocytic		
u Extramedullary plasmacytoma		
u Unclassifiable		

- u Urge him to report any infection he develops to his doctor.
- u Stress the importance of maintaining a well-balanced, high-calorie, high-protein diet.
- u Emphasize the importance of maintaining good oral hygiene during treatment to prevent stomatitis. Instruct the patient to clean his teeth with a soft-bristled toothbrush and to avoid commercial mouthwashes.
- u Teach the patient relaxation and comfort measures and encourage him to use them.
- u If appropriate, refer the patient to the social service department, home health care agencies, hospices, and support groups such as the American Cancer Society.

INTRODUCTION

The human body protects itself from diseases caused by microorganisms through an elaborate network of safeguards—the immune system.

The immune system: Structures and strategies

The immune system, also known as the host defense system, consists of physical and chemical barriers to infection as well as the inflammatory and immune responses.

Physical barriers—such as skin and mucous membranes—block invasion by most organisms. Harmful organisms that do penetrate these barriers simultaneously trigger a second line of defense: the inflammatory and immune responses. Both responses call on cells derived from a hematopoietic stem cell in bone marrow.

The inflammatory response mobilizes polymorphonuclear leukocytes, basophils, mast cells, and platelets. The immune response primarily involves forces of T lymphocytes (or T cells), B lymphocytes (or B cells), macrophages, and macrophage-like cells and their products. Some of these cells circulate continuously, whereas others stand guard in the tissues and organs of the immune system, including the thymus, lymph nodes, Peyer's patches of the intestines, spleen, and tonsils

The thymus contributes to the maturation of T cells (the blood cells associated with *cell-mediated immunity*). Here, these cells are “educated” to differentiate self from nonself. In contrast, bone marrow serves as the site of B-cell maturation. B cells provide humoral immunity. The key humoral effector mechanism is the complement cascade. The lymph nodes, spleen, and intestinal lymphoid tissue then help to destroy and remove antigens circulating in the blood and lymph.

Antigens

The immune response involves antigens and the concepts of specificity and memory. An antigen is a substance that can induce an immune response. T and B cells have specific receptors that respond to specific antigen molecular shapes (epitopes). In B cells, this receptor is an immunoglobulin (Ig) or antibody molecule known as IgD or IgM. This molecule is also called a surface immunoglobulin. The T-cell antigen receptor recognizes an antigen only in association with specific cell surface antigen determinants called the major histocompatibility complex (MHC). (See [Major histocompatibility complex](#).) Slightly different antigen receptors can recognize many distinct antigens coded for distinct, variable M-region genes.

Groups, or clones, of lymphocytes exist with identical receptors for a specific antigen. The lymphocytic clones rapidly proliferate after exposure to a specific antigen. Some lymphocytes further differentiate, and others become memory cells, allowing a faster response—the memory or *anamnestic response*—to a subsequent challenge by the antigen.

Many factors influence antigenicity (the ability to produce an immune response). Among them are the physical and chemical characteristics of the antigen, its relative foreignness, and a person's genetic makeup. Most antigens are large molecules, such as proteins and polysaccharides. (Smaller molecules, such as drugs, that aren't antigenic by themselves are known as haptens. Haptens can bind with larger molecules, or carriers, and become antigenic or immunogenic.)

The relative foreignness of the antigen influences the intensity of the immune response. For example, little or no immune response may follow transfusion of serum proteins between humans; however, a vigorous immune response (serum sickness) commonly follows transfusion of horse serum proteins to a human.

Genetic makeup may also determine why some people respond to certain antigens, whereas others don't. The genes responsible for this phenomenon—the immune response genes—are located within the MHC.

T cells

T cells and macrophages are the chief participants in cell-mediated immunity. Immature T cells derive from bone marrow and migrate to the thymus, where they mature in a process that appears to be linked to products of the MHC: human leukocyte antigen (HLA) genes.

Mature T cells can distinguish self from nonself and acquire certain surface molecules, or markers. These markers, combined with the T-cell antigen receptor, promote a particular activation of each type of T cell.

T-cell activation requires presentation of antigen as a specific HLA. Helper T cells require class II HLA; cytotoxic T cells require class I HLA. T-cell activation also involves interleukin (IL)-1, produced by macrophages, and IL-2, produced by T cells. (Interleukins are growth factors that stimulate the production of other immune

cells.) A discrete population of large lymphocytes, natural killer (NK) cells resemble T cells. NK cells recognize surface changes on body cells infected with a virus; they then bind to and usually kill the infected cells.

Major histocompatibility complex
<p>The major histocompatibility complex (MHC) plays a pivotal role in the immune response. The MHC is a cluster of genes located on human chromosome 6. These structures are inherited in an autosomal codominant manner. They're also known as human leukocyte antigen (HLA) genes.</p> <p>Each person receives a set of MHC genes (haplotype) from each parent. Both gene sets are expressed on the person's cells. These genes play an essential role in the recognition of self versus nonself and, by coding for cell surface proteins, they participate in the interaction of immunologically active cells.</p> <p>Classifications</p> <p>HLAs are grouped into three classes. Class I antigens appear on nearly all body cells. They include HLA-A, HLA-B, and HLA-C. During tissue graft rejection, they are the chief antigens recognized by the host. When cytotoxic T cells lyse a virally infected antigen, they recognize it as a class I antigen.</p> <p>Class II antigens appear only on B cells, macrophages, and activated T cells. They include HLA-D and HLA-DR. Class II antigens promote efficient collaboration between immunocompetent cells. To become activated, T cells must be presented with a class II antigen. Because class II antigens determine whether a person responds to a particular antigen, they're also known as immune response genes.</p> <p>Class III antigens include certain complement proteins (C2, C4, and factor B).</p>

B cells

B cells and their products, immunoglobulins, contribute to humoral immunity. The binding of soluble antigen with B-cell antigen receptors initiates the humoral immune response. Activated B cells differentiate into plasma cells that secrete immunoglobulins, or antibodies. This response is regulated by T cells and their products, lymphokines. These lymphokines, which include IL-2, IL-4, IL-5, and interferon (IFN) 8, are important in determining the class of immunoglobulins made by B cells.

The immunoglobulins secreted by plasma cells are four-chain molecules consisting of two heavy and two light chains. Each chain has a variable (V) region and one or more constant (C) regions, which are coded by separate genes. The V regions of both light and heavy chains participate in the binding of antigens. The C regions of the heavy chain provide a binding site for crystallizable fragment, crystallizable (Fc) receptors on cells and govern other mechanisms.

Any clone of B cells has one antigen specificity determined by the V regions of its light and heavy chains. The clone can change the class of immunoglobulin that it makes by changing the association between its V region genes and heavy chain C region genes (a process known as isotype switching). For example, a clone of B cells genetically preprogrammed to recognize tetanus toxoid first makes an IgM antibody against tetanus toxoid and later, an IgG or other antibody against it.

The five known classes of immunoglobulins—IgG, IgM, IgA, IgE, and IgD—are distinguished by the constant portions of their heavy chains. Each class has a kappa or lambda light chain, which gives rise to many subtypes and provides almost limitless combinations of light and heavy chains that give immunoglobulins their specificity.

- u *IgG*, the smallest immunoglobulin, appears in all body fluids because of its ability to move across membranes as a single structural unit (a monomer). It constitutes 75% of total serum immunoglobulins and is the major antibacterial and antiviral antibody.
- u *IgM*, the largest immunoglobulin, appears as a pentamer (five monomers joined by a J chain). Unlike IgG—which is produced mainly in the secondary, or recall, response—IgM dominates in the primary, or initial, immune response. Like IgG, IgM is involved in classic antibody reactions, including precipitation, agglutination, neutralization, and complement fixation. Because of its size, IgM can't readily cross membrane barriers and is usually present only in the vascular system. IgM constitutes 5% of total serum immunoglobulins.
- u *IgA* exists in serum primarily as a monomer. In secretory form, IgA exists almost exclusively as a dimer (two monomer molecules joined by a J chain and a secretory component chain). As a secretory immunoglobulin, IgA defends external body surfaces and is present in colostrum, saliva, tears, and nasal fluids as well as in respiratory, GI, and genitourinary secretions. This antibody is considered important in preventing antigenic agents from attaching to epithelial surfaces. IgA makes up 20% of total serum immunoglobulins.
- u *IgE*, present in trace amounts in serum, is involved in the release of vasoactive amines stored in basophils and tissue mast cell granules. When released, these bioamines cause the allergic effects characteristic of this type of hypersensitivity (erythema, itching, smooth-muscle contractions, secretions, and swelling).
- u *IgD*, present as a monomer in serum in minute amounts, is the predominant antibody found on the surface of B cells and serves mainly as an antigen receptor. It may function in controlling lymphocyte activation or suppression.

Macrophages: Key antigen-presenting cells

Macrophages are important cells of the reticuloendothelial system; they influence both the inflammatory and the immune response. Macrophage precursors (monocytes) circulate in the blood. When they collect in various tissues and organs, such as the liver, spleen, lungs, and connective tissue, they develop into macrophages with varying characteristics, depending on the receptor tissue.

Unlike B and T cells, macrophages lack surface receptors for specific antigens. Instead, they have receptors for the C region of the heavy chain (Fc region) of immunoglobulin, for fragments of the third component of complement (C3), and for other factors, such as carbohydrate molecules.

A primary function of macrophages is the presentation of an antigen to T cells. Macrophages ingest and process an antigen and then deposit it on their own surfaces with HLA. T cells become activated when they recognize this complex. Macrophages also function in the inflammatory response by producing IL-1, which generates fever, and by synthesizing complement proteins and other mediators, which produce phagocytic, microbicidal, and tumoricidal effects.

Cytokines

Cytokines are low-molecular-weight proteins involved in communication between cells. Their purpose is to induce or regulate various immune or inflammatory responses. Disorders may occur if cytokine production or regulation is impaired. Cytokines are categorized as follows:

- u *Colony-stimulating factors* function primarily as hematopoietic growth factors, guiding the division and differentiation of bone marrow stem cells. They also influence the functioning of mature lymphocytes, monocytes, macrophages, and neutrophils.
- u *Interferons* act early to limit the spread of viral infections. They also inhibit tumor growth. Mainly, they determine how well tissue cells interact with cytotoxic cells and lymphocytes.
- u *Interleukins* are a large group of cytokines. (Those produced primarily by T cells are called lymphokines. Those produced by mononuclear phagocytes are called monokines.) They are responsible for various effects, but most direct other cells to divide and differentiate.
- u *Tumor necrosis factors* are believed to play a major role in mediating inflammation and cytotoxic reactions (along with IL-1, IL-6, and IL-8).
- u *Transforming growth factor* demonstrates both inflammatory and anti-inflammatory effects. It is believed to be partially responsible for tissue fibrosis associated with many diseases. It demonstrates immunosuppressive effects on T, B, and NK cells.

Complement system

The complement system is the chief humoral effector of the inflammatory response. It consists of more than 20 serum proteins. When activated, these proteins interact in a cascadelike process that has profound biological effects. Complement activation occurs along one of two pathways. In the classical pathway, an immunoglobulin (IgM or IgG) and an antigen bind to form antigen-antibody complexes that activate the first complement component (0). This, in turn, activates C4, C2, and C3. In the alternate pathway, activating surfaces, such as bacterial membranes, directly amplify spontaneous cleavage of C3. When C3 is activated in either

pathway, activation of the terminal components—C5 to C9—follows.

The major biological effects of complement activation include phagocyte attraction (chemotaxis) and activation, histamine release, viral neutralization, promotion of phagocytosis by opsonization, and lysis of cells and bacteria. Other mediators of inflammation derived from the kinin and coagulation pathways interact with the complement system.

Polymorphonuclear leukocytes

Besides macrophages and complement, key participants in the inflammatory response are the polymorphonuclear leukocytes: neutrophils, eosinophils, and basophils.

Neutrophils, the most numerous of these cells, derive from bone marrow and proliferate dramatically in response to infection and inflammation. These highly mobile cells are attracted to areas of inflammation and are the primary constituents of pus. Neutrophils have surface receptors for immunoglobulins and complement fragments. They avidly ingest opsonized particles such as bacteria. Ingested organisms are then promptly killed by toxic oxygen metabolites and enzymes such as lysozymes. Neutrophils are so effective that they can damage host tissues even as they act to protect them by killing invading organisms.

Eosinophils, which are also derived from bone marrow, multiply in allergic disorders and parasitic infestations. Although their phagocytic function isn't clearly understood, evidence suggests that they participate in the host's defense against parasites. Their products may also dampen the inflammatory response in allergic disorders.

Two other cells that function in allergic disorders are basophils and mast cells. Basophils circulate in peripheral blood; mast cells accumulate in connective tissue, particularly in the lungs, intestines, and skin. Both cells have surface receptors for IgE. When cross-linked by an IgE-antigen complex, they release substances (mediators) characteristic of the allergic response.

Immune disorders

For various reasons, the complex processes involved in the host defense and immune response may malfunction. When the body's defenses are exaggerated, misdirected, absent, or depressed, the result may be a hypersensitivity, autoimmune, or immunodeficiency disorder, respectively.

Hypersensitivity disorders

An exaggerated or inappropriate immune response may lead to various hypersensitivity disorders. Such disorders are classified as type I through type IV, although some overlap exists. (See [*Gell and Coombs classification of hypersensitivity reactions*](#).)

▮ *Type I hypersensitivity (allergic disorders)*. In some people, certain antigens (allergens) induce B-cell production of IgE, which binds to the Fc receptors on mast cell surfaces. When these cells are reexposed to the same antigen, the antigen binds with the surface IgE, cross-links the Fc receptors, and causes mast cell degranulation with release of various mediators. (Degranulation may also be triggered by complement-derived anaphylatoxins—C3a and C5a—or by certain drugs, such as morphine.) Some of these mediators are preformed, whereas others are synthesized with mast cell activation. Preformed mediators include heparin, histamine, proteolytic and other enzymes, and chemotactic factors for eosinophils and neutrophils. Newly synthesized mediators include prostaglandins and leukotrienes.

These mediators cause vasodilation, smooth-muscle contraction, bronchospasm, increased vascular permeability, edema, mucus secretion, and cellular infiltration by eosinophils and neutrophils. Classic associated signs and symptoms include hypotension, wheezing, swelling, urticaria (hives), and rhinorrhea.

Examples of type I hypersensitivity disorders are anaphylaxis, hay fever (allergic rhinitis) and, in some cases, asthma.

▮ *Type II hypersensitivity (antibody-dependent cytotoxicity)*. In this form of hypersensitivity, antibody is directed against cell surface antigens. (Alternatively, antibody may be directed against small molecules adsorbed to cells or against cell surface receptors, rather than against cell constituents themselves.) Type II hypersensitivity then causes tissue damage through several mechanisms. Antigen-antibody binding activates complement, which ultimately disrupts cellular membranes. Another mechanism is mediated by various phagocytic cells with receptors for immunoglobulin (Fc region) and complement fragments.

In a process called phagocytosis, these cells envelop and destroy opsonized targets, such as red blood cells, leukocytes, and platelets. Antibodies to these cells may be visualized by immunofluorescence. Cytotoxic T cells and NK cells contribute to tissue damage in type II hypersensitivity

Examples of type II hypersensitivity include transfusion reactions, hemolytic disease of the newborn, acute immune hemolytic anemia, myasthenia gravis, and Goodpasture's syndrome.

▮ *Type III hypersensitivity (immune complex disease)*. In this disorder, excessive circulating antigen results in the deposition of immune complexes in tissue—most commonly in the kidneys, joints, skin, and blood vessels. (Normally, immune complexes are effectively cleared by the reticuloendothelial system.) These deposited immune complexes activate the complement cascade, resulting in local inflammation. They also trigger platelet release of vasoactive amines that increase vascular permeability, augmenting deposition of immune complexes in vessel walls.

Type III hypersensitivity may be associated with infections, such as hepatitis B and bacterial endocarditis; malignant diseases, in which a serum sickness-like syndrome may occur; and autoimmune disorders, such as glomerulonephritis, arthritis, and systemic lupus erythematosus (SLE). This type of hypersensitivity reaction may also follow drug or serum therapy.

▮ *Type IV hypersensitivity (delayed hypersensitivity)*. In this form of hypersensitivity, the macrophages process the antigens and present the result to the T cells. The sensitized T cells then release lymphokines, which recruit and activate other lymphocytes, monocytes, macrophages, and polymorphonuclear leukocytes. The coagulation, kinin, and complement pathways contribute to tissue damage in this type of reaction.

Examples of type IV hypersensitivity include tuberculin reactions, sarcoidosis, and contact hypersensitivity.

Autoimmune disorders

Characterized by a misdirected immune response, autoimmunity results when the immune system becomes self-destructive. What causes this abnormal response puzzles researchers. Although they do know that recognition of self through the MHC is a key to the effective immune response, they don't know how to prevent a response against self. Nor do they know which cells are primarily responsible. Autoimmunity may result from a combination of factors, including genetic, hormonal, and environmental influences.

Characteristic of many autoimmune disorders is B-cell hyperactivity, which is marked by proliferation of B cells and autoantibodies, and by hypergammaglobulinemia. T-cell abnormalities—especially suppressor T-cell deficiency—are also common. Viruses may contribute to autoimmunity by causing proliferation (Epstein-Barr virus) or destruction (human immunodeficiency virus [HIV]) of lymphocytes; so may macrophage abnormalities, which interfere with antigen processing and presentation. Hormonal and genetic factors strongly influence the incidence of autoimmune disorders; for example, systemic lupus erythematosus (SLE) predominantly affects women of childbearing age, and certain HLA haplotypes are associated with an increased risk of specific autoimmune disorders.

Immunodeficiency disorders

Increased susceptibility to infection is a hallmark of immunodeficiency. Caused by a depressed or absent immune response, the disorder may be classified as primary or secondary. Primary immunodeficiency denotes a defect involving T cells, B cells, or lymphoid tissues such as the thymus. Secondary immunodeficiency results from an underlying disease or factor that depresses or blocks the immune response.

Iatrogenic immunodeficiency may result from drug treatments or from treatments to prevent the body from rejecting a donor organ. (See [Understanding iatrogenic immunodeficiency.](#))

Assessing the immune system

Performing an accurate assessment of the immune system can challenge your skills. Immune disorders may cause vague symptoms, which initially seem related to other body systems.

Patient history

Begin by reviewing the patient's chief complaint. With an immune disorder, he may complain of vague symptoms, such as lack of energy, light-headedness, frequent infections or bruising, and slow wound healing.

Ask about changes in the patient's overall health because the immune system affects all body functions. Has he experienced unexplained rashes, visual disturbances, fever, or changes in elimination patterns? If the patient is a woman, find out if she has noted changes in her menstrual pattern—commonly an early sign of platelet dysfunction.

Ask about the patient's social and work environments to detect exposure to chemicals or pathogens that may affect immune function. Finally, investigate the family history for immune disorders or cancer.

Physical examination

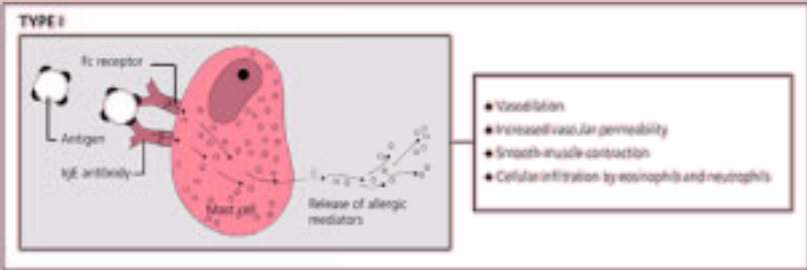

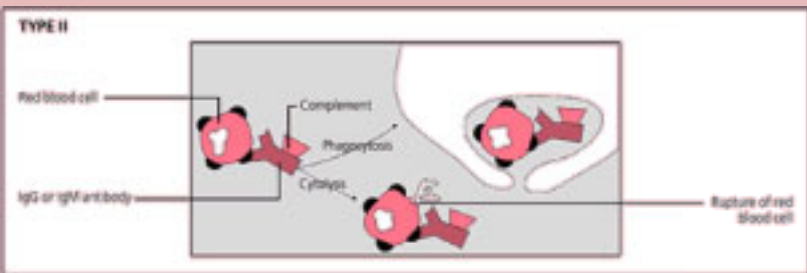

u *Inspection.* Begin by observing the patient's appearance. Does he show signs of acute illness? Does he grimace with pain or seem extremely tired? Does he show signs of chronic illness, such as emaciation or pronounced listlessness? Does he look older than his stated age, possibly from malnutrition related to chronic illness?

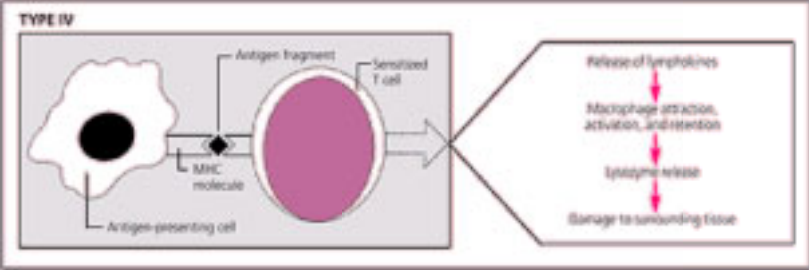

Watch the patient's movements, posture, and gait for signs that may indicate joint, spinal, and neurologic changes caused by an immune disorder. Ob-serve the coordination, balance, range of motion, and strength of the patient. Find out whether the patient has pain when he moves.

Inspect the patient's skin. Note any pallor, cyanosis, or jaundice. Note the character and distribution of any rashes. Does the rash appear red and raised, as in urticaria associated with an allergy? Or is the rash distributed across the nose like the butterfly rash associated with SLE? Does the rash itch? Inspect hair growth, noting texture, distribution, color, and amount. Also inspect nails for color, symmetry, cleanliness, length, and configuration.

Check the nose for pale, boggy turbinates (associated with chronic allergy) or the ulcerated mucous membranes associated with SLE. Look inside the patient's mouth. White patches may indicate candidiasis associated with immunosuppression. Lacy white plaques on the buccal mucosa may be the hairy leukoplakia associated with acquired immunodeficiency syndrome (AIDS).

PATHOPHYSIOLOGY

<div><div>Gell and Coombs classification of hypersensitivity reactions</div></div>			
<div><div><div>TYPE I</div></div></div>			
Reactions	Pathophysiology	Signs and symptoms	Clinical examples
Anaphylactic (immediate, atopic, immunoglobulin [Ig] E—mediated, reagenic)	Binding of antigens to IgE antibodies on mast cell surface releases allergic mediators, causing vasodilation, increased capillary permeability, smooth-muscle contraction, and eosinophilia.	<i>Systemic:</i> angioedema; hypotension; bronchospasm; GI or uterine spasm; stridor <i>Local:</i> urticaria, pruritus	Extrinsic asthma, seasonal allergic rhinitis, systemic anaphylaxis, reactions to stinging insects, some food and drug reactions, some cases of urticaria, infantile eczema

Immune complex disease	Activation of complement by immune complexes causes infiltration of polymorphonuclear leukocytes and release of lysosomal enzymes and permeability factors, producing an inflammatory reaction.	Urticaria, palpable purpura, adenopathy, joint pain, fever, serum sickness—like syndrome	Serum sickness due to serum, drugs, or viral hepatitis antigen; membranous glomerulonephritis; systemic lupus erythematosus; rheumatoid arthritis; polyarteritis; cryoglobulinemia
			
Reactions	Pathophysiology	Signs and symptoms	Clinical examples
Delayed (cell-mediated)	An antigen-presenting cell presents antigen to T cells in association with major histocompatibility complex (MHC). The sensitized T cells release lymphokines, which stimulate macrophages; lysozymes are released; and surrounding tissue is damaged.	Varies with disease; can include fever, erythema, and pruritus	Contact dermatitis, graft-versus-host disease, allograft rejection, granuloma due to intracellular organisms, some drug sensitivities, Hashimoto's thyroiditis, tuberculosis, sarcoidosis

PATHOPHYSIOLOGY

Understanding iatrogenic immunodeficiency

Although immunodeficiency or immunosuppression may occur as a complication of chemotherapy or other treatment, it may be the therapeutic goal itself. For instance, in an autoimmune disorder such as systemic lupus erythematosus (SLE), treatment aims to suppress immune-mediated tissue damage. Immunosuppression is also desirable to prevent a rejection reaction, for example, after organ transplantation.

Iatrogenic immunodeficiency may be induced by drugs, radiation therapy, or surgery.

Drug-induced immunodeficiency

Immunosuppressants include cytotoxic drugs and corticosteroids. Cytotoxic drugs kill immunocompetent cells while they're replicating. Most cytotoxic drugs aren't selective, so they interfere with all rapidly proliferating cells, reducing lymphocytes and phagocytes as well. Besides depleting lymphocyte populations, cytotoxic drugs interfere with lymphocyte synthesis and the release of immunoglobulins and lymphokines.

Cyclophosphamide, a potent and frequently used immunosuppressant, initially depletes B cells, thereby suppressing humoral immunity. Long-term cyclophosphamide therapy also depletes T cells, suppressing cell-mediated immunity as well. Cyclophosphamide may be given for SLE, Wegener's granulomatosis and other systemic vasculitides, and certain autoimmune disorders.

Other cytotoxic drugs used for immunosuppression are *azathioprine* (after kidney transplantation) and *methotrexate* (in rheumatoid arthritis, psoriasis, mycosis fungoides, and cancer).

Corticosteroids can produce potent anti-inflammatory and immunosuppressive effects. As a result, they're widely used to treat immune-mediated disorders. They act to stabilize the vascular membrane and block tissue infiltration by neutrophils and monocytes. This inhibits inflammation. Corticosteroids also “kidnap” T cells in the bone marrow, causing lymphopenia. Because these drugs aren't cytotoxic, lymphocyte concentrations can return to normal levels 24 hours after therapy stops.

Corticosteroids also appear to inhibit immunoglobulin synthesis and to interfere with the binding of immunoglobulin to antigen or to cells with Fc receptors. The most commonly used oral corticosteroid is prednisone. Other corticosteroids used for immunosuppression are *hydrocortisone*, *methylprednisolone*, and *dexamethasone*.

Some immunosuppressants, such as *cyclosporine* and *antithymocyte globulin (ATG)*, selectively suppress the proliferation and development of helper T cells. This results in depressed cell-mediated immunity. Typical uses for cyclosporine include prevention of kidney, liver, and heart transplant rejection. Its use in other disorders is investigational.

ATG has been used effectively to prevent cell-mediated rejection of tissue grafts and transplants.

Radiation-induced immunodeficiency

Because radioactive energy kills proliferating and intermitotic cells, including most lymphocytes, radiation therapy may induce profound lymphopenia, resulting in immunosuppression. Irradiation of all major lymph node areas—a procedure known as total nodal irradiation—is used to treat certain disorders, such as Hodgkin's disease. Its effectiveness in treating severe rheumatoid arthritis and lupus nephritis and in preventing kidney transplant rejection is investigational.

Surgery-induced immunodeficiency

Splenectomy may be performed to manage various disorders, including splenic injury or trauma, tumor, Hodgkin's disease, hairy cell leukemia, Felty's syndrome, Gaucher's disease, idiopathic thrombocytopenic purpura, hereditary spherocytosis and hereditary elliptocytosis, thalassemia major, and chronic lymphocytic leukemia.

Observe the eyes for redness and infection. Do the eyes tear sufficiently, or does the patient complain of burning, dry eyes? Assess the fundus with an ophthalmoscope. Do you see areas that suggest hemorrhage, aneurysm, or infiltration? They may indicate vasculitis.

Evaluate skin integrity. Does the skin appear inflamed or infected? Particularly, check for infection in areas of recent invasive procedures (such as venipunctures).

Inspect the arms, hands, legs, and feet for signs of peripheral vascular insufficiency associated with vasculitis, systemic sclerosis, and SLE. Observe for blanching, cyanosis, pallor, edema, and reddening.

Assess the patient's level of consciousness (LOC) and mental status, noting his behavior, emotional stability, and cognition. Altered blood flow and inflammation of the central nervous system (CNS) may affect LOC. CNS changes may affect patients with SLE or AIDS.

Assess other body systems, as appropriate, to determine immune-related effects:

▫ *Palpation and percussion.* Take the patient's vital signs. Are they within normal limits and stable? Fever, with or without chills, may signal infection. Assess pulse and respiratory rates and depth. Percussion that discloses lobar dullness may point to lung consolidation associated with pneumonia. Measure the patient's blood pressure while he lies down, sits, and stands.

Feel the lymph nodes, noting any enlargement. Begin with the neck area and proceed to other nodes as each related area of the body is examined. Enlarged lymph nodes may indicate inflammation. Tender nodes may indicate acute infection. Generalized lymphadenopathy (involving three or more node groups) can indicate an autoimmune disorder such as SLE, or an infectious or a neoplastic disorder.

Palpate and percuss various organs. Be alert for tenderness associated with enlargement, inflammation, or masses. If findings suggest splenic enlargement, suspect an infection, typical in patients with immunodeficiency.

Assess musculoskeletal integrity and range of motion, particularly in the hands, wrists, and knees. Palpate the joints to detect nodules, swelling, tenderness, and pain. Autoimmune disorders, such as SLE and rheumatoid arthritis, limit range of motion and cause joint enlargement.

▫ *Auscultation.* To detect abnormal breath sounds, auscultate the lungs. Pneumonia associated with immunodeficiency may cause crackles and decreased breath sounds.

Identify heart sounds. Listen for abnormal rate, rhythm, and sounds. Particularly note pericardial friction rub, which occurs in about 50% of SLE patients.

Listen for bowel sounds in all abdominal quadrants. Increased sounds may occur in autoimmune disorders that cause diarrhea. Decreased sounds may occur in disorders that cause constipation. Palpate and assess the abdomen, examining for hepatosplenomegaly and tenderness.

Diagnostic tests

General cellular and humoral studies include such tests as T- and B-cell assays to help diagnose primary and secondary immunodeficiencies and complement assays to help detect immunomediated diseases.

By measuring various proteins in serum or urine, protein electrophoresis helps detect diseases associated with excess or deficient gamma globulin.

Immunoelectrophoresis is used to differentiate monoclonal from polyclonal increases in immunoglobulins; to identify IgA, IgG, and IgM; and to help identify abnormal immunoglobulins and an allergic response.

Immunofixation electrophoresis provides results more rapidly and shows higher resolution of low levels of monoclonal immunoglobulin chains.

A sensitive but nonspecific indicator of inflammatory disorders, the erythrocyte sedimentation rate helps detect rheumatoid arthritis and systemic sclerosis.

Delayed hypersensitivity skin tests, such as patch and scratch allergy tests and intradermal skin tests, help evaluate cell-mediated immunity. Viral, bacterial, and fungal tests help diagnose specific infections such as candidiasis

Another disorder-specific test is the enzyme-linked immunosorbent assay. Test results can show exposure to HIV, rheumatoid factor (to confirm rheumatoid arthritis), and lupus erythematosus cell (to confirm SLE).

C-reactive protein is produced by the liver and excreted with the blood during acute inflammation.

Allergic disorders

Characterized by a harmful reaction to extrinsic materials or allergens, allergic disorders include allergic rhinitis, anaphylaxis, blood transfusion reaction, and urticaria and angioedema.

ALLERGIC RHINITIS

Inhaled, airborne allergens may trigger an immune response in the upper airway in susceptible people. Depending on the allergen, the resulting rhinitis and conjunctivitis may occur seasonally (hay fever) or year-round (perennial allergic rhinitis). The term “hay fever” is a misnomer because hay doesn't cause allergic rhinitis, nor is fever associated with it. Because it affects more than 20 million Americans, allergic rhinitis is the most common atopic allergic reaction. Although the disorder can affect anyone at any age, it's most prevalent in young children and adolescents.

Causes

Seasonal allergic rhinitis (commonly called hay fever) is an immunoglobulin (Ig) E-mediated type I hypersensitivity response to an environmental antigen (allergen) in a genetically susceptible person. It's usually induced by airborne pollens: in spring by tree pollens (oak, elm, maple, alder, birch, cottonwood); in summer by grass and weed pollens (fescue, bluegrass, English plantain, sheep sorrel); and in fall by weed pollens (ragweed). Occasionally, in summer and fall, it's induced by mold spores.

In perennial allergic rhinitis, inhaled allergens provoke antigen responses that produce signs and symptoms year-round. Major perennial allergens and irritants include house dust and dust mites that feed on the dust, feathers (in pillows and quilts), molds, tobacco smoke, processed materials or industrial chemicals, and animal danders. In many patients, the offending allergens can't be identified. Seasonal pollen allergy may exacerbate symptoms of perennial rhinitis.

Complications

Swelling of the turbinates and mucous membranes may trigger secondary sinus and middle ear infections, especially in perennial allergic rhinitis. Nasal polyps, which may result from edema and infection, can increase nasal obstruction.

Assessment findings

In seasonal allergic rhinitis, the patient typically complains of paroxysmal sneezing, profuse watery rhinorrhea, nasal obstruction or congestion, pruritus of the nose and eyes, and headache or sinus pain. Some patients also complain of an itchy throat, malaise, and fever. Inspection may reveal pale, cyanotic, edematous nasal mucosa; red, edematous eyelids and conjunctivae; and excessive lacrimation.

In perennial allergic rhinitis, the patient seldom reports conjunctivitis and other extranasal effects. He commonly complains of chronic and extensive nasal obstruction or stuffiness, which can obstruct the eustachian tube, particularly in children. Inspection may reveal nasal polyps.

In both conditions, dark circles may appear under the patient's eyes (allergic shiners), a result of venous congestion in the maxillary sinuses. The severity of signs and symptoms may vary from year to year.

To distinguish between allergic rhinitis and other disorders of the nasal mucosa, remember these differences:

- u In chronic vasomotor rhinitis, signs and symptoms don't affect the eyes, rhinorrhea is mucoid, and seasonal variation is absent.
- u In infectious rhinitis (the common cold), the nasal mucosa appears beet red; nasal secretions contain polymorphonuclear (not eosinophilic) exudate; and signs and symptoms include fever and pharyngitis.
- u In rhinitis medicamentosa, which results from excessive use of nasal sprays or drops, nasal drainage and mucosal redness and swelling subside when medication is discontinued.

Diagnostic tests

Microscopic examination of sputum and nasal secretions reveals a high number of eosinophils. Blood chemistry studies show normal or elevated IgE levels, possibly linked to seasonal overproduction of interleukin (IL)-4 and IL-5 (involved in the allergic inflammatory process). The patient's history and skin test results (including documented responses to various environmental stimuli) can help pinpoint the responsible allergens.

In children, the differential diagnosis should rule out a foreign body (such as a bean or pea) lodged in the nose.

Treatment

Appropriate therapy controls signs and symptoms by eliminating the environmental antigen, if possible, and by using drug therapy and immunotherapy in allergic rhinitis.

Antihistamines effectively block histamine effects (such as a runny nose and watery eyes) but commonly produce unpleasant effects, such as sedation, dry mouth, nausea, dizziness, blurred vision, and nervousness. Nonsedating antihistamines, such as terfenadine and astemizole, produce fewer annoying effects and are less likely to cause drowsiness. Newer antihistamines, such as cetirizine and loratadine, have proven effective in clinical trials. Fexofenadine, a derivative of terfenadine, may be effective and carries a lower risk of cardiac arrhythmias than terfenadine.

Taken as prescribed, intranasal corticosteroids may reduce local inflammation with minimal systemic adverse effects. Commonly used drugs are flunisolide and beclomethasone. Usually, these drugs aren't effective for acute exacerbations; nasal decongestants and oral antihistamines may be used instead. Cromolyn sodium may help prevent allergic rhinitis but may take up to 4 weeks to produce a satisfactory effect and must be taken regularly during allergy season. Drug therapy for seasonal allergies requires close dosage regulation.

Long-term management includes immunotherapy or desensitization with injections of allergen extracts administered preseasonally, coseasonally, or perennially. Local nasal immunotherapy is being studied as an alternative route of allergen administration.

Nursing diagnoses

- u Altered health maintenance
- u Impaired skin integrity
- u Ineffective airway clearance
- u Ineffective breathing pattern
- u Knowledge deficit
- u Pain
- u Risk for infection
- u Sensory or perceptual alterations (olfactory)

Key outcomes

- u The patient will maintain current health status.
- u The patient and family members will verbalize feelings and concerns.
- u The patient will express feelings of comfort.
- u The patient will perform skin care routine.

Nursing interventions

- u Implement measures to relieve signs and symptoms and increase the patient's comfort.
- u Increase the patient's fluid intake to loosen secretions.
- u Elevate the head of the bed and provide humidification to ease breathing.
- u Monitor the patient's compliance with the prescribed drug regimen. Note changes in control of signs and symptoms as well as indications of drug misuse.
- u Before desensitization injections, assess the patient's symptoms. After giving the injection, observe him for 30 minutes to detect adverse reactions, including anaphylaxis and severe localized erythema. Make sure epinephrine and emergency resuscitation equipment are ready to use.

Patient teaching

- u Instruct the patient to call the doctor if experiencing a delayed reaction to the desensitizing injections.
- u Instruct the patient to reduce environmental exposure to airborne allergens by sleeping with the windows closed; avoiding the countryside during pollination season; using air conditioning, if possible, to filter allergens and minimize humidity and dust; keeping pets outside; and removing dust-collecting items, such as wool blankets, deep-pile carpets, and heavy draperies, from the home.
- u Tell the patient to apply a skin protectant on and below the nose to help prevent excoriation from constant nose blowing.
- u In severe and resistant allergic rhinitis, discuss possible lifestyle changes, such as relocation to a pollen-free area either seasonally or year-round.
- u Review medications, teaching proper dosages, administration, and adverse effects.

ANAPHYLAXIS

Anaphylaxis is a dramatic, acute atopic reaction marked by the sudden onset of rapidly progressive urticaria and respiratory distress. A severe reaction may initiate vascular collapse, leading to systemic shock and, possibly, death.

Causes

Anaphylactic reactions result from systemic exposure to sensitizing drugs or other specific antigens. Such substances may be serums (usually horse serum), vaccines, allergen extracts (such as pollen), enzymes (L-asparaginase), hormones, penicillin and other antibiotics, sulfonamides, local anesthetics, salicylates, polysaccharides (such as iron dextran), diagnostic chemicals (sodium dehydrocholate, radiographic contrast media), foods (legumes, nuts, berries, seafood, egg albumin) and sulfite-containing food additives, insect venom (honeybees, wasps, hornets, yellow jackets, fire ants, and certain spiders) and, rarely, a ruptured hydatid cyst.

The most common anaphylaxis-causing antigen is penicillin. This drug induces a reaction in 1 to 4 of every 10,000 patients treated with it. Penicillin is most likely to induce anaphylaxis after parenteral administration or prolonged therapy.

After initial exposure to an antigen, the immune system responds by producing specific immunoglobulin (Ig) antibodies in the lymph nodes. Helper T cells enhance the process. These antibodies (IgE) then bind to membrane receptors located on mast cells (found throughout connective tissue, often near small blood vessels) and basophils.

When the body reencounters the antigen, the IgE antibodies, or cross-linked IgE receptors, recognize the antigen as foreign. This activates a series of cellular reactions that trigger degranulation—the release of chemical mediators (such as histamine, prostaglandins, and platelet-activating factor) from mast cell stores. IgG or

IgM enters into the reaction and activates the release of complement factors. (See [What happens in anaphylaxis.](#))

Complications

Untreated anaphylaxis can cause respiratory obstruction, systemic vascular collapse, and death minutes to hours after the first symptoms (although a delayed or persistent reaction may occur for up to 24 hours).

PATHOPHYSIOLOGY

What happens in anaphylaxis

An anaphylactic reaction requires previous sensitization or exposure to the specific antigen. The following illustrates the anaphylactic process.

1 Response to the antigen

Immunoglobulin (Ig) M and IgG recognize the antigen as a foreign substance and attach themselves to it.

The antigen destruction process (known as the complement cascade) begins but can't finish either because of insufficient amounts of the protein catalyst A or because the antigen inhibits certain complement enzymes. The patient exhibits no signs or symptoms at this stage.

2 Released chemical mediators

The antigen's continued presence activates IgE (attached to basophils). The activated IgE promotes the release of mediators, including histamine, serotonin, and slow-reacting substance of anaphylaxis (SRS-A).

The sudden release of histamine causes vasodilation and increases capillary permeability. The patient begins to exhibit signs and symptoms, including sudden nasal congestion; itchy, watery eyes; flushing; sweating; weakness; and anxiety.

3 Intensified response

The activated IgE stimulates mast cells located in connective tissue along the venule walls. These mast cells release more histamine (H) and eosinophil chemotactic factor of anaphylaxis (ECF-A). These substances produce disruptive lesions, which weaken the venules.

Itchy red skin, wheals, and swelling appear. Signs and symptoms worsen.

4 Distress

In the lungs, the histamine causes endothelial cells to burst and endothelial tissue to tear away from surrounding tissue. Fluids leak into the alveoli, and SRS-A prevents alveoli from expanding, thereby reducing pulmonary compliance.

Tachypnea, crowing, use of accessory muscles for breathing, and cyanosis signal respiratory distress. Resulting neurologic signs and symptoms include change in level of consciousness, severe anxiety and, possibly, seizures.

Tachypnea, crowing, use of accessory muscles for breathing, and cyanosis signal respiratory distress. Resulting neurologic signs and symptoms include change in level of consciousness, severe anxiety and, possibly, seizures.

5 Deterioration

Meanwhile, basophils and mast cells begin to release prostaglandins and bradykinin, along with histamine and serotonin. These substances increase vascular permeability, causing fluids to leak from the vessels.

Shock; confusion; cool, pale skin; generalized edema; tachycardia; and hypotension signal rapid vascular collapse.

6 Failed compensatory mechanism

Damage to endothelial cells causes basophils and mast cells to release heparin. Eosinophils release arylsulfatase B (to neutralize SRS-A), phospholipase D (to neutralize heparin), and cyclic adenosine monophosphate and the prostaglandins E1 and E2 (to increase the metabolic rate). But this response can't reverse anaphylaxis.

Hemorrhage, disseminated intravascular coagulation, and cardiopulmonary arrest result.

Assessment findings

The patient, a relative, or another responsible person may report the patient's exposure to an antigen. Immediately after exposure, the patient may complain of a feeling of impending doom or fright and exhibit apprehension, restlessness, cyanosis, cool and clammy skin, erythema, edema, tachypnea, weakness, sweating, sneezing, dyspnea, nasal pruritus, and urticaria. He may impress you as being extremely anxious. Keep in mind that the sooner signs and symptoms appear after exposure to the antigen, the more severe the anaphylaxis.

On inspection, the patient's skin may display well-circumscribed, discrete cutaneous wheals with erythematous, raised serpiginous borders and blanched centers. They may coalesce to form giant hives.

Angioedema may cause the patient to complain of a “lump” in his throat, or you may hear hoarseness or stridor. Wheezing, dyspnea, and complaints of chest tightness suggest bronchial obstruction. They are early signs of impending, potentially fatal respiratory failure.

Other effects may follow rapidly. The patient may report GI and genitourinary effects, including severe abdominal cramps, nausea, diarrhea, and urinary urgency and incontinence. Neurologic effects may include dizziness, drowsiness, headache, restlessness, and seizures. Cardiovascular effects include hypotension, shock and, sometimes, angina and cardiac arrhythmias, which, if untreated, can precipitate vascular collapse.

Diagnostic tests

No tests are required to identify anaphylaxis. The patient's history and signs and symptoms establish the diagnosis. If signs and symptoms occur without a known allergic stimulus, other possible causes of shock, such as acute myocardial infarction, status asthmaticus, and heart failure, must be ruled out.

Skin testing may help to identify a specific allergen. Because skin tests can cause serious reactions, a scratch test should be done first in high-risk situations.

Treatment

Always an emergency, anaphylaxis requires an *immediate* injection of epinephrine 1:1,000 aqueous solution, 0.1 to 0.5 ml for mild signs and symptoms. If signs and symptoms are severe, repeat the dose every 5 to 20 minutes, as directed.

In the early stages of anaphylaxis, when the patient remains conscious and normotensive, give epinephrine I.M. or subcutaneously. Speed it into circulation by massaging the injection site. In severe reactions, when the patient is unconscious and hypotensive, give the drug I.V., as ordered.

Establish and maintain a patent airway. Watch for early signs of laryngeal edema (stridor, hoarseness, and dyspnea), which will probably require endotracheal tube

insertion or a tracheotomy and oxygen therapy.

If cardiac arrest occurs, begin cardiopulmonary resuscitation. Assist with ventilation, closed-chest cardiac massage, and sodium bicarbonate administration, as ordered.

Watch for hypotension and shock. As ordered, maintain circulatory volume with volume expanders (plasma, plasma expanders, normal saline solution, and albumin), as needed. As prescribed, administer I.V. vasopressors, norepinephrine, and dopamine to stabilize blood pressure. Monitor blood pressure, central venous pressure, and urine output.

After the initial emergency, administer other medication, such as subcutaneous epinephrine, long-acting epinephrine, corticosteroids, and diphenhydramine I.V., for long-term management and aminophylline I.V. over 10 to 20 minutes for bronchospasm.

ALERT Rapid infusion of aminophylline can cause or aggravate severe hypotension.

Nursing diagnoses

u Altered thought processes u Anxiety u Decreased cardiac output u Fear u Fluid volume deficit u Impaired gas exchange u Impaired skin integrity u Ineffective breathing pattern u Pain u Powerlessness

Key outcomes

- u The patient will maintain a patent airway.
- u The patient's ventilation will remain adequate.
- u The patient's fluid volume will remain within normal range.
- u The patient will express feelings of comfort and decreased pain.
- u The patient's cardiac output will remain within normal range; pulses will remain palpable, and heart rate will remain within normal range.

Nursing interventions

- u Provide supplemental oxygen and observe the patient's response. If hypoxia continues, prepare to help insert an artificial airway.
- u Insert a peripheral I.V. line for administering emergency drugs and volume expanders, as needed.
- u After the initial emergency, administer other medications as ordered: subcutaneous epinephrine, longer-acting epinephrine, corticosteroids, and diphenhydramine I.V. for urticaria and aminophylline I.V. for bronchospasm. (Remember: Rapid infusion of aminophylline may cause or aggravate severe hypotension.)
- u Continually reassure the patient, and explain all tests and treatments to reduce fear and anxiety. If necessary, reorient the patient to the situation and surroundings.
- u If the patient undergoes skin or scratch testing, monitor for signs of a serious allergic response. Keep emergency resuscitation equipment nearby during and after the test.
- u If the patient must receive a drug to which he's allergic, prevent a severe reaction by making sure he receives careful desensitization with gradually increasing doses of the antigen or with advance administration of corticosteroids. A person with a history of allergies should receive a drug with high anaphylactic potential only after cautious pretesting for sensitivity. Closely monitor the patient during testing. Be sure you have resuscitation equipment and epinephrine readily available. When any patient receives a drug with high anaphylactic potential (particularly parenteral drugs), make sure he receives close medical observation.
- u Monitor the patient undergoing diagnostic procedures that use radiographic contrast media, such as excretory urography, cardiac catheterization, and angiography.

Patient teaching

- u After the acute anaphylactic event has been controlled, the patient must be counseled about the risk of delayed symptoms. Any recurrence of shortness of breath, chest tightness, sweating, angioedema, or other symptoms must be reported immediately.
- u Teach the patient to avoid exposure to known allergens. If he has a food or drug allergy, instruct him not to consume the offending food or drug in any of its combinations or forms. If he's allergic to insect stings, he should avoid open fields and wooded areas during the insect season.

HOME CARE

Using an anaphylaxis kit

If the doctor prescribes an anaphylaxis kit for the patient to use in an emergency, explain to the patient that the kit contains everything he needs to treat an allergic reaction:a prefilled syringe containing two doses of epinephrine, alcohol swabs, a tourniquet, and antihistamine tablets.

Instruct the patient to notify the doctor at once if anaphylaxis occurs (or to ask someone else to call him) and to use the anaphylaxis kit as follows.

Getting ready

- Take the prefilled syringe from the kit and remove the needle cap. Hold the syringe with the needle pointing up. Expel air from the syringe by pushing in the plunger until it stops.
- Next, clean about 4" (10 cm) of the skin on your arm or thigh with an alcohol swab. (If you're right-handed, clean your left arm or thigh. If you're left-handed, clean your right arm or thigh.)

Injecting the epinephrine

- Rotate the plunger one-quarter turn to the right so that it's aligned with the slot. Insert the entire needle—like a dart—into the skin.
- Push down on the plunger until it stops. It will inject 0.3 ml of the drug. Withdraw the needle.

Note: The dose and administration for infants and children under age 12 must be directed by a doctor.

Removing the insect's stinger

- Quickly remove the insect's stinger if it's visible. Use a dull object, such as a fingernail or tweezers, to pull it straight out. If the stinger can't be removed quickly, stop trying. Go on to the next step.

Applying the tourniquet

- If you were stung on an arm or a leg, apply a tourniquet between the sting site and your heart. Tighten the tourniquet by pulling the string.
- After 10 minutes, release the tourniquet by pulling on the metal ring.

Taking the antihistamine tablets

- Chew and swallow the antihistamine tablets. (Children age 12 and younger should follow the directions supplied by the doctor or provided in the kit.)

Following up

- Apply ice packs, if available, to the sting site. Avoid exertion, keep warm, and see a doctor or go to an emergency facility.
- Important:* If you don't notice an improvement within 10 minutes, give yourself a second injection by following the directions in the kit. If the syringe has a preset second dose, don't depress the plunger until you're ready to give the second injection. Proceed as before, following the injection instructions.

Special instructions

- Keep the kit handy for emergency treatment at all times.
- Ask the pharmacist for storage guidelines.
- Periodically check the epinephrine in the preloaded syringe. If the solution is pinkish brown, it needs to be replaced.
- Note the kit's expiration date and replace the kit before that date.

- Advise the patient to carry an anaphylaxis kit whenever he's outdoors. Urge him to familiarize himself with the kit and how to use it before the need arises. (See [Using an anaphylaxis kit.](#))
- Tell the patient to wear a medical identification bracelet indicating his allergies.

BLOOD TRANSFUSION REACTION

Mediated by immune or nonimmune factors, a transfusion reaction accompanies or follows I.V. administration of blood components. Its severity varies from mild (fever and chills) to severe (acute renal failure or complete vascular collapse and death), depending on the amount of blood transfused, the type of reaction, and the patient's general health.

Causes and pathophysiology

The immune response to blood can be directed against red blood cells (RBCs), white blood cells, platelets, or one or more immunoglobulin (Ig).

A hemolytic reaction follows the transfusion of mismatched blood. Transfusion with serologically incompatible blood triggers the most serious reaction, marked by intravascular agglutination of RBCs. The recipient's antibodies (IgG or IgM) attach to the donor RBCs, leading to widespread clumping and destruction of the recipient's RBCs.

Understanding the Rh system

The Rh system contains more than 30 antibodies and antigens. Of the world's population, about 85% are Rh-positive, which means that their red blood cells carry the D or Rh antigen. The rest of the population are Rh-negative and don't have this antigen.

Effects of sensitization

When an Rh-negative person receives Rh-positive blood for the first time, he becomes sensitized to the D antigen but shows no immediate reaction to it. If he receives Rh-positive blood a second time, he experiences a massive hemolytic reaction.

For example, an Rh-negative mother who delivers an Rh-positive baby is sensitized by the baby's Rh-positive blood. During her next Rh-positive pregnancy, her sensitized blood will cause a hemolytic reaction in the fetal circulation.

Preventing sensitization

To prevent the formation of antibodies against Rh-positive blood, an Rh-negative mother should receive RhoGAM (Rh _o[D] immune globulin [human]) I.M. within 72 hours after delivering an Rh-positive baby.

Transfusion with Rh-incompatible blood triggers a less serious reaction, known as Rh isoimmunization, within several days to 2 weeks. Rh reactions are most likely to occur in women who are sensitized to RBC antigens by prior pregnancy or unknown factors, such as bacterial or viral infection, and in people who have received more

than five transfusions. (See [Understanding the Rh system.](#))

A febrile nonhemolytic reaction, the most common type of reaction, apparently develops when cytotoxic or agglutinating antibodies in the recipient's plasma attack antigens on transfused lymphocytes, granulocytes, or plasma cells.

Transfused soluble antigens can react with surface IgE molecules on mast cells and basophils, causing degranulation and release of allergic mediators. Antibodies against IgA in an IgA-deficient recipient can also trigger a severe allergic reaction (anaphylaxis).

Complications

Bronchospasm can develop (possibly leading to acute respiratory failure) as well as acute tubular necrosis leading to acute renal failure, anaphylactic shock, vascular collapse, and disseminated intravascular coagulation (DIC).

Assessment findings

The immediate effects of a hemolytic transfusion reaction occur within a few minutes or hours after transfusion begins. The patient complains of chills, nausea, vomiting, chest tightness, and chest and back pain.

Vital signs indicate fever, tachycardia, and hypotension. The patient appears dyspneic and apprehensive. Skin inspection reveals urticaria and angioedema. If bronchospasm occurs, wheezing is detected on auscultation. The patient may also show signs of anaphylaxis, shock, heart failure, and pulmonary edema. In a surgical patient, anesthesia masks these signs, but note blood oozing from mucous membranes or the incision site.

A hemolytic reaction that occurs several weeks after the transfusion can produce fever, an unexpected decrease in serum hemoglobin level, and jaundice.

The patient with an allergic reaction has similar signs and symptoms but no fever. Mild to severe fever is the hallmark of a febrile nonhemolytic reaction that begins at the start of transfusion or within 2 hours after its completion.

Diagnostic tests

Confirmation of a hemolytic transfusion reaction requires proof of blood incompatibility and evidence of hemolysis, such as hemoglobinuria, anti-A or anti-B antibodies in the serum, decreased serum hemoglobin levels, and elevated serum bilirubin levels. A patient who is suspected of having such a reaction should have his blood retyped and crossmatched with the donor's blood.

After a hemolytic transfusion reaction, laboratory tests show increased indirect bilirubin and serum hemoglobin levels, decreased haptoglobin levels, and hemoglobin in urine. As the reaction progresses, test results may be consistent with those of DIC—such as thrombocytopenia, increased prothrombin time, and decreased fibrinogen level—and signs of acute tubular necrosis—such as increased blood urea nitrogen and serum creatinine levels.

Treatment

If a hemolytic reaction occurs, the transfusion should be stopped immediately. Osmotic or loop diuretics can prevent acute tubular necrosis. Other symptomatic treatment includes I.V. vasopressors and normal saline solution to combat shock, epinephrine to treat dyspnea and wheezing, diphenhydramine to combat cellular histamine released from mast cells, corticosteroids to reduce inflammation, and mannitol or furosemide to maintain urinary tract function. Dialysis may also be necessary if acute tubular necrosis occurs.

Treatment for a nonhemolytic febrile reaction calls for antipyretics.

Nursing diagnoses

⌞ Anxiety ⌞ Decreased cardiac output ⌞ Impaired gas exchange ⌞ Impaired tissue integrity ⌞ Pain ⌞ Powerlessness ⌞ Risk for altered body temperature ⌞ Risk for injury

Key outcomes

- ⌞ The patient won't exhibit any arrhythmias.
- ⌞ The patient's skin will remain warm and dry.
- ⌞ The patient won't exhibit signs of active bleeding.
- ⌞ The patient will maintain adequate ventilation.
- ⌞ The patient will express feelings of comfort and relief of pain.

Nursing interventions

- ⌞ Monitor the patient's vital signs every 15 to 30 minutes, watching for signs of shock.
- ⌞ Maintain a patent I.V. line with normal saline solution, and insert an indwelling urinary catheter. Monitor intake and output.
- ⌞ Monitor laboratory results as ordered, and check for signs of complications.
- ⌞ Report early signs of complications.
- ⌞ Cover the patient with blankets to ease chills.
- ⌞ In the surgical or semicomatose patient, deliver supplemental oxygen at a low flow rate through a nasal cannula or handheld resuscitation bag.
- ⌞ Afterward, fully document the transfusion reaction on the patient's chart, noting the duration of the transfusion and the amount of blood absorbed. Provide a complete description of the reaction and any interventions.
- ⌞ To prevent a hemolytic transfusion reaction, first make sure you know your facility's policy about giving blood before administering a transfusion. Then make sure you have the right blood and the right patient. Check and double-check the patient's name, identification number, ABO group, and Rh status. If you find any discrepancy, don't administer the blood. Notify the blood bank immediately and return the unopened unit.

Patient teaching

- ⌞ During the transfusion reaction, explain what is happening. After recovery, tell the patient what kind of transfusion reaction he had and answer his questions.

URTICARIA AND ANGIOEDEMA

Also known as hives, urticaria and angioedema are common allergic reactions. Urticaria is an episodic, rapidly occurring, usually self-limiting skin reaction. It involves only the superficial portion of the dermis, which erupts with local wheals surrounded by an erythematous flare. Angioedema, another dermal eruption, involves additional skin layers (including subcutaneous tissue) and produces deeper, larger wheals (usually on the hands, feet, lips, genitalia, and eyelids). Angioedema causes diffuse swelling of loose subcutaneous tissue and may affect the upper respiratory and GI tracts.

Urticaria and angioedema can occur separately or simultaneously, but angioedema may persist longer. Urticaria and angioedema affect about 20% of the general population at some time. Episodes are more common after adolescence, with the highest incidence in people who are in their 30s. Recurrent acute episodes last less than 6 weeks; if episodes persist longer than 6 weeks, the condition is considered chronic.

Causes and pathophysiology

Urticaria and angioedema may result from allergy to drugs, foods, insect stings and, occasionally, inhalant allergens (animal dander, cosmetics) that provoke an immunoglobulin (Ig) E-mediated response to protein allergens. Certain drugs may cause urticaria without an IgE response. When urticaria and angioedema are part of an anaphylactic reaction, they almost always persist long after the systemic response subsides because circulation to the skin is restored last after an allergic reaction. This slows histamine reabsorption at the reaction site.

Urticaria and angioedema that aren't triggered by an allergen are probably also related to histamine release. External physical stimuli, such as cold (usually in young adults), heat, water, and sunlight, may also provoke urticaria and angioedema. Dermatographism, which develops after stroking or scratching the skin, may affect as much as 20% of the population. Such urticaria develops with varying pressure, most often under tight clothing, and is aggravated by scratching. Angioedema without urticaria occurs with C1 inhibitor deficiency, which can occur as an autosomal dominant characteristic (hereditary angioedema) or be acquired with lymphoproliferative disorders

Several mechanisms and disorders may provoke urticaria and angioedema. They include IgE-induced release of mediators from cutaneous mast cells; binding of IgG or IgM to antigen, resulting in complement activation; and such disorders as localized or secondary infection (respiratory tract infection), neoplastic disease (Hodgkin's disease), connective tissue diseases (systemic lupus erythematosus), collagen vascular disease, and psychogenic disease.

Complications

Skin abrasion and secondary infection can result from scratching. Angioedema that involves the upper respiratory tract can cause life-threatening laryngeal edema. GI involvement can cause severe abdominal colic that can lead to unnecessary surgery.

Assessment findings

The patient's history may reveal the source of the offending substance. Check the drug history, including nonprescription preparations, such as vitamins, aspirin, and antacids.

Investigate frequently troublesome foods, such as strawberries, milk products, and seafood. Environmental allergens may include pets, clothing (wool or down), soap, inhalants (hair sprays), cosmetics, hair dyes, and insect bites or stings. Remember to inquire about exposure to physical factors, such as cold, sunlight, exercise, and trauma (dermatographism).

Skin inspection typically discloses distinct, raised, evanescent dermal wheals surrounded by a reddened flare (urticaria). The lesions vary in size and typically erupt on the extremities, external genitalia, and face, particularly around the eyes and lips. In cholinergic urticaria, the wheals may appear tiny and blanched with an erythematous rim.

Angioedema characteristically produces nonpitted swelling of deep subcutaneous tissue on the eyelids, lips, genitalia, and mucous membranes. Usually, these swellings don't itch but may burn and tingle.

With upper respiratory tract involvement, auscultation may detect respiratory stridor and hoarseness caused by laryngeal obstruction. The patient may appear anxious, gasp for breath, and have difficulty speaking. With GI involvement, he may complain of abdominal colic with or without nausea and vomiting.

Diagnostic tests

The diagnosis can be confirmed through careful skin testing with the suspected offending substance to see if a local wheal and flare result. Diagnosis may also be confirmed by injecting the patient's serum into a skin site of a normal recipient, resulting in a wheal and flare reaction to the antigen (Prausnitz-Küstner reaction). Total IgE elevation or peripheral eosinophilia may be present.

An elimination diet and a food diary documenting foods eaten and times, amounts, and circumstances may help to pinpoint provoking allergens. Or the food diary may suggest other allergies. For instance, a patient allergic to fish may also be allergic to an iodine-based radiographic contrast medium.

Laboratory tests (complete blood count, urinalysis, and erythrocyte sedimentation rate) and chest X-rays may be done to rule out infections.

Recurrent angioedema without urticaria, along with a family history of angioedema, points to hereditary angioedema. Decreased serum levels of C1, C2, and C4 inhibitors confirm the diagnosis.

Treatment

Appropriate treatment prevents or limits the patient's contact with triggering factors. When the triggering stimulus has been removed, urticaria usually subsides in a few days, unless it results from a drug reaction. Then it may persist for as long as the drug remains in the tissues.

Treatment may involve desensitization to the triggering antigen. During desensitization, progressively larger doses of specific antigens (identified by skin testing) are injected intradermally. Diphenhydramine or another antihistamine can ease itching and swelling.

Nursing diagnoses

u Altered body image u Altered oral mucous membrane u Anxiety u Impaired skin integrity u Ineffective breathing pattern u Knowledge deficit u Pain u Powerlessness u Risk for infection

Key outcomes

- u The patient's airway will remain patent.
- u The patient will express feelings of comfort and relief of pain.
- u The patient will exhibit improved or healed lesions or wounds.
- u The patient won't develop complications or they will be minimized.
- u The patient will correlate precipitating factors with appropriate skin care regimen.
- u The patient will voice feelings about changed body image.

Nursing interventions

- u Reduce or minimize environmental exposure to offending allergens and irritants, such as wools and harsh detergents. This may be easier if the offending substance is known. If it isn't, gradually eliminate suspected substances and monitor the patient's condition to document improvement.
- u If food is a suspected cause, gradually eliminate foods from the diet and watch for improvement of signs and symptoms.
- u Inspect the skin for signs of secondary infection caused by scratching.

Patient teaching

- u To help identify the cause of urticaria and angioedema, teach the patient how to keep a diary. Elements to record include exposure to suspected offending substances and signs and symptoms that appear after exposure.
- u If the patient modifies his diet to exclude food allergens, teach him to monitor his nutritional status. Provide him with a list of food replacements for nutrients lost by excluding allergy-provoking foods and beverages.
- u Instruct the patient to keep his fingernails short to avoid abrading the skin when scratching.

u Review signs and symptoms that indicate a skin infection. Explain hygiene measures for managing minor infection, and direct the patient to seek medical attention as needed.

Autoimmune disorders

Autoimmune disorders are marked by an abnormal immune response to oneself. Autoimmunity leads to a sequence of tissue reactions and damage that may produce diffuse, systemic signs and symptoms. Among the autoimmune disorders are ankylosing spondylitis, fibromyalgia syndrome, Goodpasture's syndrome, graft rejection syndrome, juvenile rheumatoid arthritis, lupus erythematosus, polymyalgia rheumatica, polymyositis and dermatomyositis, Reiter's syndrome, rheumatoid arthritis, Sjögren's syndrome, systemic sclerosis, and vasculitis.

ANKYLOSING SPONDYLITIS

Ankylosing spondylitis—also called rheumatoid spondylitis or Marie-Strümpell disease—primarily affects the sacroiliac, apophyseal, and costocervical joints and the adjacent ligamentous or tendinous attachments to bone.

This inflammatory disease progressively restricts spinal movement. It begins in the sacroiliac and gradually progresses to the lumbar, thoracic, and cervical spine. Bone and cartilage deterioration leads to fibrous tissue formation and eventual fusion of the spine or peripheral joints. Symptoms can unpredictably remit, exacerbate, or arrest at any stage. An autoimmune correlation is possible.

Ankylosing spondylitis usually occurs as a primary disorder, but it may also occur secondary to reactive arthritis (Reiter's syndrome), psoriatic arthritis, or inflammatory bowel disease. These disorders, together with primary ankylosing spondylitis, are classified as seronegative spondyloarthropathies.

In primary disease, sacroiliitis is usually bilateral and symmetrical; in secondary disease, it's commonly unilateral and asymmetrical. The patient may also have extra-articular disease, such as acute anterior iritis (in about 25% of patients), proximal root aortitis and heart block, and apical pulmonary fibrosis. Rarely, extra-articular disease appears as caudal adhesive leptomeningitis and immunoglobulin (Ig) A nephropathy.

Ankylosing spondylitis affects men more often than women. Progressive disease is well recognized in men but often overlooked or missed in women, who have more peripheral joint involvement.

Causes

Studies suggest a familial tendency for ankylosing spondylitis; however, the exact cause of the disease is unknown. In more than 90% of patients with this disease, circulating immune complexes and human leukocyte antigen (HLA)-B27 (the histocompatibility antigen) suggest immune system activity.

Complications

Rarely, disease progression can impose severe physical restrictions on activities of daily living and occupational functions. Atlantoaxial subluxation is a rare complication of primary ankylosing spondylitis.

Detecting spondylitis in women

Because ankylosing spondylitis seldom occurs in women, the disorder may be easily overlooked. Typically, if a woman's symptoms include pelvic pain, diagnosticians suspect pelvic inflammatory disease rather than ankylosing spondylitis. That is one reason to carefully assess if your female patient has apparent pelvic inflammatory disease but culture results identify no apparent cause.

In compiling a thorough health and social history, investigate any possible family history of ankylosing spondylitis. Otherwise, misdiagnosis can lead to unwarranted invasive tests and treatments and cause the patient needless anxiety related to contracting a sexually transmitted disease.

Assessment findings

Varying assessment findings depend on the disease stage. The patient may first complain of intermittent low back pain that is most severe in the morning or after inactivity and is relieved by exercise. He may also report mild fatigue, fever, anorexia, and weight loss. If he has symmetrical or asymmetrical peripheral arthritis, he may describe pain in his shoulders, hips, knees, and ankles.

The patient may also complain of pain over the symphysis pubis, which may lead to its mistaken identity as pelvic inflammatory disease. (See [Detecting spondylitis in women](#).)

Observe the patient's movements. Note stiffness or limited motion of the lumbar spine; pain and limited expansion of the chest, resulting from costovertebral and sternomanubrial joint involvement; and limited range of motion, resulting from hip deformity.

Inspect the spine. In advanced disease, expect to see kyphosis (caused by chronic stooping to relieve discomfort). Inspect the eyes for redness and inflammation resulting from iritis.

Palpate affected joints. Note any warmth, swelling, or tenderness. Auscultate the heart and listen for an aortic murmur caused by regurgitation and cardiomegaly. Also auscultate the lungs. When present, upper lobe pulmonary fibrosis, which mimics tuberculosis, may reduce vital capacity to 70% or less of predicted volume.

Diagnostic tests

Diagnosis of primary ankylosing spondylitis requires meeting established criteria. (See [Diagnosing primary ankylosing spondylitis](#).)

Laboratory tests never confirm the diagnosis, but the following findings may support the diagnosis:

- u Serum findings include HLA-B27 in about 95% of patients with primary ankylosing spondylitis and up to 80% of patients with secondary disease. The absence of rheumatoid factor helps to rule out rheumatoid arthritis, which produces similar symptoms.
- u Erythrocyte sedimentation rate and serum alkaline phosphatase and creatine kinase levels may be slightly elevated in active disease.
- u Serum IgA levels may be elevated.
- u X-ray studies define characteristic changes in ankylosing spondylitis. These changes may not appear for up to 3 years after the disease's onset. They include bilateral sacroiliac involvement (the hallmark of the disease); blurring of the joints' bony margins in early disease; patchy sclerosis with superficial bony erosions; eventual squaring of vertebral bodies; and “bamboo spine” with complete ankylosis.

Treatment

Because no treatment reliably stops disease progression, management is used to delay further deformity by stressing the importance of good posture, stretching and deep-breathing exercises and, if appropriate, braces and lightweight supports. Heat, warm showers, baths, ice, and nerve stimulation measures may relieve symptoms in some patients. Nonsteroidal anti-inflammatory drugs, such as aspirin, indomethacin, and sulindac, control pain and inflammation. Phenylbutazone may be used in

severe cases.

Severe hip involvement, which affects about 15% of patients, usually necessitates hip replacement surgery. Severe spinal involvement may require a spinal wedge osteotomy to separate and reposition the vertebrae. This surgery is reserved for selected patients because of possible spinal cord damage and a lengthy convalescence.

Nursing diagnoses

u Activity intolerance u Altered role performance u Body image disturbance u Fatigue u Impaired gas exchange u Impaired physical mobility u Pain u Powerlessness u Risk for injury

Key outcomes

- u The patient will express feelings of comfort and decreased pain.
- u The patient will express feelings of increased energy.
- u The patient will recognize limitations imposed by illness and express feelings about these limitations.
- u The patient will identify factors that increase the potential for injury.
- u The patient will express feelings of comfort in maintaining gas exchange.

Nursing interventions

- u Keep in mind the patient's limited range of motion when planning self-care tasks and activities.
- u Offer support and reassurance.
- u Give analgesics, as ordered.
- u Apply heat locally and massage as indicated. Assess mobility and comfort level frequently.
- u Have the patient perform active range-of-motion exercises to prevent restricted, painful movement.
- u Pace periods of exercise and rest to help the patient achieve comfortable energy levels and oxygenation of lungs.
- u Assess the patient's respiratory status. Breathing may be compromised because of severe kyphosis.
- u If treatment includes surgery, ensure proper body alignment and positioning.
- u Because ankylosing spondylitis is a chronic, progressively crippling condition, you need to involve other caregivers, such as a social worker, visiting nurse, and dietitian.

Patient teaching

- u To minimize deformities, advise the patient to avoid any physical activity that places stress on the back such as lifting heavy objects.
- u Teach the patient to stand upright; to sit upright in a high, straight-backed chair; and to avoid leaning over a desk.
- u Instruct the patient to sleep in a prone position on a hard mattress and to avoid using pillows under the neck or knees.
- u Advise the patient to avoid prolonged walking, standing, sitting, or driving; to perform regular stretching and deep-breathing exercises; and to swim regularly, if possible.
- u Muscle-strengthening exercises can increase muscle flexibility.
- u Instruct the patient to have his height measured every 3 to 4 months to detect kyphosis.
- u Encourage a nutritious diet and weight maintenance.
- u Suggest that the patient seek vocational counseling if work requires standing or prolonged sitting at a desk.

Diagnosing primary ankylosing spondylitis

The following are the diagnostic criteria for primary ankylosing spondylitis. For a reliable diagnosis, the patient must meet the following:

- u criterion 7 and any one of criteria 1 through 5 or
- u any five of criteria 1 through 6 if he doesn't have criterion 7.

Seven criteria

1. Axial skeleton stiffness of at least 3 months' duration relieved by exercise
2. Lumbar pain that persists at rest
3. Thoracic cage pain of at least 3 months' duration that persists at rest
4. Past or current iritis
5. Decreased lumbar range of motion
6. Decreased chest expansion (age-related)
7. Bilateral, symmetrical sacroiliitis demonstrated by radiographic studies

- u Tell the patient to contact the local arthritis agency or the Ankylosing Spondylitis Association for additional information and support.

FIBROMYALGIA SYNDROME

Fibromyalgia syndrome (FMS), previously called fibrositis, is a diffuse pain syndrome and one of the most common causes of chronic musculoskeletal pain. FMS is observed in up to 15% of patients seen in a general rheumatology practice and 5% of general medicine clinic patients. It's characterized by diffuse musculoskeletal pain, daily fatigue, and poor-quality sleep, along with multiple tender points on examination (in specific areas). Women are affected much more often than men, and although FMS may occur at almost any age, the peak incidence is in people ages 20 to 60.

FMS has also been reported in children, who have more diffuse pain and a higher incidence of sleep disturbances than adult patients. They may have fewer tender points and often improve after 2 to 3 years of follow-up.

Causes

The cause of FMS is obscure, but it may be a primary disorder or occur in association with an underlying disease such as systemic lupus erythematosus, rheumatoid arthritis, osteoarthritis, and sleep apnea syndromes.

Many theories regarding the pathophysiology of FMS have been studied over the years. The pain is located mainly in muscle areas, but no distinct abnormalities have been documented on microscopic evaluation of biopsies of tender points when compared with normal muscle. One theory suggests that blood flow to the muscle is decreased (due to poor muscle aerobic conditioning, rather than other physiologic abnormalities); another suggests that blood flow in the thalamus and caudate nucleus is decreased, leading to a lowered pain threshold. Still other theories suggest that the cause lies in endocrine dysfunction, such as abnormal pituitary-adrenal axis responses, or in abnormal levels of the neurotransmitter serotonin in brain centers, which affect pain and sleep. Abnormal functioning of other pain-processing pathways may also be involved.

Considerable overlap of symptoms with other pain syndromes, such as chronic fatigue syndrome, raises the question of an association with infection such as

parvovirus B19 and others.

The development of FMS may be multifactorial and influenced by stress (physical and mental), physical conditioning, poor-quality sleep, neuroendocrine factors, psychiatric factors and, possibly, hormonal factors (due to the predominance in women).

Assessment findings

The primary symptom of FMS is diffuse, dull, aching pain that is typically concentrated across the neck and shoulders and in the lower back and proximal limbs. It can involve all body quadrants (bilateral upper trunk and arms, and bilateral lower trunk and legs) and typically is worse in the morning, when it's associated with stiffness. The pain can vary from day to day and be exacerbated by stress, lack of sleep, weather changes, and inactivity.

Sleep disturbance in FMS is another suggested factor in the development of symptoms. Many patients with this syndrome describe a habit of being a light sleeper, with frequent arousal and fragmented sleep (possibly secondary to pain in patients with underlying illnesses such as osteoarthritis and rheumatoid arthritis). Many other patients awaken frequently throughout the night but are unaware of the arousals. The patient awakens feeling fatigued and remains so throughout the day, hence the term nonrestorative sleep. Fatigue is commonly present from a half-hour to several hours after rising in the morning and can last for the rest of the day.

Other associated features that can occur with FMS include irritable bowel syndrome, tension headaches, puffy hands (sensation of hand swelling, especially in the morning), and paresthesia.

ASSESSMENT TIP FMS shouldn't be confused with chronic myofascial pain, which is characterized by:

- unilateral, typically focal or regional pain (as opposed to the bilateral and diffuse pain of FMS)
- minimal fatigue or stiffness and few focal tender points, often distinguished as trigger points that may cause a radiating pain along a muscle group or tendon (unlike FMS tender points, which usually aren't associated with radiating pain).

The symptoms of myofascial pain are usually temporary but can recur and are treated with local measures, such as stretching, physical therapy, heat, and local trigger point injections.

Diagnostic tests

Diagnostic testing in FMS that isn't associated with an underlying disease is generally negative for significant abnormalities. Examination of joints doesn't reveal synovitis or significant swelling, the neurologic examination is normal, and no laboratory or radiologic abnormalities are common to FMS patients.

Tender points are elicited by applying a moderate amount of pressure to a specific location. This examination can be fairly subjective, but many FMS patients with true tender points wince or withdraw when pressure is applied to an appropriate intensity. Nontender control points, such as midforehead, distal forearm, and midanterior thigh, can also be tested to assess for conversion reactions (psychogenic rheumatism), in which patients hurt everywhere or exhibit other psychosomatic illnesses. (See [Tender points of fibromyalgia.](#))

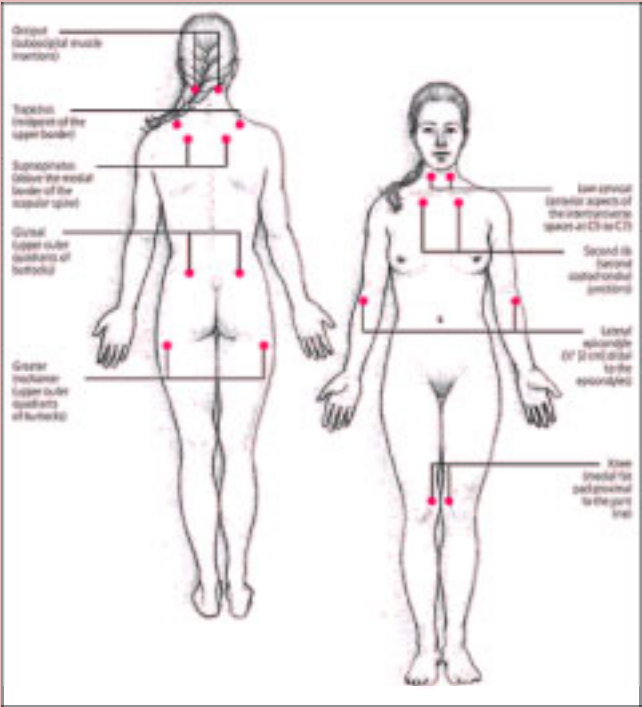

Overall, the diagnosis of FMS is made clinically in a patient with characteristic symptoms, multiple tender points on examination, and exclusion of other illnesses that can cause similar features. A workup for arthritis, primary sleep disorders, endocrinopathies (such as hypothyroidism), infections (such as Lyme disease and human immunodeficiency virus infection), and psychiatric illness (such as major depression) should be considered.

Treatment

The most important aspect in FMS management is patient education. Patients must understand that although FMS pain can be severe and is often chronic, the syndrome is common and does *not* lead to deforming or life-threatening complications.

Tender points of fibromyalgia

The patient with fibromyalgia may complain of specific areas of tenderness. These areas are indicated in the the illustrations below.

A regular, low-impact aerobic exercise program can be effective in improving muscle conditioning, energy levels, and the patient's overall sense of well-being. The FMS patient should be taught preexercise and postexercise stretching to minimize injury and should begin a program, such as walking, bicycling, or swimming, at a low intensity with slow, gradual increase as tolerated.

A physical therapist may assist in the management of FMS through the use of education, injection of tender points, massage therapy, and ultrasound treatments for particularly problematic areas. In a few studies, acupuncture and phototherapy have been somewhat beneficial.

Medications are typically used to improve sleep and control pain. A bedtime dose of amitriptyline, nortriptyline, or cyclobenzaprine may be useful to improve sleep, but tricyclic antidepressants can be associated with anticholinergic adverse effects and daytime drowsiness. Hypnotic agents, such as many benzodiazepines, are less useful because they generally don't prevent frequent awakening through the night. The combination of a tricyclic antidepressant at bedtime and a daytime dose of a serotonin uptake inhibitor, such as fluoxetine, may be useful.

Nonsteroidal anti-inflammatory drugs (NSAIDs) and corticosteroids are typically not effective against FMS pain, although NSAIDs may be used for coexisting tendinitis or arthritis. Narcotics to control the chronic pain of FMS should be used only with extreme caution, preferably under the guidance of a pain clinic.

Nursing diagnoses

▫ Activity intolerance ▫ Altered health maintenance ▫ Altered role performance ▫ Energy field disturbance ▫ Fatigue ▫ Hopelessness ▫ Impaired physical mobility ▫ Pain ▫

Powerlessness u Risk for infection

Key outcomes

- u The patient will express feelings of comfort and decreased pain.
- u The patient will attain the highest degree of mobility possible within the confines of disease.
- u The patient will state her feelings about limitations.
- u The patient will continue to receive treatments that help to relax her and promote inner well-being.
- u The patient will express an increased sense of well-being.

Nursing interventions

- u Monitor the patient's sensory disturbances and level of pain. Administer medications such as analgesics as ordered, and watch for adverse reactions.
- u Provide emotional support. Remember that the patient can easily become depressed, discouraged, and irritable. Encourage discussion of her fears concerning dependency, disability, sexuality, body image, and self-esteem. Refer her to appropriate counseling as needed.
- u Joints that aren't put through a regular range of motion (because of stiffness or pain) can “freeze” because of tendon and ligament shortening or adhesive capsulitis. A daily stretching program can help to preserve range of motion in the neck, shoulders, and hips. Teach the patient how to do these stretches safely and effectively, and encourage her to perform them regularly.

ALERT The combination of oral corticosteroids and an NSAID can put a patient at increased risk for peptic ulcer disease. For patients who require the steroids for treatment and don't tolerate the discontinuation of their regular NSAID (for underlying arthritis, for example), the addition of a GI protective agent, such as misoprostol, should be considered.

- u Reassurance and social support are extremely important. The FMS patient commonly goes through extensive diagnostic workups and multiple consultations with no significant abnormal findings. The patient may think that no one believes that the pain is present and that it's “all in her head.” Reassure the patient that FMS is common and, although chronic, can be treated.

Patient teaching

- u Exercise (low-impact, aerobic) can be helpful in maintaining muscle conditioning (which may reduce pain), improving energy and, possibly, improving sleep quality.
- u The deconditioned FMS patient may experience increased muscle pain with the initiation of a new exercise program. Reassure her that this may occur, and if it does, she may reduce the duration or intensity of her exercise.
- u Encourage the patient not to stop exercising altogether (unless specifically told to do so) because even a limited amount of exercise each day may be beneficial.
- u A bedtime dose of a tricyclic antidepressant can cause morning drowsiness in some patients. Sometimes taking the dose 1 to 2 hours before bedtime can improve sleep benefits while reducing this morning-after effect.

GOODPASTURE'S SYNDROME

In Goodpasture's syndrome, hemoptysis and rapidly progressive glomerulonephritis result from the deposition of antibodies against alveolar and glomerular basement membranes (GBM). This disorder can occur at any age but most commonly strikes men between ages 20 and 30. The prognosis improves with aggressive immunosuppressant and antibiotic therapy and with dialysis or kidney transplantation.

Causes and pathophysiology

The cause of Goodpasture's syndrome is unknown. Although some cases have been associated with exposure to hydrocarbons or with type II hypersensitivity reaction, many patients have no precipitating events. The high incidence of human leukocyte antigen DR2 in patients with this disorder suggests a genetic predisposition.

Abnormal production and deposition of antibodies against GBM and alveolar basement membrane activate the complement and inflammatory responses, resulting in glomerular and alveolar tissue damage.

Complications

Renal failure, requiring dialysis or transplantation, and severe pulmonary complications, such as pulmonary edema and hemorrhage, can occur.

Assessment findings

Initially, the patient with Goodpasture's syndrome may complain of malaise, fatigue, and pallor—signs and symptoms associated with severe iron deficiency anemia.

Your assessment may reveal hematuria and signs of peripheral edema associated with renal involvement and decreased urine output. You may also note signs of pulmonary involvement, such as dyspnea, tachypnea, labored breathing, orthopnea, decreased vital capacity, restlessness, and hemoptysis, ranging from a cough with blood-tinged sputum to frank pulmonary hemorrhage. The patient may have had subclinical pulmonary bleeding for months or years before developing overt hemorrhage and signs of renal disease.

Diagnostic tests

Measurement of circulating anti-GBM antibodies by radioimmunoassay as well as linear staining of GBM and alveolar basement membrane by immunofluorescence confirm the diagnosis.

- u Immunofluorescence of alveolar basement membrane shows linear deposition of immunoglobulins as well as C3 and fibrinogen. Immunofluorescence of GBM also shows linear deposition of immunoglobulins. This finding, along with circulating anti-GBM antibodies, distinguishes Goodpasture's from other pulmonary-renal syndromes, such as Wegener's granulomatosis, polyarteritis, and systemic lupus erythematosus.

Lung biopsy shows interstitial and intra-alveolar hemorrhage with hemosiderin-laden macrophages. Chest X-rays reveal pulmonary infiltrates in a diffuse, nodular pattern, and renal biopsy usually shows focal necrotic lesions and cellular crescents.

Serum creatinine and blood urea nitrogen (BUN) levels typically increase to two to three times normal. Urinalysis may reveal red blood cells and cellular casts, which typify glomerular inflammation. Tests may also show granular casts and proteinuria.

Treatment

Plasmapheresis can be used to remove antibodies, and immunosuppressants can be prescribed to suppress antibody production. Patients with renal failure can benefit from dialysis or kidney transplantation. Aggressive ultrafiltration helps to relieve pulmonary edema that may aggravate pulmonary hemorrhage. High-dose I.V. corticosteroids also help to control pulmonary hemorrhage.

Nursing diagnoses

- u Activity intolerance
- u Altered oral mucous membrane
- u Altered urinary elimination
- u Anxiety
- u Fatigue
- u Fear
- u Fluid volume excess
- u Impaired gas exchange
- u Ineffective airway clearance
- u Ineffective breathing pattern
- u Pain
- u Risk for injury

Key outcomes

- u The patient will maintain a patent airway.
- u The patient's ventilation will remain adequate.
- u The patient will maintain fluid balance within range; intake will equal output.
- u The patient will express feelings of increased energy.
- u The patient's mucous membranes will remain intact.
- u The patient won't develop complications.

Nursing interventions

- u Elevate the head of the bed and administer humidified oxygen to promote adequate oxygenation. Assess respiratory rate and breath sounds regularly, and note the quantity and quality of the patient's sputum.
- u Encourage the patient to conserve his energy. If he's bedridden, provide range-of-motion exercises. Assist with activities of daily living, and provide frequent rest periods.
- u Monitor the patient's vital signs, arterial blood gas levels, hematocrit, and coagulation studies.
- u Monitor the patient's daily intake and output, daily weight, creatinine clearance, and BUN and serum creatinine levels, and observe his signs and symptoms to determine the status of his renal function.
- u Transfuse blood and administer corticosteroids, as ordered. Watch the patient closely for signs of a transfusion reaction or an adverse reaction to the corticosteroids.

Patient teaching

- u Teach the patient and family members about the disease process.
- u Stress the importance of conserving energy, especially if the patient develops iron deficiency anemia.
- u Teach the patient to follow an appropriate diet, usually a low-protein, low-sodium diet if renal disease is significant. Explain that his fluid intake may also be restricted. Stress the importance of complying with these measures to prevent further deterioration of renal tissue.
- u Review the name, dosage, purpose, and adverse effects of all medications.
- u Teach the patient how to effectively deep-breathe and cough.
- u Encourage the patient to obtain regular follow-up care.
- u If the patient has a sore, dry mouth, advise him to suck on sugarless hard candy.
- u Teach the patient and his family how to recognize the signs of respiratory or genitourinary bleeding. Tell them to report such signs to the doctor at once.
- u If the patient requires dialysis or kidney transplantation, refer him to a renal support group.

GRAFT REJECTION SYNDROME

As the clinical practice of solid organ transplantation evolves in sophistication and frequency, the focus on the mechanisms and treatment of graft rejection grows.

Tissues commonly transplanted may include the kidney, liver, heart, lung, and cornea. Bone marrow transplantation represents a unique setting, in that the host's immune system is markedly suppressed and an immune-mediated response can occur when the transplanted bone marrow contains cells that react against host antigens (called graft-versus-host disease). The incidence of graft rejection has declined significantly with the improvement in compatibility screening techniques and immunosuppressive regimens.

Causes and pathophysiology

The donated organ, called an allograft if the donor and recipient are unrelated, is transplanted into the recipient, call the host. Rejection can occur when the host's immune responses are directed against the graft. The rapidity and reversibility of rejection depends on the variety of mechanisms that can be involved, such as peritransplant ischemia and mechanical trauma, antibody interactions with graft antigens, alloantigen-reactive T cells, and abnormal tissue remodeling.

Graft rejection syndromes include three subtypes based on the time of onset and mechanisms involved: hyperacute rejection, acute rejection, and chronic rejection.

Hyperacute rejection

Hyperacute rejection occurs within minutes to hours after graft transplantation. It is rare and affects less than 1% of transplant recipients because of improved pretransplantation screenings. This response occurs when preformed circulating host antibodies recognize and bind to graft antigens (such as ABO blood group proteins and major histocompatibility complex proteins). Binding of these antibodies leads to initiation of the complement cascade, recruitment of neutrophils, platelet activation, damage to graft endothelial cells, and stimulation of coagulation reactions. This leads to rapid thrombosis, loss of vascular integrity, tissue infarction, and loss of graft function.

Acute rejection

Acute rejection occurs in 50% of transplant patients (with only 10% progressing to graft loss). Acute rejection may occur several hours to days (even weeks) after transplantation. Graft loss has been reduced because of new antirejection therapies.

Acute rejection occurs when alloantigen-reactive T cells from the host infiltrate the graft and are activated by contact with foreign, graft-related proteins that are presented to them by antigen-presenting cells. These T cells may lead to graft tissue damage, either by direct killing of graft cells (cytolytic T cells) or by production by pro-inflammatory cytokines, such as tumor necrosis factor, interleukin-1, and interferon. These cytokines are vasoactive and perpetuate inflammatory cell recruitment and infiltration. As a result, graft inflammation progresses, leading to tissue distortion, vascular insufficiency, and cell destruction, all of which can eventually compromise graft function.

The incidence of acute rejection has decreased significantly with the successful use of immunosuppressant agents, such as cyclosporine and azathioprine.

Chronic rejection

Chronic rejection occurs in 50% of transplant patients within 10 years after the transplantation. This form of rejection is characterized by the development of blood vessel luminal occlusion due to progressive thickening of the intimal layers of medium and large arterial walls.

Chronic rejection represents a pathologic tissue remodeling response that develops at a variable rate after graft endothelial cells are traumatized by mechanical, ischemic, and immunologic injury during and after transplantation. These damaged vascular endothelial cells produce cytokines and tissue growth factors that initiate vascular repair, causing underlying smooth-muscle cells to begin proliferating. Large amounts of intimal matrix are produced, leading to increasingly occlusive vessel wall thickening. A slowly progressing reduction in blood flow results in regional tissue ischemia, cell death, and tissue fibrosis.

Assessment findings

The signs and symptoms of graft rejection vary markedly, depending on the type of rejection, underlying illnesses, and type of organ transplanted. Most commonly, the evidence of a rejection process is a rapid or gradual progression of organ dysfunction, such as oliguria and increasing serum creatinine and blood urea nitrogen levels in the kidney; elevated transaminase levels, decreased albumin levels, and hypocoagulability in the liver; and hypotension, heart failure, and edema in the heart. Differentiation of the subtype of rejection is usually based on the timing of the response.

Diagnostic tests

Confirmation of a graft rejection can be made with a biopsy of the transplanted tissue.

Graft tissue undergoing hyperacute rejection is characterized by large numbers of polymorphonuclear leukocytes in the graft blood vessels, widespread microthrombi, platelet accumulation, and interstitial hemorrhage. There is little or no interstitial inflammation.

Acutely rejected tissue displays focal regions of perivascular infiltration by leukocytes (which become more widespread as the process progresses). Eventually, tissue distortion and cellular necrosis and debris are seen.

With chronic rejection, graft vessels display markedly thickened walls, which may be occluded. Diffuse interstitial fibrosis is prominent. Leukocyte infiltration is usually mild or absent.

Treatment

Management of the transplant patient involves postoperative care after transplantation, close monitoring of the function of the grafted organ, immunosuppressive therapy to prevent and control acute rejection, and surveillance with prophylactic measures against opportunistic infections.

The primary method for managing hyperacute rejection is prevention. Avoiding high-risk donor-recipient combinations and thorough pretransplant screening for cross-reactive antibodies are important. When a hyperacute rejection reaction is initiated, no pharmacologic agents can halt it. Management then becomes supportive until another donor organ can be found.

With acute rejection, immunosuppressants, usually given in combination regimens, can be effective. Commonly used agents include corticosteroids, cyclosporine, tacrolimus (FK 506), and azathioprine. Antirejection therapies such as OKT3, an immunosuppressive monoclonal antibody directed at the CD3 molecule on T cells, are promising.

There is no accepted therapeutic strategy for the treatment of chronic rejection. Preventive strategies to minimize peritransplant ischemia and reperfusion injury are under investigation and include such measures as the use of pulsatile graft perfusion devices during transport and peritransplant graft treatments to minimize the release of mediators in response to vascular trauma

Because graft rejection can be compounded by coexisting opportunistic infections, prophylaxis and early antibiotic or antiviral interventions are indicated.

Nursing diagnoses

- u Activity intolerance
- u Altered family processes
- u Altered health maintenance
- u Altered nutrition: Less than body requirements
- u Altered oral mucous membrane
- u Altered protection
- u Body image disturbance
- u Fatigue
- u Hopelessness
- u Hyperthermia
- u Impaired skin integrity
- u Impaired tissue integrity
- u Ineffective individual coping
- u Powerlessness
- u Risk for fluid volume deficit
- u Risk for infection
- u Social isolation

Key outcomes

- u The patient won't experience fever, chills, and other signs and symptoms of illness.
- u The patient will demonstrate the use of protective measures, including conserving energy, maintaining a balanced diet, and getting plenty of rest.
- u The patient will use support systems to assist with coping.
- u The patient will voice feelings about the condition.
- u The patient will perform health maintenance activities according to the level of his ability.
- u The patient won't develop complications of illness.
- u The patient will comply with the treatment regimen.

Nursing interventions

- u Pretransplant screening is a comprehensive evaluation that is best performed as a multidisciplinary approach. Information regarding the patient's history and physical status, underlying medical illnesses, psychiatric health, social and financial support, compliance, and lifestyle can all indicate areas in which counseling and intervention may be useful to the patient and family members before transplantation.
- u Recognize that organ transplantation may be undertaken in case of multiple treatment failures for the patient's underlying disease. Graft rejection, therefore, can be associated with a significant psychological as well as physical impact. The patient and his family may need extensive social support.

Patient teaching

- u Instruct the patient how to recognize signs and symptoms of organ dysfunction.
- u Advise the patient to immediately report fever, chills, and other symptoms of infection.
- u Medication compliance is vital to successful immunosuppressive therapy for prevention of acute graft rejection. Make sure that the patient understands that this compliance may be long-term, if not lifelong.

JUVENILE RHEUMATOID ARTHRITIS

Juvenile rheumatoid arthritis (JRA) affects children under age 16 and consists of several conditions characterized by chronic synovitis and joint swelling, pain, and tenderness. The disease can also produce extra-articular signs and symptoms that involve the skin, heart, lungs, liver, spleen, and eyes. Major types of JRA include *systemic* (Still's disease or acute febrile type), *polyarticular*, and *pauciarticular*. (See [Types of juvenile rheumatoid arthritis.](#))

Depending on the type, JRA may occur as early as age 6 weeks but seldom before age 6 months; peak onset is between ages 1 and 3 and 8 and 12. JRA is the major chronic rheumatic disorder of childhood and occurs in an estimated 150,000 to 250,000 children in the United States, affecting twice as many girls as boys.

Causes

Researchers continue to probe for the causes of JRA. Various findings suggest links to genetic factors or to an abnormal immune response. Viral or bacterial (particularly streptococcal) infection, trauma, and emotional stress may be precipitating factors, but their exact relation to the disease remains unclear.

Complications

JRA may involve structures besides the joints, including the skin, heart, lungs, liver, spleen, lymph nodes, and eyes. Chronic iridocyclitis (insidious inflammation of the iris and ciliary body) may lead to such complications as ocular damage and loss of vision. It often occurs without obvious early signs and symptoms. Growth disturbances, such as overgrowth or undergrowth of such structures as bone and tissue that are adjacent to inflamed joints, are also complications of JRA.

Assessment findings

Almost all patients complain of joint stiffness in the morning or after periods of inactivity. Young children with JRA are typically irritable and listless. Other signs and symptoms vary with the type of JRA.

With *systemic JRA*, the child may experience mild, transient arthritis or frank polyarthritis associated with fever and rash. Joint involvement may not be evident at first, but the child's behavior may clearly suggest joint pain and fatigue. For example, she may favor sitting in a flexed position. She may walk very little or refuse to walk at all.

Types of juvenile rheumatoid arthritis
Signs and symptoms of juvenile rheumatoid arthritis (JRA) vary according to type. The types include systemic, polyarticular, and pauciarticular JRA.
Systemic JRA <ul style="list-style-type: none">Accounts for 20% to 30% of JRA casesCan affect any joint and either sexCauses a “sawtooth” fever pattern—an intermittent fever that begins suddenly, spikes to 103° F (39.4° C) or more once or twice daily (usually in late afternoon), and rapidly returns to normal or subnormalCan't be easily detected by laboratory tests because serum findings are negative for rheumatoid factor (RF) and antinuclear antibodies (ANAs)Develops into severe arthritis in about 20% of patients
Polyarticular JRA <p>This type of arthritis may be mild (RF-negative) or severe (RF-positive).</p> <p><i>RF-negative polyarticular JRA</i></p> <ul style="list-style-type: none">Affects girls four to nine times more often than boysInvolves five or more jointsUsually develops insidiouslyMostly affects the wrists, elbows, knees, ankles, and small joints of the hands and feet but can also affect larger joints, including the temporomandibular and those of the cervical spine, hips, and shouldersResults in negative findings for RF; however, in about 25% of patients, test findings disclose ANAsDevelops into severe arthritis in about 10% of patients <p><i>RF-positive polyarticular JRA</i></p> <ul style="list-style-type: none">Affects girls six times more often than boysUsually occurs late in childhoodCan affect any jointIs marked by positive RF findings in serum tests; in about 75% of patients, test findings disclose ANAsMimics adult rheumatoid arthritis in about 50% of patients who have severe, destructive disease <p>Pauciarticular JRA</p> <ul style="list-style-type: none">Subtypes: pauciarticular JRA with iridocyclitis, pauciarticular JRA with sacroiliitis, and JRA without iritisInvolves four or fewer jointsCauses stiffness of joints in the morning or after periods of inactivityPossibly causes growth disturbances (overgrowth or undergrowth of bone and other tissues adjacent to inflamed joints) <p><i>Pauciarticular JRA with iridocyclitis</i></p> <ul style="list-style-type: none">Accounts for about 45% of pauciarticular JRA casesStrikes girls under age 6 about seven times more often than boysAffects mostly knee, elbow, and ankle joints as well as the irisInvolves chronic iridocyclitis in about 40% of patientsDevelops into polyarthritis in about 20% of patientsIs marked by RF-negative findings in serum tests; about 60% of patients have positive ANA test findings <p><i>Pauciarticular JRA with sacroiliitis</i></p> <ul style="list-style-type: none">Strikes boys over age 8 nine times more often than girlsIs marked by positive HLA-B27 findings in serum testsInvolves the hips, sacroiliac, heels, and feetTest findings negative for RF and ANAsMay develop into the sacrolumbar arthritis characteristic of ankylosing spondylitisMay occur with acute iritis <p><i>JRA without iritis</i></p> <ul style="list-style-type: none">Includes patients with joint involvement who test negative for ANA and HLA-B27 and don't develop iritisCharacterized by asymmetrical involvement of large and small jointsStrikes at any age during childhoodBetter prognosis than first and second typesMay progress to polyarticular disease

An intermittent, spiking (sawtooth) fever is common. (In fact, this sign helps to differentiate the disease from other inflammatory disorders.) When fever spikes, inspect the skin for a characteristic evanescent rheumatoid rash. Small, pale or salmon-pink macules most commonly appear on the trunk and proximal extremities and, occasionally, on the face, palms, and soles. Massaging or applying heat intensifies the rash, which usually is most conspicuous in areas subjected to rubbing or pressure (for example, from underclothing).

The child may complain of painful breathing (if she has pleuritis with systemic JRA) and nonspecific abdominal pain.

If the child has myocarditis, you may note fatigue, shortness of breath, palpitations, and fever. Assessment may also disclose resting or exertional tachycardia, arrhythmias, neck vein distention, increased amplitude of S₁ and S₂ or the presence of S₄ gallops, and systolic ejection murmurs—all suggesting heart failure.

Palpation and percussion may reveal hepatic, splenic, and lymph node enlargement. Auscultation findings may include a friction rub associated with pericarditis.

With *polyarticular JRA*, the child may complain mostly of pain in the wrists, elbows, knees, ankles, and small joints of the hands and feet. She may also complain of

pain in larger joints, including the temporomandibular and those of the cervical spine, hips, and shoulders.

On inspection, you may notice joint swelling. Tenderness and stiffness are also typical. Usually, the arthritis occurs symmetrically. It may be remittent or indolent. The child may have a low-grade fever with daily peaks. Parents may report weight loss in the child and describe her as being listless. You may also observe noticeable developmental retardation.

Palpation and percussion may disclose hepatic, splenic, and lymph node enlargement. You may also find subcutaneous nodules on the elbows or heels.

With *pauciarticular* JRA, the child typically complains of pain in the hips, knees, heels, feet, ankles, and elbows. With inflammation of the iris and ciliary body, she may complain of pain, redness, blurred vision, and photophobia. With sacroiliitis, she typically reports lower back pain.

Diagnostic tests

Complete blood count usually shows decreased serum hemoglobin levels and increased neutrophil (neutrophilia) and platelet (thrombocytosis) levels. Other blood test findings include an elevated erythrocyte sedimentation rate and elevated C-reactive protein, serum haptoglobin, immunoglobulin, and C3 complement levels.

Antinuclear antibody test results may be positive in patients with polyarticular JRA and in those with pauciarticular JRA with chronic iridocyclitis.

Rheumatoid factor (RF) appears in about 15% of patients with JRA. In contrast, about 85% of patients with rheumatoid arthritis test positive for RF. Patients with polyarticular JRA may test positive for RF.

The presence of human leukocyte antigen (HLA)-B27 in blood tests may forecast later development of ankylosing spondylitis.

X-ray studies demonstrate early structural changes associated with JRA. These include soft-tissue swelling, effusion, and periostitis in affected joints. Later evidence includes osteoporosis and accelerated bone growth followed by subchondral erosions, joint space narrowing, bone destruction, and fusion.

Treatment

Successful JRA management usually calls for antiinflammatory drugs, physical therapy, carefully planned nutrition and exercise, and regular ophthalmologic examinations. Both the child and the parents must be involved in therapy.

Aspirin is the initial drug of choice. Dosage is based on the child's weight. Additional nonsteroidal anti-inflammatory drugs (NSAIDs) may be used. If they prove ineffective, gold salts, hydroxychloroquine, and penicillamine can be tried. Because of adverse effects, corticosteroids are reserved for treating systemic disorders (such as pericarditis and iritis) that resist treatment with NSAIDs. Corticosteroids and mydriatic drugs are commonly prescribed for iridocyclitis. Investigational drug therapy includes low-dose cytotoxic agents, such as methotrexate.

Physical therapy promotes regular exercise to maintain joint mobility and muscle strength, thereby preventing contractures, deformity, and disability. Good posture, gait training, and joint protection are also beneficial. Splints help reduce pain, prevent contractures, and maintain correct joint alignment. Applying heat during passive exercises (for example, by whirlpool, paraffin, or hot packs) is beneficial.

Surgery is usually limited to soft-tissue releases to improve mobility. Joint replacement is delayed until the child matures physically and can tolerate vigorous rehabilitation.

Nursing diagnoses

u Activity intolerance u Altered growth and development u Altered role performance u Fatigue u Impaired physical mobility u Ineffective family coping u Ineffective individual coping u Pain u Powerlessness u Risk for injury u Self-care deficit

Key outcomes

u The patient will express feelings of comfort and decreased pain.
u The patient will demonstrate age-appropriate skills and behaviors as much as possible.
u The patient will express feelings of increased energy.
u The patient will recognize limitations imposed by illness and express feelings about these limitations.
u The patient will identify factors that increase the potential for injury.
u The patient will attain the highest degree of mobility possible within the confines of the disease.

Nursing interventions

u Focus nursing care on reducing the patient's pain and promoting mobility.
u During inflammatory exacerbations, be sure to administer NSAIDs or prescribed medication on a regular schedule. The patient will be more likely to participate in physical therapy exercises if she has minimal pain before beginning.
u Consult an occupational therapist to assess the patient's home care needs. Provide specialized eating utensils, a high commode or toilet seat, a lowered sink, and a tub or shower chair, as needed.
u Allow the patient to rest frequently throughout the day to conserve energy for times when she must be mobile.
u Arrange the patient's environment for participation in activities of daily living so that she feels capable of accomplishing tasks.

Patient teaching

u Advise parents and health care professionals to encourage the child to be as independent as possible and to develop a positive attitude toward school, social development, and vocational planning.
u Encourage regular slit-lamp examinations to help ensure early diagnosis and treatment of iridocyclitis. Children with pauciarticular JRA with chronic iridocyclitis should be checked every 3 months during periods of active disease and every 6 months during remissions.
u Teach parents about reportable signs of bleeding secondary to aspirin or NSAID therapy.
u Teach parents and the patient about signs and symptoms of exacerbation, and stress the need to notify the pediatrician about these symptoms.
u Explain the need for proper nutrition and calorie consumption.
u Review exercises in which the child is encouraged to participate.
u Explain the child's special needs to teachers and the school principal.

LUPUS ERYTHEMATOSUS

Lupus erythematosus is a chronic inflammatory autoimmune disorder that affects the connective tissues. Lupus erythematosus takes two forms: discoid lupus erythematosus (DLE) and systemic lupus erythematosus (SLE). DLE affects only the skin; SLE affects multiple organs (including the skin) and can be fatal. (See [Discoid lupus erythematosus.](#))

Researchers think that clinical signs and symptoms result from antibody-antigen trapping in specific organ capillaries. Like rheumatoid arthritis, SLE is characterized by recurrent seasonal remissions and exacerbations, especially during the spring and summer.

SLE strikes women 8 times more often than men (15 times more often during childbearing years). It occurs worldwide but is most prevalent among Asians and blacks.

The prognosis improves with early detection and treatment but remains poor for patients who have cardiovascular, renal, or neurologic complications or severe bacterial infections.

Causes

The exact cause of SLE remains a mystery, but available evidence points to interrelated immune, environmental, hormonal, and genetic factors. Scientists think that autoimmunity is the primary cause. In autoimmunity, the body produces antibodies, such as antinuclear antibodies (ANAs), against its own cells. The formed antigen-antibody complexes then suppress the body's normal immunity and damage tissues. A significant feature in patients with SLE is their ability to produce antibodies against many different tissue components, such as red blood cells (RBCs), neutrophils, platelets, lymphocytes, and almost any organ or tissue in the body.

Certain predisposing factors can make a person susceptible to SLE. They include stress, streptococcal or viral infections, exposure to sunlight or ultraviolet light, injury, surgery, exhaustion, nervous tension, emotional upsets, immunization, pregnancy, and abnormal estrogen metabolism.

Complications

Pulmonary abnormalities can result in pleurisy, pleural effusions, pneumonitis, pulmonary hypertension, and pulmonary infections. Cardiac involvement can include pericarditis, myocarditis, endocarditis, and coronary atherosclerosis. Renal disease can progress to renal failure. Seizures and mental dysfunction can result.

Assessment findings

The onset of SLE, which can be acute or insidious, produces no characteristic clinical pattern. The patient may complain of fever, anorexia, weight loss, malaise, fatigue, abdominal pain, nausea, vomiting, diarrhea, constipation, rash, and polyarthralgia. When taking the patient's history, be sure to check the drug history.

Discoïd lupus erythematosus

Discoïd lupus erythematosus (DLE) is a form of lupus erythematosus that is marked by chronic skin eruptions. DLE can cause scarring and permanent disfigurement if untreated. About 5% of patients with DLE later develop systemic lupus erythematosus (SLE). An estimated 60% of patients with DLE are women in their late 20s or older. The disease seldom occurs in children. Its exact cause isn't known, but evidence suggests an autoimmune process.

Assessment findings

The patient with DLE has lesions that appear as raised, red, scaling plaques with follicular plugging and central atrophy. The raised edges and sunken centers give the lesions a coinlike appearance. Although these lesions can appear anywhere on the body, they usually erupt on the face, scalp, ears, neck, and arms or on any part of the body that is exposed to sunlight. Such lesions can resolve completely or may cause hypopigmentation or hyperpigmentation, atrophy, and scarring. Facial plaques sometimes assume the butterfly pattern characteristic of SLE. Hair becomes brittle and may fall out in patches.

Diagnostic tests

As a rule, the patient's history and the rash are enough to form the diagnosis. Positive findings in the lupus erythematosus (LE) cell test (in which polymorphonuclear leukocytes engulf cell nuclei to form so-called LE cells) occur in less than 10% of patients. Positive skin biopsy results of lesions typically disclose immunoglobulins or complement components. SLE must be ruled out.

Treatment

Patients with DLE must avoid prolonged exposure to the sun, fluorescent lighting, and reflected sunlight. They should wear protective clothing, use sunscreens, avoid outdoor activity during peak sunlight periods (between 10 a.m. and 2 p.m.), and report any changes in the lesions.

As in SLE, drug treatment consists of topical, intralesional, and systemic medications.

ASSESSMENT TIP Be sure to obtain a complete drug history of your patient with suspected SLE. Nearly 25 drugs can cause an SLE-like reaction. The most commonly implicated drugs include procainamide, hydralazine, isoniazid, methyldopa, anticonvulsants and, less frequently, penicillins, sulfa drugs, and oral contraceptives.

SLE can involve every organ system. Women may report irregular menstruation or amenorrhea, particularly during flare-ups. In about 90% of patients, joint involvement resembles that of rheumatoid arthritis. Raynaud's phenomenon affects about 20% of patients. The patient may complain that sunlight (or ultraviolet light) provokes or aggravates skin eruptions. She may report chest pain (indicating pleuritis) and dyspnea (suggesting parenchymal infiltrates and pneumonitis),

Cardiopulmonary signs and symptoms occur in about 50% of patients. Watch for repeated arterial clotting to manifest itself in dyspnea, tachycardia, central cyanosis, and hypotension. These signs and symptoms may herald pulmonary emboli. Also be alert for altered level of consciousness, weakness of the extremities, and speech disturbances that point to cerebrovascular accident.

Seizure disorders and mental dysfunction may indicate neurologic damage, and some signs and symptoms signal added central nervous system (CNS) involvement. They include emotional instability, psychosis, organic brain syndrome, headaches, irritability, and depression.

If the patient reports oliguria, be alert for possible renal failure. If she complains of urinary frequency, dysuria, and bladder spasms, watch for other signs of urinary tract infection.

During inspection, observe for skin lesions. Ordinarily, these eruptions appear as an erythematous rash in areas exposed to light. The classic butterfly rash over the nose and cheeks appears in less than 50% of patients. The rash may vary in severity from malar erythema to discoïd lesions (plaque). Also watch for patchy alopecia, which is common.

Check the patient's vital signs, intake and output, and weight. Inspect the mucous membranes, noting any painless ulcers. Look at the patient's hands and feet. Vasculitis may develop, especially in the digits. Inspect the skin of the arms and legs for infarctive lesions, necrotic leg ulcers, and digital gangrene.

With palpation, you may detect lymph node enlargement (diffuse or local and nontender). During auscultation, note any signs of cardiopulmonary abnormalities, such as pericardial friction rub (signaling pericarditis). Also note tachycardia and other signs of myocarditis and endocarditis.

Diagnostic tests

Laboratory tests include a complete blood count with differential (which may show anemia and a reduced white blood cell [WBC] count); platelet count (which may be decreased); erythrocyte sedimentation rate (usually elevated); and serum electrophoresis (which may detect hypergammaglobulinemia).

Difficult to detect, CNS involvement may account for abnormal EEG results in about 70% of patients. But brain and magnetic resonance imaging scans may be normal

in patients with SLE despite CNS disease. (See [Diagnostic signs of SLE.](#))

Specific tests for SLE include ANA, anti-DNA, and lupus erythematosus (LE) cell tests, which produce positive findings in most patients with active SLE, but are only marginally useful in diagnosing the disease. The ANA test is sensitive but not specific for SLE, the anti-DNA test is specific but not sensitive, and the LE cell test is neither sensitive nor specific for SLE.

Urine studies may detect RBCs, WBCs, urine casts and sediment, and significant protein loss (more than 3.5 g in 24 hours). Blood studies may demonstrate decreased serum complement (C3 and C4) levels, indicating active disease. Leukopenia, mild thrombocytopenia, and anemia also are seen during active disease.

Chest X-rays may disclose pleurisy or lupus pneumonitis. Electrocardiography may show a conduction defect with cardiac involvement or pericarditis.

Renal biopsy can show progression of SLE and the extent of renal involvement. Skin biopsy shows immunoglobulin and complement deposition in the dermal-epidermal junction in 90% of patients.

C-reactive protein may be increased during flare-ups. Rheumatoid factor is positive in 30% to 40% of patients.

Treatment

The mainstay of SLE treatment is drug therapy. The patient with mild disease requires little or no medication. Nonsteroidal anti-inflammatory drugs (NSAIDs), including aspirin, usually control arthritis and arthralgia symptoms. Skin lesions need topical medications and protection from exposure to the sun. Recommend that the patient use sunscreening agents with a sun protection factor of at least 15. Topical corticosteroid creams, such as triamcinolone and hydrocortisone, may be prescribed for mild disease.

Fluorinated steroids may control acute or discoid lesions. Refractory skin lesions may respond to intralesional or systemic corticosteroids or antimalarials such as hydroxychloroquine and chloroquine. Because hydroxychloroquine and chloroquine can cause retinal damage, such treatment requires ophthalmologic examination every 6 months. Dapsone helps many patients.

Corticosteroids remain the treatment of choice for systemic symptoms of SLE, for acute generalized exacerbations, and for serious disease-related injury to vital organ systems from pleuritis, pericarditis, nephritis related to SLE, vasculitis, and CNS involvement. With initial prednisone doses (equivalent to 60 mg or more), the patient's condition usually improves noticeably within 48 hours. Then, with symptoms under control, the patient discontinues prednisone use or tapers off slowly. (Note: Increasing serum complement levels and decreasing anti-DNA titers indicate patient response.)

ADVANCED PRACTICE

Diagnostic signs of SLE

Diagnosing systemic lupus erythematosus (SLE) is far from easy because the disease so often mimics other disorders. Signs may be vague and vary from patient to patient. For these reasons, the American Rheumatism Association has devised criteria for identifying SLE. Usually, four or more of the following signs must appear at some time in the disease course:

- u discoid rash
- u facial erythema (butterfly rash)
- u hematologic abnormality (hemolytic anemia, leukopenia, lymphopenia, or thrombocytopenia)
- u immune dysfunction (identified by positive anti-DNA test)
- u neurologic disorder
- u nonerosive arthritis
- u oral ulcers
- u photosensitivity
- u positive antinuclear antibody test results
- u renal disorder
- u serositis.

If the patient has glomerulonephritis, she requires treatment with large doses of corticosteroids. If renal failure occurs despite treatment, dialysis or kidney transplantation may be necessary.

In some patients, cytotoxic drugs, such as azathioprine, chlorambucil (Leukeran), cyclophosphamide, and methotrexate, can delay or prevent renal deterioration. Antihypertensive drugs and dietary changes can also be effective. Additionally, warfarin is indicated for antiphospholipid antibodies, which can cause clotting in vascular structures.

Joint replacement may be indicated if chronic synovitis and pain are problematic.

Nursing diagnoses

u Altered nutrition: Less than body requirements u Altered oral mucous membrane u Altered urinary elimination u Body image disturbance u Constipation u Decreased cardiac output u Diarrhea u Fatigue u Impaired physical mobility u Impaired skin integrity u Impaired tissue integrity u Ineffective breathing pattern u Pain u Risk for infection u Sensory or perceptual alterations

Key outcomes

- u The patient will express feelings of comfort and decreased pain.
- u The patient's cardiac output will remain within range.
- u The patient will express feelings of increased energy.
- u The patient will maintain joint mobility and range of motion.
- u The patient will maintain skin integrity.
- u The patient will maintain fluid balance; intake will equal output.

Nursing interventions

- u Continually assess for signs and symptoms of organ involvement while offering the patient encouragement, emotional support, and thorough patient teaching.
- u Monitor especially for hypertension, weight gain, and other signs of renal involvement.
- u Evaluate possible neurologic damage signaled by personality changes, paranoid or psychotic behavior, depression, ptosis, and diplopia.
- u Check urine, stools, and GI secretions for blood. Check the scalp for hair loss and the skin and mucous membranes for petechiae, bleeding, ulceration, pallor, and bruising.
- u Provide a balanced diet. Foods high in protein, vitamins, and iron help maintain optimum nutrition and prevent anemia. Renal involvement may mandate a low-sodium, low-protein diet. Provide bland, cool foods if the patient has a sore mouth.
- u Urge the patient to get plenty of rest. Schedule diagnostic tests and procedures to allow adequate rest.

- u Describe all tests and procedures to the patient. Explain that several blood samples are needed initially and then periodically to monitor progress.
- u Apply heat packs to relieve joint pain and stiffness. Encourage regular exercise to maintain full range of motion and to prevent contractures.
- u Explain the expected benefit of prescribed medications, and watch for adverse effects, especially when administering high doses of corticosteroids or NSAIDs.
- u Institute seizure precautions if you suspect CNS involvement.
- u Warm and protect the patient's hands and feet if she has Raynaud's phenomenon.
- u Arrange for a physical therapy and occupational therapy consultation if musculoskeletal involvement compromises the patient's mobility.
- u Support the patient's self-image. Offer female patients helpful tips. Suggest hypoallergenic cosmetics. As needed, refer her to a hairdresser who specializes in scalp disorders. Offer male patients similar advice, suggesting hypoallergenic hair care and shaving products.

Patient teaching

- u Teach range-of-motion exercises and body alignment and postural techniques.
- u Be sure the patient understands ways to avoid infection. Direct her to avoid crowds and people with known infections.
- u Advise the patient to notify the doctor if fever, cough, or rash occurs or if chest, abdominal, muscle, or joint pain worsens.
- u Teach the importance of eating a balanced diet and the restrictions associated with medications.
- u Teach the patient and family members about prescribed medications. Include information such as adverse effects, whether the medication needs to be taken with food, and correct administration.
- u Teach the importance of good skin care, avoiding dryness and the use of irritating soaps, hair dryers, hair coloring, and permanent wave solutions.
- u Encourage exercise, such as aerobics, swimming, walking, bicycling, and range-of-motion exercises.
- u Stress the importance of keeping regular follow-up appointments and contacting the doctor if flare-ups occur.
- u Instruct the photosensitive patient to wear protective clothing (hat, sunglasses, long-sleeved shirts or sweaters, and slacks) and to use a sunscreen when outdoors.
- u Teach the patient to perform meticulous mouth care to relieve discomfort and prevent infection.
- u Because SLE usually strikes women of childbearing age, questions associated with pregnancy commonly arise. The best evidence available indicates that a woman with SLE can have a safe, successful pregnancy if she sustains no serious renal or neurologic impairment. Advise her to seek additional medical care from a rheumatologist during her pregnancy. As indicated, explain that her doctors may order low-dose aspirin to reduce the risk of thrombosis during pregnancy.
- u Warn the patient against trying unproven miracle drugs to relieve arthritis symptoms.
- u Refer the patient to the Lupus Foundation of America and the Arthritis Foundation, as necessary.

POLYMYALGIA RHEUMATICA

Polymyalgia rheumatica (PMR) is an inflammatory syndrome typically manifested by significant stiffness and dull, aching pain of the proximal muscle groups; weight loss; malaise; and fever. It is more common among people of northern European descent, is rare among blacks and Asians, and favors the elderly (onset is rare in people under age 50). Twice as many women are affected as men. PMR can also be associated with giant cell (temporal) arteritis.

Causes

The pathogenesis of PMR is unclear. A genetic predisposition is suggested by the involvement of predominantly Caucasians, a tendency to run in families, and a possible association with human leukocyte antigen DR4. Although PMR is associated with muscular symptoms, inflammatory myositis isn't seen on tissue biopsies. There is evidence of a systemic, immune-mediated, anti-inflammatory process in patients who have elevated serum levels of interleukin (IL)-6 and IL-1 receptor antagonists.

Because PMR shares many clinical features with giant cell arteritis, some believe that PMR is an expression of underlying arteritis, whereas others believe that these two illnesses are different but overlapping. Whether PMR and giant cell arteritis share a similar causative factor is yet to be seen.

Assessment findings

Most patients experience an insidious onset of stiffness and pain in the muscles of the neck, shoulders, hips, and thighs; others report a rapid or sudden onset. Muscle stiffness can be severe, leading to difficulty rising out of a car or bed, difficulty with grooming and dressing, and problems climbing stairs. Fever, weight loss, and malaise are commonly noted. Peripheral arthritis with joint pain and swelling is occasionally seen and usually involves large joints, such as the shoulders and hips.

Objective findings are usually scarce on physical examination. Muscle tenderness without marked swelling or atrophy can be found. Overall muscle strength may be normal, but muscle strength testing is commonly limited by pain. Joint swelling may be mild, but marked synovitis isn't common.

Diagnostic tests

Laboratory findings in most PMR patients include an elevated erythrocyte sedimentation rate (ESR) and C-reactive protein. Thrombocytopenia, anemia, and abnormal liver function studies may be present.

The diagnosis is made when a consistent history is noted (such as pain and stiffness in at least two large muscle groups) in an elderly person (age 50 and older) with an elevated ESR. Syndromes that start with similar complaints, such as rheumatoid arthritis, infection, systemic lupus erythematosus, and neoplastic disorders, should be excluded. The diagnosis can be confirmed by the patient's rapid relief of symptoms in response to corticosteroid treatment. (See [Giant cell arteritis.](#))

Treatment

Corticosteroids, such as prednisone and prednisolone, are the treatment of choice for PMR. In the absence of giant cell arteritis, 15 to 30 mg daily is commonly used as the starting dose, depending on the patient. Patients usually note a rapid improvement of symptoms; regular observation for the recurrence of symptoms and elevation of ESR can be used to guide the corticosteroid taper (usually about 2.5 to 5 mg every month) until a maintenance dose of 5 to 7.5 mg daily is reached. The duration of therapy varies from patient to patient, but after 6 to 12 months of absence of symptoms and a normal ESR on low doses of steroids, the remaining medication can be slowly tapered off.

About one-half of patients remain symptom-free; the remainder may relapse over the next several months. Patients who relapse can be treated with lower doses of corticosteroids, such as 10 to 15 mg daily, again with plans for a slow taper.

In the presence of giant cell arteritis, the starting dose of corticosteroid therapy is generally much higher (50 to 60 mg daily) with I.V. pulses of steroids indicated in case of vision changes and possible impending vision loss.

Some clinicians use steroid-sparing immunosuppressants such as methotrexate to taper a patient off corticosteroids more quickly (decreasing the risk of adverse effects associated with long-term steroid use). Other studies focus on I.M. steroids given every 3 to 4 weeks instead of daily oral dosing. Further controlled trial data on the use of these regimens is needed.

ADVANCED PRACTICE

Giant cell arteritis

When a patient has symptoms of polymyalgia rheumatica, carefully observe for signs and symptoms of coexisting giant cell arteritis. New-onset headaches, jaw claudication (fatigue or discomfort of muscles of mastication during chewing), scalp tenderness, vision changes, diplopia, or aortic arch syndrome necessitates a temporal artery biopsy to confirm the diagnosis of arteritis. On examination, the temporal arteries may be thickened and tender to palpation.

Because arterial involvement (seen as mural disruption and infiltration with lymphocytes, macrophages, and giant cells) may be patchy or segmental, a 3- to 6-cm-long segment of artery should be obtained and examined at several levels. The use of ultrasonography in diagnosing this form of arteritis is under investigation. Prompt initiation of corticosteroid therapy is important because giant cell arteritis can cause retinal ischemia, leading to sudden, painless, and permanent loss of vision.

Nursing diagnoses

u Activity intolerance u Altered health maintenance u Altered role performance u Energy field disturbance u Fatigue u Hopelessness u Impaired physical mobility u Pain u Powerlessness u Risk for infection

Key outcomes

- u The patient will express feelings of comfort and decreased pain.
- u The patient will attain the highest degree of mobility possible within the confines of the disease.
- u The patient will state feelings about limitations.
- u The patient will continue to receive treatments that help to relax her and promote inner well-being.
- u The patient will express an increased sense of well-being.

Nursing interventions

- u Monitor the patient's sensory disturbances and level of pain. Administer medications such as analgesics as ordered, and watch for adverse reactions.
- u Provide emotional support. Remember that the patient can easily become depressed, discouraged, and irritable. Encourage discussion of her fears concerning dependency, disability, sexuality, body image, and self-esteem. Refer her to appropriate counseling, as needed.
- u In the absence of giant cell arteritis, patients should be maintained on the lowest dose of corticosteroids necessary to minimize the cumulative amount given.
- u Long-term corticosteroid therapy can be associated with diabetes mellitus, osteoporosis, osteonecrosis (avascular necrosis) of the hips, glaucoma, and cataracts.
- u Joints that aren't put through a regular range of motion (because of stiffness or pain) can be at risk for “freezing” because of tendon and ligament shortening or adhesive capsulitis. A daily stretching program can help to preserve range of motion in the neck, shoulders, and hips. Teach the patient how to do these stretches safely and effectively, and encourage her to perform them regularly.

ALERT The combination of oral corticosteroids and a nonsteroidal anti-inflammatory drug (NSAID) can put a patient at increased risk for peptic ulcer disease. For patients who require the steroids for PMR treatment and don't tolerate the discontinuation of their regular NSAID (for underlying arthritis, for example), consider adding a GI protective agent such as misoprostol.

Patient teaching

- u Caution the patient not to discontinue corticosteroids abruptly because this may lead to serious complications of adrenal insufficiency, such as weakness, fatigue, arthralgias, hypoglycemia, hypotension with dizziness or fainting and, in severe cases, death. Tell the patient to follow a schedule to taper down the steroid doses as instructed.
- u Inform elderly patients that they may be more sensitive to the central nervous system adverse effects of corticosteroid therapy, such as insomnia, euphoria or mania, and psychotic behavior (particularly with high doses).

POLYMYOSITIS AND DERMATOMYOSITIS

Polymyositis and dermatomyositis are diffuse, inflammatory myopathies that produce symmetrical weakness of striated muscles, especially proximal muscles of the shoulder, pelvic girdle, neck, and pharynx. In dermatomyositis, such weakness is accompanied by cutaneous involvement. These disorders usually progress slowly, with frequent exacerbations and remissions.

Polymyositis and dermatomyositis are twice as common in women as in men (with the exception of dermatomyositis with cancer, which is most common in men over age 40). Generally, the prognosis worsens with age. Although 80% to 90% of affected children regain normal function if properly treated, untreated childhood dermatomyositis may rapidly progress to disabling contractures and muscle atrophy.

Causes

Although the cause of polymyositis and dermatomyositis is unknown, the disorders may result from autoimmunity, perhaps combined with defective T-cell function. Presumably, the patient's T cells inappropriately recognize muscle fiber antigens as foreign and release lymphotoxins that cause diffuse or focal muscle fiber degeneration. Regeneration of new muscle cells follows, producing remission.

These disorders may be associated with allergic reactions, systemic lupus erythematosus (SLE), scleroderma, rheumatoid arthritis, Sjögren's syndrome, penicillamine administration, systemic viral infection, and carcinomas of the lung, breast, and other organs.

Complications

Associated cancer, respiratory disease, and heart failure can cause death.

Assessment findings

Onset of polymyositis can be acute or insidious with weakness, tenderness, and discomfort. The patient may complain of these symptoms in such proximal muscles as the shoulder and pelvic girdle more commonly than in distal muscles; she may also complain of aching pain in the buttocks. She may report weakness that impairs ordinary activities. For instance, she may have trouble getting up from a chair or a kneeling position, combing her hair, reaching into a high cupboard, climbing stairs, or even raising her head from a pillow.

Other musculoskeletal signs and symptoms include an inability to move against resistance, proximal dysphagia (regurgitation of fluid through the nose), and dysphonia (nasal voice). The patient may also report signs of Raynaud's phenomenon. Palpation may reveal tenderness in the buttocks area.

A patient with dermatomyositis may report a rash over much of her upper body and swelling around her eyes. Inspection may reveal a dusky red rash, usually located on the butterfly area of the face, neck, upper back, chest, shoulders, arms, and around the nail beds. A characteristic heliotropic (purplish) rash may appear on the eyelids, accompanied by periorbital edema. Inspection of the fingers may disclose subungual erythema, cuticular telangiectasis, and scaly, violet, flat-topped patches over the dorsum of the proximal interphalangeal and metacarpophalangeal joints (Gottron's papules).

Diagnostic tests

Muscle biopsy that shows necrosis, degeneration, regeneration, and interstitial chronic lymphocytic infiltration allows diagnosis.

Appropriate laboratory tests differentiate polymyositis from disorders that cause similar muscular or cutaneous symptoms, such as muscular dystrophy, advanced

trichinosis, psoriasis, seborrheic dermatitis, and SLE. Typical results in polymyositis include the following:

- mildly elevated erythrocyte sedimentation rate
- elevated white blood cell count
- elevated serum muscle enzyme levels (creatine kinase, aldolase, aspartate aminotransferase) not attributable to hemolysis of red blood cells or hepatic or other diseases
- elevated urine creatine levels (more than 150 mg/24 hours)
- decreased creatinine levels
- electromyography showing polyphasic, short-duration potentials; fibrillation (positive spikes); and bizarre, high-frequency, repetitive changes
- positive antinuclear antibodies.

Treatment

High-dose corticosteroid therapy (40 to 60 mg/day) relieves inflammation and lowers muscle enzyme levels. Within 2 to 6 weeks after treatment begins, serum muscle enzyme levels usually return to normal and muscle strength improves, permitting a gradual titration of corticosteroid dosage. If the patient responds poorly to corticosteroids, treatment may include cytotoxic or immunosuppressant drugs, such as cyclophosphamide, azathioprine, and methotrexate, given intermittently I.V or daily by mouth.

Supportive therapy includes bed rest during the acute phase, range-of-motion exercises to prevent contractures, analgesics and application of heat to relieve painful muscle spasms, and diphenhydramine to relieve itching. Patients over age 40 need thorough assessment for coexisting cancer.

Nursing diagnoses

- Activity intolerance
- Altered urinary elimination
- Body image disturbance
- Fatigue
- Fear
- Impaired physical mobility
- Impaired skin integrity
- Ineffective individual coping
- Pain
- Risk for altered body temperature
- Risk for infection
- Risk for injury
- Self-care deficit: Bathing and hygiene

Key outcomes

- The patient will express feelings of comfort and decreased pain.
- The patient will express feelings of increased energy.
- The patient will maintain joint mobility and range of motion.
- The patient will remain free from signs and symptoms of infection.
- The patient will attain the highest degree of mobility possible within the confines of disease.

Nursing interventions

- Assess the patient's level of pain, weakness, and range of motion daily. Administer analgesics, as needed.
- If the patient is confined to bed, prevent pressure ulcers by giving good skin care. To prevent footdrop and contractures, make sure the patient wears high-topped sneakers, and assist with passive range-of-motion exercises at least four times daily. Begin exercise therapy as soon as possible to prevent deterioration and contractures. Allow the patient's family to assist in performing these exercises.
- If 24-hour urine collection for creatine and creatinine tests are necessary, make sure the staff, patient, and family understand the collection procedure.
- When you assist with muscle biopsy, make sure the biopsy specimen isn't taken from an area of recent needle insertion, such as an injection or electromyography site.
- If the patient has a rash, warn her against scratching, which may cause infection. If antipruritic drugs don't relieve severe itching, apply tepid sponges or compresses. If the patient is young or scratches during her sleep, provide lightweight cotton gloves to protect the skin.
- Alternate activities with rest periods to prevent excessive fatigue.

Patient teaching

- Explain the disease and its complications to the patient, and encourage her to express her anxiety. Ease her fear of dependence by reassuring her that weakness usually passes.
- Prepare the patient and family members for diagnostic procedures and possible adverse effects of corticosteroid therapy, such as hirsutism and edema.
- Reassure the patient that corticosteroid-induced weight gain will diminish when therapy ends, but warn her not to discontinue the drug abruptly. Discuss the weaning process with the patient or family.
- Advise the patient to follow a low-sodium, nutritious diet to prevent fluid retention.
- Teach the family how to help the patient with range-of-motion exercises. Involve the family in the prescribed home exercise program.
- Encourage the patient to feed and dress herself to the best of her ability but to ask for help when needed. Advise her to pace her activities to combat weakness.

REITER'S SYNDROME

The dominant feature of Reiter's syndrome is polyarthritis. This self-limiting syndrome also causes urethritis, mucocutaneous lesions, and conjunctivitis or, less commonly, uveitis.

Reiter's syndrome usually affects young men ages 20 to 40; it seldom occurs in women and children. Most patients recover in 2 to 16 weeks. About one-half of the patients have recurrent acute attacks; the remainder follow a chronic course, experiencing continued synovitis and sacroiliitis.

Causes

Although the exact cause of Reiter's syndrome is unknown, most cases follow venereal or enteric infection. The high incidence of human leukocyte antigen (HLA)-B27 in patients with Reiter's syndrome suggests a genetic susceptibility. The disease has also followed infections caused by *Mycoplasma*, *Shigella*, *Campylobacter*, *Salmonella*, *Yersinia*, and *Chlamydia* organisms. It's common in patients infected with the human immunodeficiency virus (HIV) and usually precedes or follows the onset of acquired immunodeficiency syndrome.

Complications

Chronic heel pain, ankylosing spondylitis, and persistent joint pain and swelling commonly result from Reiter's syndrome. Up to 25% of patients have such crippling effects that they must change occupations. If anterior uveitis doesn't respond to treatment, ocular disease may progress to blindness. Reiter's syndrome may also cause such genitourinary complications as prostatitis and hemorrhagic cystitis.

Assessment findings

The patient may initially complain of dysuria, hematuria, urgent and frequent urination, and mucopurulent penile discharge with swelling and reddening of the urethral meatus. He may also report suprapubic pain, fever, and anorexia with weight loss. Inspection of the penis may reveal small, painless ulcers on the glans penis (balanitis); these ulcers may coalesce to form irregular patches that cover the penis and scrotum.

Arthritic symptoms usually follow genitourinary or enteric signs and symptoms and often last for 2 to 4 months. The patient is most likely to complain of asymmetrical and extremely variable polyarticular arthritis, usually in weight-bearing joints of the legs and sometimes in the low back or sacroiliac joints. If arthritis has developed, the patient may report warm, erythematous, and painful joints, or he may have only mild symptoms with minimal synovitis.

On inspection, you may note muscle wasting near affected joints. The patient's fingers and toes may appear swollen and sausagelike.

Ocular signs and symptoms include mild bilateral conjunctivitis, possibly complicated by uveitis, keratitis, iritis, retinitis, or optic neuritis. In severe cases, the patient

may complain of burning, itching, and profuse mucopurulent discharge. Inspection of the eyes may reveal redness and swelling.

In 30% of patients, you may observe skin lesions (keratoderma blennorrhagicum) that resemble pustular psoriasis with involvement of the skin and nails. These lesions develop 4 to 6 weeks after the onset of other signs and symptoms and may last for several weeks. They occur most commonly on the palms and soles but can develop anywhere on the trunk, extremities, or scalp.

You may also note that the patient's nails are thick, opaque, and brittle with an accumulation of keratic debris under the nails. In many patients, painless, transient ulcerations erupt on the buccal mucosa, palate, and tongue.

Diagnostic tests

Most patients with Reiter's syndrome test positive for HLA-B27. Tests also show an elevated white blood cell (WBC) count and erythrocyte sedimentation rate as well as mild anemia. Examination of urethral discharge and synovial fluid reveals many WBCs, mostly polymorphonuclear leukocytes; synovial fluid is also grossly purulent and high in complement and protein. Cultures of urethral discharge and synovial fluid rule out other causes, such as disseminated gonococcal disease.

During the first few weeks of the syndrome, X-rays are normal. They may remain so, but in some patients they can show osteoporosis in inflamed areas. If inflammation persists, X-rays may show erosions of the small joints, periosteal proliferation (new bone formation) of involved joints, and calcaneal spurs. Late findings include asymmetrical sacroillitis. Testing may also be done for HIV infection.

Treatment

No specific treatment exists for Reiter's syndrome. During acute stages, the patient may be restricted to limited weight bearing or may require complete bed rest.

Nonsteroidal anti-inflammatory drugs (NSAIDs) such as indomethacin can help relieve discomfort and fever. If the patient doesn't respond to NSAIDs, the doctor may prescribe such cytotoxic agents as azathioprine and methotrexate to alleviate debilitating signs and symptoms. Corticosteroids may help to control persistent skin lesions; gold therapy may have limited value for bony erosion.

Physical therapy includes range-of-motion and strengthening exercises and the use of padded or supportive shoes to prevent contractures and foot deformities.

Nursing diagnoses

u Altered nutrition: Less than body requirements u Altered oral mucous membrane u Altered role performance u Altered sexuality patterns u Altered urinary elimination u Fatigue u Impaired physical mobility u Impaired skin integrity u Impaired tissue integrity u Pain u Risk for infection

Key outcomes

- u The patient won't have further weight loss.
- u The patient will express feelings of increased energy.
- u The patient will express feelings of comfort and decreased pain.
- u The patient will attain the highest degree of mobility possible within the confines of disease.
- u The patient will state feelings about limitations.
- u The patient will continue treatments that help to relax him and promote inner well-being.

Nursing interventions

- u Maintain an accepting, nonjudgmental attitude to relieve any embarrassment the patient may feel if the disorder is associated with sexual activity.
- u Follow standard precautions. Be particularly careful when handling linens, dressings, and clothing that has touched the patient's genitalia.
- u Provide rest and analgesia, as needed.
- u Provide a high-calorie, high-protein diet to ensure adequate nutrition.
- u Develop an exercise regimen with the physical therapist and patient. Make sure it helps the patient to maintain flexion, good body alignment, and posture.
- u If the patient has severe or chronic joint impairment, arrange for occupational counseling.

Patient teaching

- u Explain Reiter's syndrome to the patient. Counsel him to use condoms and to avoid multiple sex partners, and teach him steps he can take to avoid exposure to enteric pathogens such as avoiding anal intercourse.
- u Explain the recommended medications and their possible adverse effects. Warn the patient to take NSAIDs with meals or milk to prevent GI bleeding.
- u Encourage normal daily activity and moderate exercise as well as good posture and body mechanics. Suggest that the patient use a firm mattress.

RHEUMATOID ARTHRITIS

Rheumatoid arthritis is a chronic, systemic, symmetrical inflammatory disease. It primarily attacks peripheral joints and surrounding muscles, tendons, ligaments, and blood vessels. Spontaneous remissions and unpredictable exacerbations mark the course of this potentially crippling disease. A similar condition, psoriatic arthritis, has the same arthritic component along with psoriasis of the skin and nails (see [Psoriatic arthritis](#)).

Rheumatoid arthritis occurs worldwide. The disease strikes women three times more often than men. Although it can occur at any age, the peak onset is between ages 35 and 50.

Rheumatoid arthritis usually requires lifelong treatment and, sometimes, surgery. In most patients, the disease follows an intermittent course and allows normal activity, although 10% suffer total disability from severe articular deformity or associated extra-articular symptoms, or both. The prognosis worsens with the development of nodules, vasculitis, and high titers of rheumatoid factor (RF).

Causes and pathophysiology

The cause of the chronic inflammation characteristic of rheumatoid arthritis isn't known, but infection (viral or bacterial), hormonal factors, and lifestyle may influence disease onset. Some patients develop an immunoglobulin (Ig) M antibody against their body's own IgG, which is called RF.

The cartilage damage that results from the inflammation triggers further immune responses, including complement activation. Complement, in turn, attracts polymorphonuclear leukocytes and stimulates the release of inflammatory mediators, which exacerbates joint destruction.

If it isn't arrested, joint inflammation occurs in four stages. First, synovitis develops from congestion and edema of the synovial membrane and joint capsule. Formation of pannus (thickened layers of granulation tissue) marks the onset of the second stage. Pannus covers and invades cartilage and eventually destroys the joint capsule and bone.

Progression to the third stage is characterized by fibrous ankylosis—fibrous invasion of the pannus and scar formation that occludes the joint space. Bone atrophy and misalignment cause visible deformities and disrupt the articulation of opposing bones, causing muscle atrophy, imbalance and, possibly, partial dislocations or subluxations. In the fourth stage, fibrous tissue calcifies, resulting in bony ankylosis and immobility.

Complications

Pain associated with movement may restrict active joint use and cause fibrous or bony ankylosis, soft-tissue contractures, and joint deformities. Vasculitis can lead to skin lesions, leg ulcers, and multisystem complications.

Between 15% and 20% of patients develop Sjögren's syndrome with keratoconjunctivitis sicca. Rheumatoid arthritis can also destroy the odontoid process, part of the second cervical vertebra. Rarely, spinal cord compression can occur, particularly in patients with long-standing deforming rheumatoid arthritis.

Other complications include subluxations, carpal tunnel syndrome, popliteal (Baker's) cysts, osteoporosis, vasculitis, amyloidosis, recurrent infections, anemia, necrosis of the hip joint, cardiac and pulmonary disorders, renal insufficiency, GI disturbances, and pleural effusions.

Assessment findings

The patient's history may reveal an insidious onset of nonspecific symptoms, including fatigue, malaise, anorexia, persistent low-grade fever, weight loss, and vague articular symptoms.

Later, more specific localized articular symptoms develop, commonly in the fingers at the proximal interphalangeal, metacarpophalangeal, and metatarsophalangeal joints. These symptoms usually occur bilaterally and symmetrically and can extend to the wrists, elbows, knees, and ankles. Articular symptoms are painful, red, swollen arms and stiff joints.

The patient may report that affected joints stiffen after inactivity, especially on rising in the morning. She may complain that joints are tender and painful, at first only when she moves them but eventually even at rest. Ultimately, joint function is diminished. She may also experience paresthesia in the fingers, the result of synovial pressure on the median nerve from carpal tunnel syndrome.

Other complaints include stiff, weak, or painful muscles. If the patient has peripheral neuropathy, she may report numbness or tingling in the feet or weakness or loss of sensation in the fingers. If pleuritis develops, she may complain of pain on inspiration (although pleuritis often causes no symptoms). The patient with pulmonary nodules or fibrosis may complain of shortness of breath.

Inspection of the patient's joints may show deformities and contractures, especially if active disease continues. The fingers may appear spindle-shaped from marked edema and congestion in the joints. Proximal interphalangeal joints may develop flexion deformities or become hyperextended. Metacarpophalangeal joints may swell dorsally, and volar subluxation and stretching of tendons may pull the fingers to the ulnar side (ulnar drift). The fingers may become fixed in a characteristic swan-neck deformity or in a boutonniere deformity. Carpal tunnel syndrome from synovial pressure on the medial nerve causes paresthesia in the fingers. The hands appear foreshortened and the wrists appear boggy. Inspection of pressure areas, such as the elbows, hands, and Achilles tendon, may reveal rheumatoid nodules (subcutaneous, round or oval, nontender masses)—the most common extra-articular finding.

If the patient has vasculitis, you may observe such extra-articular signs as lesions, leg ulcers, and multisystem complications. If she has scleritis or episcleritis, you may observe redness of the eye.

Psoriatic arthritis
<p>Psoriatic arthritis is marked by rheumatoid-like joint disease and psoriasis of the skin and nails. It usually occurs in a mild form with intermittent flare-ups and rarely progresses to crippling arthritis mutilans.</p> <p>Psoriatic arthritis affects nearly 20% of male and female patients with psoriasis. A streptococcal infection or trauma usually precedes onset (typically between ages 30 and 35). Predisposition to psoriatic arthritis is apparently hereditary.</p> <p>The patient with severe psoriatic arthritis may have arthritis symptoms and skin lesions simultaneously and complain of malaise and fever. Swelling, tenderness, warmth, and restricted movement of one or several joints are typical, most commonly in the hands. Fingers can appear sausagelike, with pitting, ridging, yellowing, and possible destruction of the nails.</p> <p>Rheumatoid nodules don't develop and serologic test results for rheumatoid factor are negative. X-ray studies confirm joint involvement. An elevated erythrocyte sedimentation rate and increased uric acid level are common. Other tests rule out disorders such as fungal infections, Reiter's disease, gout, and rheumatoid arthritis.</p> <p>For mild psoriatic arthritis, treatment includes immobilizing the affected joints, isometric exercises, paraffin baths, heat therapy, and nonsteroidal anti-inflammatory drugs. Low-dose systemic and topical corticosteroids may control skin lesions. In resistant cases, gold salts and methotrexate therapy may reduce symptoms.</p>

Palpation may reveal joints that are warm to the touch. If the patient has pericarditis, auscultation may reveal pericardial friction rub (although pericarditis may produce no signs).

Peripheral neuropathy may produce numbness or tingling in the feet or weakness and loss of sensation in the fingers. Stiff, weak, or painful muscles are common. If spinal cord compression occurs, your assessment may reveal signs of upper motor neuron disorder, such as a positive Babinski's sign and weakness. Other extra-articular findings include temporomandibular joint disease, infection, osteoporosis, myositis, cardiopulmonary lesions, lymphadenopathy, and peripheral neuritis.

Diagnostic tests

No test definitively diagnoses rheumatoid arthritis, but several are useful. In early stages, X-rays show bone demineralization and soft-tissue swelling. Later, they help determine the extent of cartilage and bone destruction, erosion, subluxations, and deformities. They also show the characteristic pattern of these abnormalities, particularly symmetrical involvement, although no particular pattern is conclusive for rheumatoid arthritis.

Classifying rheumatoid arthritis

The criteria of the American Rheumatism Association allow the classification of rheumatoid arthritis.

Guidelines

A patient who meets four of seven criteria is classified as having rheumatoid arthritis. She must experience the first four criteria for at least 6 weeks, and a doctor must observe the second through fifth criteria.

A patient with two or more other clinical diagnoses can also be diagnosed with rheumatoid arthritis.

Criteria

- u Morning stiffness in and around the joints that lasts for 1 hour before full improvement
- u Arthritis in three or more joint areas, with at least three joint areas (as observed by a doctor) exhibiting soft-tissue swelling or joint effusions, not just bony overgrowth (the 14 possible areas involved include the right and left proximal interphalangeal, metacarpophalangeal, wrist, elbow, knee, ankle, and metatarsophalangeal joints)
- u Arthritis of hand joints, including the wrist, the metacarpophalangeal joint, or the proximal interphalangeal joint
- u Arthritis that involves the same joint areas on both sides of the body
- u Subcutaneous rheumatoid nodules over bony prominences
- u Demonstration of abnormal amounts of serum rheumatoid factor by any method that produces a positive result in less than 5% of patients without rheumatoid arthritis
- u Radiographic changes, usually on posteroanterior hand and wrist radiographs; these changes must show erosions or unequivocal bony decalcification localized in or most noticeable adjacent to the involved joints.

An RF test is positive in 75% to 80% of patients, as indicated by a titer of 1:160 or higher. Although the presence of RF doesn't confirm rheumatoid arthritis, it does help determine the prognosis; a patient with a high titer usually has more severe and progressive disease with extra-articular manifestations.

Synovial fluid analysis shows increased volume and turbidity but decreased viscosity and complement (C3 and C4) levels. The white blood cell count often exceeds 10,000/μl.

A serum protein electrophoresis test may show elevated serum globulin levels.

The erythrocyte sedimentation rate (ESR) is elevated in 85% to 90% of patients. Because an elevated ESR frequently parallels disease activity, this test may help monitor the patient's response to therapy (as may a C-reactive protein test).

A complete blood count usually shows moderate anemia and slight leukocytosis.

Magnetic resonance imaging and computed tomography scans may provide information about the extent of damage

The criteria for classifying rheumatoid arthritis developed by the American Rheumatism Association can also serve as guidelines for establishing a diagnosis. But keep in mind that failure to meet these criteria—particularly early in the disease—doesn't exclude the diagnosis. (See [Classifying rheumatoid arthritis.](#))

Treatment

Treatment requires a multidisciplinary health care team to reduce the patient's pain and inflammation, preserve functional capacity, resolve pathologic processes, and bring about improvement.

Salicylates, particularly aspirin, are the mainstay of therapy because they decrease inflammation and relieve joint pain. The patient may also receive other nonsteroidal anti-inflammatory drugs (such as indomethacin, fenoprofen, and ibuprofen), antimalarials (hydroxychloroquine), gold salts, penicillamine, and corticosteroids (prednisone), although corticosteroid therapy can cause osteoporosis. Other therapeutic drugs include such immunosuppressants as cyclophosphamide, methotrexate, and azathioprine, which are used in the early stages of the disease. (See [Drug therapy for rheumatoid arthritis.](#))

Supportive measures include increased sleep (8 to 10 hours every night), frequent rest periods between daily activities, and splinting to rest inflamed joints (although, like corticosteroid therapy, immobilization can cause osteoporosis).

A physical therapy program that includes range-of-motion exercises and carefully individualized therapeutic exercises forestalls the loss of joint function; application of heat relaxes muscles and relieves pain. Moist heat (hot soaks, paraffin baths, whirlpools) usually works best for patients with chronic disease. Ice packs help during acute episodes.

Early intervention, under the guidance of an occupational therapist, with splinting and joint protection devices can delay the progression of joint deformities. A well-balanced diet and weight control along with the use of adaptive devices and ambulatory support (such as a cane, crutches, and a walker) are beneficial.

Useful surgical procedures include metatarsal head and distal ulnar resectional arthroplasty and insertion of a Silastic prosthesis between the metacarpophalangeal and proximal interphalangeal joints. Arthrodesis (joint fusion) can bring about stability and relieve pain but at the price of decreased joint mobility. Synovectomy (removal of destructive, proliferating synovium, usually in the wrists, fingers, and knees) can halt or delay the course of the disease. Osteotomy (the cutting of bone or excision of a wedge of bone) can realign joint surfaces and redistribute stresses. Tendons that rupture spontaneously require surgical repair. Tendon transfers can prevent deformities or relieve contractures. The patient may need joint reconstruction or total joint arthroplasty in advanced disease.

Nursing diagnoses

- u Activity intolerance u Altered health maintenance u Altered tissue perfusion (peripheral) u Altered role performance u Energy field disturbance u Fatigue u Hopelessness u Impaired physical mobility u Pain u Powerlessness u Risk for impaired skin integrity u Risk for infection u Self-care deficit

Key outcomes

- u The patient will express feelings of comfort and decreased pain.
- u The patient will attain the highest degree of mobility possible within the confines of disease.
- u The patient will state feelings about limitations.
- u The patient will continue to receive treatments that promote relaxation and inner well-being.
- u The patient will express an increased sense of well-being.
- u The patient will regain skin integrity.

Nursing interventions

- u Monitor the patient's vital signs, and note weight changes, sensory disturbances, and level of pain. Administer analgesics as ordered, and watch for adverse reactions.
- u Perform meticulous skin care. Check for rheumatoid nodules. Also monitor for pressure ulcers and skin breakdown, especially if the patient is in traction or wearing splints. These complications can result from immobility, vascular impairment, corticosteroid treatment, and improper splinting. Use lotion or cleansing oil—not soap—on dry skin.

- u Monitor the duration of morning stiffness. Duration, rather than intensity of the stiffness, more accurately reflects the severity of the disease.
- u Supply a zipper pull, easy-to-open beverage cartons, lightweight cups, and unpackaged silverware to make it easier for the patient to perform activities of daily living, such as dressing and feeding herself. Allow the patient enough time to calmly perform these tasks.
- u Provide emotional support. Remember that the patient can easily become depressed, discouraged, and irritable. Encourage discussion of her fears concerning dependency, disability, sexuality, body image, and self-esteem. Refer her to appropriate counseling, as needed.

After total knee or hip arthroplasty:

- u Monitor and record vital signs. Watch for complications, such as steroid crisis and shock in a patient receiving corticosteroids. Monitor the patient's distal leg pulses often, marking them with a waterproof marker to make them easier to find.
- u As soon as the patient awakens, have her perform active dorsiflexion; if she can't, report this immediately. Supervise isometric exercises every 2 hours. After total hip arthroplasty, check traction for pressure areas, and keep the head of the bed raised between 30 and 45 degrees.
- u Change or reinforce dressings as needed using aseptic technique. Check wounds for hematoma, excessive drainage, color changes, and foul odor—all possible signs of hemorrhage or infection. (The rheumatoid arthritis patient's wounds may heal slowly.) Make sure you don't contaminate dressings when helping the patient use the urinal or bedpan.
- u Administer blood replacement products, antibiotics, and pain medication, as ordered. Monitor serum electrolyte and hemoglobin levels and hematocrit.
- u Have the patient turn, cough, and breathe deeply every 2 hours; then percuss her chest.
- u After total knee arthroplasty, keep the patient's leg extended and slightly elevated.
- u After total hip arthroplasty, keep the patient's hip in abduction to prevent dislocation. Watch for and immediately report any inability to rotate the hip or bear weight on it, increased pain, or a leg that appears shorter. All may indicate dislocation.

Drug therapy for rheumatoid arthritis	
DRUG AND ADVERSE EFFECTS	CLINICAL CONSIDERATIONS
Aspirin u Prolonged bleeding time; GI disturbances, including nausea, dyspepsia, anorexia, ulcers, and hemorrhage; hypersensitivity reactions ranging from urticaria to anaphylaxis; salicylism (mild toxicity: tinnitus, dizziness; moderate toxicity: restlessness, hyperpnea, delirium, marked lethargy; and severe toxicity: coma, seizures, severe hyperpnea)	<ul style="list-style-type: none">u Don't use in neonates and in patients with GI ulcers, bleeding, or hypersensitivity.u Give with food, milk, an antacid, or a large glass of water to reduce adverse GI effects.u Monitor salicylate level. Remember that toxicity can develop rapidly in febrile, dehydrated children.u Teach the patient to reduce the dose, one tablet at a time, if tinnitus occurs.u Teach the patient to watch for signs of bleeding, such as bruising, melena, and petechiae.
Fenoprofen, ibuprofen, naproxen, piroxicam, sumac, and tolmetin u Prolonged bleeding time; central nervous system abnormalities (headache, drowsiness, restlessness, dizziness, tremor); GI disturbances, including hemorrhage and peptic ulcer, increased blood urea nitrogen (BUN) and liver enzyme levels	<ul style="list-style-type: none">u Don't use in neonates and in patients with GI ulcers, bleeding, or hypersensitivity.u Use cautiously in patients with GI disorders or cardiac disease and in patients who are allergic to other nonsteroidal anti-inflammatory drugs.u Give with milk or food to reduce adverse GI effects.u Tell the patient that the drug's effect may be delayed for 2 to 3 weeks.u Monitor kidney, liver, and auditory functions in long-term therapy. Stop the drug if abnormalities develop.u Use cautiously in elderly patients; they may experience severe GI bleeding without warning.
Hydroxychloroquine u Blood dyscrasias, GI irritation, corneal opacities, keratopathy or retinopathy	<ul style="list-style-type: none">u Contraindicated in patients with retinal or visual field changes.u Use cautiously in patients with hepatic disease, alcoholism, glucose-6-phosphate dehydrogenase deficiency, or psoriasis.u Perform complete blood count (CBC) and liver function tests before therapy and during chronic therapy. Patients should also have regular ophthalmologic examinations.u Give with food or milk to reduce adverse GI effects.u Warn patient that dizziness may occur.
Gold (oral and parenteral) u Dermatitis, pruritus, rash, stomatitis, nephrotoxicity, blood dyscrasias, nitritoid crisis, GI distress and diarrhea (with oral form)	<ul style="list-style-type: none">u Watch for adverse effects. Observe for nitritoid reaction (flushing, fainting, sweating).u Check urine for blood and albumin before each dose; if positive, drug may need to be withheld. Stress the need for regular follow-up, including blood and urine testing.u To avoid local nerve irritation, mix drug well and give deep I.M. injection in buttock.u Advise patient not to expect improvement for 3 to 6 months.u Instruct the patient to report rash, bruising, bleeding, hematuria, or oral ulcers.
Methotrexate u Tubular necrosis, bone marrow depression, leukopenia, thrombocytopenia, pulmonary interstitial infiltrates, stomatitis, hyperuricemia, rash, pruritus, dermatitis, alopecia, diarrhea, dizziness, cirrhosis, hepatic fibrosis	<ul style="list-style-type: none">u Don't give to breast-feeding or pregnant women or to alcoholic patients.u Monitor uric acid (UA) levels, CBC, and liver function tests.u Monitor intake and output.u Warn patient to report any unusual bleeding (especially GI) or bruising promptly.u Warn patient to avoid alcohol.u Advise patient to follow prescribed regimen.

Sulfasalazine <ul style="list-style-type: none">u Nausea, vomiting, abdominal pain, rash, bone marrow suppression, headache, hypersensitivity reaction	<ul style="list-style-type: none">u Give in divided doses.u Don't give to patients with known sulfa allergy.u Monitor CBC and UA and liver enzyme levels.u Caution patient not to take sulfasalazine at same time as antacids, which interfere with absorption.
Cyclosporine <ul style="list-style-type: none">u Nephrotoxicity (increase in BUN and serum creatinine levels), hypertension, bone marrow suppression, nausea, vomiting, paresthesia, bone pain	<ul style="list-style-type: none">u Avoid use in patients with preexisting hypertension or renal disease.u Monitor blood pressure closely.u Monitor BUN and serum creatinine levels.u Be aware that levels of cyclosporine may be increased by other medications that are metabolized by the liver.
Prednisone <ul style="list-style-type: none">u Hyperglycemia, hypertension, fluid retention, weight gain, acne, cataracts, indigestion, muscle weakness, osteoporosis, mental status changes, insomnia, psychosis	<ul style="list-style-type: none">u Give as an initial high dose to suppress inflammation, followed by slow tapering to the lowest possible dose.u Advise patient not to stop the drug suddenly because this can lead to adrenal insufficiency.u Monitor blood glucose levels and blood pressure.

u As soon as possible, help the patient get out of bed and sit in a chair, keeping her weight on the unaffected side. When she's ready to walk, consult with the physical therapist for walking instruction and aids.

Patient teaching

- u Explain the nature of rheumatoid arthritis. Make sure the patient and her family understand that rheumatoid arthritis is a chronic disease that may require major changes in lifestyle and that miracle cures don't work.
- u Explain all diagnostic tests and procedures.
- u Encourage a balanced diet, but make sure the patient understands that special diets don't cure rheumatoid arthritis. Stress the need for weight control because obesity further stresses the joints.
- u Discuss the patient's sexual concerns. If pain creates problems during intercourse, discuss trying alternative positions, taking analgesics beforehand, and using moist heat to increase mobility.
- u Before discharge, make sure the patient knows how and when to take prescribed medications and how to recognize adverse effects. (See [Living with rheumatoid arthritis.](#))

If the patient requires total knee or hip arthroplasty, she needs special preoperative teaching.

- u Explain all preoperative and surgical procedures. If possible, show the patient the prosthesis that will be used.
- u Teach postoperative exercises (such as isometrics) and supervise her practice. Also, teach the deep-breathing and coughing exercises she must perform after surgery.
- u Explain that total hip or knee arthroplasty requires frequent range-of-motion exercises of the leg after surgery; total knee arthroplasty also requires frequent leg-lift exercises.
- u Show the patient how to use a trapeze to move herself about in bed after surgery, and make sure she has a fracture bedpan handy.
- u Tell her what kind of dressings to expect after surgery. After total knee arthroplasty, the patient's knee may be placed in a constant-passive-motion device to increase mobility and prevent emboli. After total hip arthroplasty, an abduction pillow is placed between the legs to help keep the hip prosthesis in place.

HOME CARE

Living with rheumatoid arthritis

Follow these guidelines to help your patient learn to live with rheumatoid arthritis:

- u Teach the patient how to use correct posture when standing, sitting, and walking.
- u Recommend using chairs with high seats and armrests.
- u Recommend using a raised toilet seat.
- u Teach the patient proper body mechanics: avoiding flexion, keeping her hands close to the center of the body, and sliding rather than lifting objects.
- u Suggest that the patient take a hot shower or bath just before bed or in the morning to help relieve pain.
- u Refer the patient for physical and occupational therapy to help increase her mobility, strength, and ability to perform activities of daily living.
- u Reinforce instructions about the need for adaptive devices, such as dressing aids (long-handled shoehorn, reacher, elastic shoelaces, zipper pull, and button hook) and eating utensils.
- u Inspect the patient's home for possible safety hazards, and work with the patient and family to remove them. Encourage the use of grab bars and safety mats or strips in the tub or shower.
- u Advise the patient to save her strength by pacing her activities and dressing in a sitting position whenever possible.
- u Refer the patient to the Arthritis Foundation.

SJÖGREN'S SYNDROME

Sjögren's syndrome is the next most common autoimmune disorder after rheumatoid arthritis. It results from a chronic exocrine gland dysfunction and is marked by diminished lacrimal and salivary gland secretion (sicca complex). The syndrome affects more women (about 90%) than men. The mean age of occurrence is 50.

Sjögren's syndrome may be a primary disorder, or it may be associated with inflammatory connective tissue disorders, such as rheumatoid arthritis (about 50% of patients), scleroderma, systemic lupus erythematosus, primary biliary cirrhosis, Hashimoto's thyroiditis, polyarteritis, and interstitial pulmonary fibrosis.

Nephritis (seldom leading to chronic renal failure) may affect up to 40% of patients with primary Sjögren's syndrome and can result in renal tubular acidosis in about 25% of patients.

Patients with Sjögren's syndrome may also have Raynaud's phenomenon (about 20%) and vasculitis (usually limited to the skin and may be systemic or localized in the legs). Sensory polyneuropathy and biochemical hypothyroidism (resembling Hashimoto's thyroiditis) occur in up to 50% of patients. Rarely, systemic necrotizing vasculitis develops and involves the skin, peripheral nerves, and GI tract.

Overall, the prognosis for a patient with Sjögren's syndrome is good.

Causes

No one knows what causes Sjögren's syndrome, but researchers think that genetic and environmental factors may contribute to its development. Viral or bacterial infection—or possibly exposure to pollen—may trigger this disease in a genetically susceptible person. Tissue damage results from infiltration by lymphocytes or deposition of immune complexes. Lymphocytic infiltration may be classified as benign lymphoma, malignant lymphoma, or pseudolymphoma (nonmalignant but tumorlike aggregates of lymphoid cells).

Complications

The disease seldom produces significant complications. Ocular complications include corneal ulceration or perforation, ocular vascularization, infection, or symblepharon. Oral complications include infection, ulceration, and dental complications. Pulmonary and respiratory complications include dry nasal mucosa with epistaxis, hoarseness, dysphagia, deafness, otitis media, and lower respiratory tract complications. GI complications include splenomegaly, decreased gastric acid, constipation, and pancreatic and hepatic insufficiency. Renal complications include renal tubular necrosis, aminoaciduria, glycosuria, and hypergammaglobulinemia purpura. Other complications include leukopenia, vasculitis with leg ulcers, chronic thyroiditis, and lymphoproliferative disease.

Assessment findings

The patient typically reports slowly developing dryness that affects the eyes (xerophthalmia), mouth (xerostomia), and other organs. Initially, she may describe a foreign-body sensation in the eye (gritty, sandy eye) along with redness, burning, photosensitivity, eye fatigue, itching, and mucoid discharge. She may also complain of a film across her eyes.

With oral dryness, the patient may report difficulty swallowing and talking; an abnormal taste or smell sensation (or both); thirst; ulcers of the tongue, mouth, and lips (especially at the corners of the mouth); and severe dental caries. If the patient's history suggests Sjögren's syndrome, be sure to find out which prescription and nonprescription drugs she takes. Keep in mind that more than 200 commonly used drugs produce dry mouth.

With other dryness—of the respiratory tract, for example—the patient may report epistaxis, hoarseness, chronic nonproductive cough, recurrent otitis media, and frequent respiratory tract infections. With vaginal dryness, the patient may report dyspareunia and pruritus.

Additional complaints include generalized itching, fatigue, recurrent low-grade fever, and arthralgia or myalgia.

Inspection may disclose mouth ulcers, dental caries and, possibly, enlarged salivary glands.

Palpable purpura may be evident if the patient also has vasculitis. Palpable lymph node enlargement may be the first sign of malignant lymphoma or pseudolymphoma.

Diagnostic tests

For a diagnosis of Sjögren's syndrome, symptoms must meet specific criteria. (See [Diagnosing Sjögren's syndrome.](#))

Laboratory test values in patients with Sjögren's syndrome include:

- elevated erythrocyte sedimentation rate in more than 90% of patients
- mild anemia and leukopenia in about 30% of patients
- hypergammaglobulinemia in about 50% of patients.

Various autoantibodies are also common, including antisalivary duct antibodies. Typically, 75% to 90% of patients test positive for rheumatoid factor, and between 50% and 80% of patients test positive for antinuclear antibodies.

Other test findings help support the diagnosis. To measure eye involvement, the patient may undergo Schirmer's test and a slit-lamp examination with rose bengal dye. Labial biopsy (to detect lymphoid foci) is a simple procedure with minimal risk and the only specific diagnostic technique.

Salivary gland involvement may be evaluated by measuring the volume of parotid saliva, by secretory sialography, and by salivary scintigraphy. Salivary gland biopsy results typically show lymphocytic infiltration in Sjögren's syndrome; lower lip biopsy findings show salivary gland infiltration by lymphocytes.

Diagnosis must rule out other causes of ocular and oral dryness, including sarcoidosis, endocrine disorders, anxiety or depression, and effects of certain therapies, such as radiation to the head and neck. In patients with salivary gland and lymph node enlargement, diagnosis also must rule out cancer.

Diagnosing Sjögren's syndrome

For a diagnosis of Sjögren's syndrome, the patient must have the following:

- keratoconjunctivitis sicca
- diminished salivary gland flow
- a positive salivary gland biopsy, showing mononuclear cell infiltration
- the presence of autoantibodies in a serum sample, indicating a systemic autoimmune process.

Treatment

The goal of treatment is to relieve the patient's symptoms. Treatment includes conservative measures to moisten the eyes and mouth. Artificial tears and sustained-release cellulose capsules help to relieve ocular dryness. If an eye infection develops, the patient receives antibiotics; topical steroids should be avoided.

Mouth dryness can be relieved by using a methylcellulose swab or spray and by drinking plenty of fluids, especially at mealtime. New agents for treatment of saliva hypofunction, such as pilocarpine hydrochloride and bromnetine, may be useful. Meticulous oral hygiene includes regular flossing, brushing, fluoride treatments, and frequent dental checkups.

Other treatment measures vary according to extraglandular effects. For parotid gland enlargement, treatment involves local heat and analgesia; for arthritis and arthralgias, hydroxychloroquine or nonsteroidal anti-inflammatory drugs. For interstitial pulmonary and renal disease, treatment relies on corticosteroids; for cutaneous vasculitis, corticosteroids are less effective.

For the patient with lymphoma, treatment includes a combination of chemotherapy, surgery, and radiation therapy.

Nursing diagnoses

- Altered oral mucous membrane
- Altered sexuality patterns
- Body image disturbance
- Fatigue
- Impaired skin integrity
- Impaired swallowing
- Impaired tissue

integrity u Pain u Risk for fluid volume deficit u Risk for infection u Risk for injury u Sensory or perceptual alterations u Sexual dysfunction

Key outcomes

- u The patient will state feelings of increased comfort.
- u The patient's oral mucosa membranes will be pink and moist.
- u The patient won't develop complications or they'll be minimized.
- u The patient will demonstrate oral hygiene practices.
- u The patient will acknowledge a problem or potential problem in sexual function.

Nursing interventions

- u Instill artificial tears as often as every 30 minutes to prevent eye damage (corneal ulcerations, corneal opacifications) from insufficient tear secretions. The patient may also benefit from instilling an eye ointment at bedtime or from using sustained-release cellulose capsules twice daily.
- u Provide plenty of fluids—especially water—for the patient to drink and sugarless chewing gum or candy to promote oral moisture without tooth decay.

Patient teaching

- u Teach the patient how to instill eyedrops, ointments, or sustained-release capsules.
- u Recommend that the patient wear sunglasses to protect her eyes from dust, wind, and strong light. Because dry eyes are more susceptible to infection, direct the patient to keep her face clean and to avoid rubbing her eyes.
- u Advise the patient to avoid saliva-decreasing drugs, such as atropine derivatives, antihistamines, anticholinergics, and antidepressants. Many nonprescription drugs contain these compounds.
- u Instruct the patient to perform meticulous oral hygiene, including rinsing her mouth with a sodium bicarbonate solution (1 tsp [5 ml] of sodium bicarbonate per 8 oz [240 ml] of water) to slow bacterial growth.
- u If mouth lesions make eating painful, suggest high-calorie, protein-rich liquid supplements to prevent malnutrition.
- u Encourage a nutritious diet in whatever form is most satisfactory to the patient.
- u Instruct the patient to avoid sugar, which contributes to dental caries, as well as tobacco, alcohol, and spicy, salty, or highly acidic foods, which cause mouth irritation.
- u Urge the patient to humidify her home and work environments to help relieve respiratory tract dryness. Suggest using normal saline solution (in drop or spray form) to relieve nasal dryness.
- u Advise the patient to avoid prolonged hot showers and baths and to use moisturizing lotions on dry skin. Suggest using a water-soluble gel as a vaginal lubricant.
- u As appropriate, refer the patient to the Sjögren's Syndrome Foundation for further information and support.

SYSTEMIC SCLEROSIS

Also called scleroderma, systemic sclerosis is a diffuse connective tissue disease. It's characterized by fibrotic, degenerative and, occasionally, inflammatory changes in skin, blood vessels, synovial membranes, skeletal muscles, and internal organs (especially the esophagus, intestinal tract, thyroid, heart, lungs, and kidneys).

Systemic sclerosis occurs in two distinct forms: localized (CREST syndrome) and diffuse. CREST syndrome, the more benign form, accounts for 80% of cases. It causes akinesis cutis, Raynaud's phenomenon, esophageal dysfunction, sclerodactyly, and telangiectasia. Diffuse systemic sclerosis, which accounts for 20% of cases, is marked by generalized skin thickening and the invasion of internal organ systems.

Eosinophilic fasciculitis, a rare variant of systemic sclerosis, causes skin changes similar to those of diffuse systemic sclerosis but limited to the fascia. Other differences from systemic sclerosis include eosinophilia, an absence of Raynaud's phenomenon, a good response to prednisone, and an increased risk of aplastic anemia.

Systemic sclerosis is twice as common in women as in men. It usually occurs between ages 30 and 50.

Causes

The cause of systemic sclerosis is unknown.

Complications

In advanced disease, cardiac and pulmonary fibrosis produce arrhythmias and dyspnea. Renal involvement usually causes malignant hypertension, the major cause of death from this disease. Other complications include renal failure, bowel obstruction and perforation, aspiration pneumonia, pulmonary hypertension, heart failure, cor pulmonale, respiratory failure, cardiomyopathy, and death.

Assessment findings

Ninety percent of patients complain of symptoms of Raynaud's phenomenon—blanching, cyanosis, and erythema of the fingers and toes—in response to stress or exposure to cold. These symptoms may precede diagnosis of systemic sclerosis by months or even years. As the disease progresses, the patient may complain of pain, stiffness, and swelling of fingers and joints.

Eventually, the patient may complain of frequent reflux, heartburn, dysphagia (in 90% of patients), and bloating after meals, all stemming from motility abnormalities, GI fibrosis, and malabsorption. These symptoms may cause her to eat less and lose weight. Other common GI complaints include abdominal distention, diarrhea, constipation, and malodorous floating stools.

In the early stages, inspection may reveal thickened, hidelike skin with loss of normal skin folds. You may also note telangiectasia and areas of pigmentation and depigmentation. The patient's fingers may have shortened because of progressive phalangeal resorption. You may observe slowly healing ulcers on the tips of the fingers or toes—the result of compromised circulation. These ulcers may lead to gangrene.

Later, inspection may disclose taut, shiny skin over the entire hand and forearm from skin thickening. Facial skin may also appear tight and inelastic, causing a wrinkle-free, masklike appearance and a pinched mouth. As tightening progresses, contractures may develop.

With pulmonary involvement, you may observe dyspnea and auscultate decreased breath sounds. With cardiac involvement, you may auscultate an irregular cardiac rhythm, pericardial friction rub, and an atrial gallop. Your assessment may also reveal hypertension if renal involvement occurs.

Diagnostic tests

Typical cutaneous changes provide the first clue to diagnosis. Results of diagnostic tests include the following:

- u Blood studies show mild anemia, slightly elevated erythrocyte sedimentation rate, hypergammaglobulinemia, positive rheumatoid factor (in 25% to 35% of patients), positive lupus erythematosus preparation, positive antinuclear antibody (low titer, speckled or nucleolar pattern) and, with diffuse systemic sclerosis, scleroderma antibody (in about 35% of patients).
- u Urinalysis reveals proteinuria, microscopic hematuria, and casts (with renal involvement).
- u Hand X-rays show terminal phalangeal tuft resorption, subcutaneous calcification, and joint space narrowing and erosion.
- u Chest X-rays demonstrate bilateral basilar pulmonary fibrosis.
- u GI X-rays disclose distal esophageal hypomotility and stricture, duodenal loop dilation, small-bowel malabsorption pattern, and large diverticula.

- u Pulmonary function studies reveal decreased diffusion, vital capacity, and lung compliance.
- u Electrocardiography detects possible nonspecific abnormalities related to myocardial fibrosis.
- u Skin biopsy shows possible changes consistent with the progress of the disease, such as marked thickening of the dermis and occlusive vessel changes.
- u Muscle biopsy reveals increased collagen deposition and accumulation of lymphocytes and plasma cells.

Treatment

No cure exists for systemic sclerosis. The goal of treatment is to preserve normal body functions and minimize complications. Immunosuppressants, such as chlorambucil, can help relieve symptoms. Used experimentally, corticosteroids and colchicine seem to stabilize symptoms; D-penicillamine may also be helpful. The patient should have her platelet levels monitored throughout immunosuppressant therapy. Experimental treatments include methotrexate, interferon-alpha, interferon-gamma, and FK 506.

Other treatment varies according to symptoms:

- u *Raynaud's phenomenon*. Treatment consists of various vasodilators, calcium channel blockers, and antihypertensive agents (such as methyldopa), along with intermittent cervical sympathetic blockade or, rarely, thoracic sympathectomy.
- u *Chronic digital ulcerations*. A digital plaster cast immobilizes the affected area, minimizes trauma, and maintains cleanliness. The patient may also need surgical debridement.
- u *Esophagitis with stricture*. The patient receives antacids, a histamine₂ antagonist (such as omeprazole, cimetidine, or ranitidine), a soft bland diet, and periodic esophageal dilatation.
- u *Small-bowel involvement*. The patient receives broad-spectrum antibiotics, such as erythromycin and tetracycline, to counteract bacterial overgrowth in the duodenum and jejunum related to hypomotility.
- u *Scleroderma kidney (with malignant hypertension and impending renal failure)*. The patient requires dialysis, antihypertensives, and calcium channel blockers; if hypertensive crisis develops, she may receive an angiotensin-converting enzyme inhibitor.
- u *Hand debilitation*. Treatment consists of physical therapy to maintain function, prevent contractures, and promote muscle strength; heat therapy to relieve joint stiffness; and patient teaching to help the patient perform activities of daily living.
- u *Pulmonary manifestations*. The patient receives oral or parenteral cyclophosphamide to relieve dyspnea, crackles, and symptoms of constrictive pulmonary function.

Nursing diagnoses

- u Activity intolerance
- u Altered nutrition: Less than body requirements
- u Altered tissue perfusion
- u Body image disturbance
- u Decreased cardiac output
- u Diarrhea
- u Fatigue
- u Fear
- u Impaired gas exchange
- u Impaired physical mobility
- u Impaired skin integrity
- u Ineffective family coping: Disabling
- u Ineffective individual coping
- u Pain
- u Risk for infection

Key outcomes

- u The patient will express feelings of comfort and decreased pain.
- u The patient will express positive feelings about herself.
- u The patient will maintain joint mobility and range of motion.
- u The patient's cardiac output will remain within normal range.
- u The patient's ventilation will remain within normal range.
- u The patient will exhibit healing of wounds and lesions.

Nursing interventions

- u Regularly assess mobility restrictions, vital signs, level of pain, intake and output, respiratory function, and daily weight.
- u Because of compromised digital circulation, don't perform fingerstick blood tests. Provide gloves or sock mittens after warming therapy.
- u Use plaster wraps or topical ointments to lessen the painful effects of digital ulcerations.
- u Use skin lubricants for dry skin.
- u Administer medications and monitor effects.
- u If the patient smokes, provide access to a smoking cessation program.
- u If the patient has cardiac and pulmonary fibrosis, provide rest and pulmonary exercises. Coughing, deep breathing, and chest physiotherapy will help to keep her lungs clear.
- u Provide a high-calorie diet that is smooth, cool, and palatable. Consult the dietitian to ensure that the patient has a nutritious, appealing diet. Treat GI disturbances as necessary with antacids and antidiarrheals.
- u If the patient suffers from delayed gastric emptying, offer her small, frequent meals and have her remain upright for at least 2 hours after eating. This should help to improve her digestion and maintain weight.
- u Whenever possible, let the patient participate in treatment by measuring her own intake and output, planning her own diet, assisting in dialysis, giving herself heat therapy, and performing prescribed exercises.
- u Help the patient and her family accept the fact that this condition is incurable. Encourage them to express their feelings, and help them cope with their fears and frustrations.

Patient teaching

- u Teach the patient and her family about the disease, its treatment, and relevant diagnostic tests.
- u Warn the patient to avoid air conditioning, cool showers and baths, and preparing food under cold running water, which may aggravate Raynaud's phenomenon. Also, advise her to wear gloves or mittens outside, even in mild weather; she may want to wear them indoors too.
- u Help the patient and her family adjust to her new body image and to the limitations and dependence that these changes cause. To reduce fatigue, teach the patient to pace her activities and organize schedules to include necessary rest and exercise.
- u Advise the patient to avoid contact with people who have active infections (especially of the upper respiratory tract).
- u Teach the patient and family members the purpose, administration, and adverse effects of all medications.
- u Teach range-of-motion exercises to be performed at home.
- u Teach methods of stress management.
- u Urge the patient to maintain a high-calorie diet. Warn her that supplements may not help her overall condition because they often contribute to diarrhea.
- u Advise the patient with GI involvement to avoid late-night meals, to elevate the head of the bed, and to use prescribed antacids and histamine₂ antagonists to reduce the incidence of reflux and resulting scarring.
- u Instruct the patient to cut food into small pieces, chew thoroughly, drink water to soften foods, and eat slowly. Encourage her to avoid gas-producing and spicy foods. Explain that she may have to limit certain foods and liquids for the rest of her life.
- u If the patient needs dialysis, refer her to the National Kidney Foundation's local support group. Reassure her that dialysis can be done close to or in her home.

VASCULITIS

Vasculitis is an autoimmune condition that includes a broad spectrum of disorders characterized by blood vessel inflammation and necrosis. Clinical effects depend on the vessels involved and reflect tissue ischemia caused by blood flow obstruction.

The prognosis varies with the disease form. For example, hypersensitivity vasculitis is usually benign and limited to the skin, whereas the more extensive polyarteritis nodosa can be rapidly fatal.

Except for the mucocutaneous lymph node syndrome, which affects only children, vasculitis can affect a person at any age. Vasculitis may be a primary disorder or

secondary to other disorders, such as rheumatoid arthritis and systemic lupus erythematosus.

Causes and pathophysiology

Exactly how vascular damage develops in vasculitis isn't well understood. Some think that vasculitis may follow a serious infectious disease, such as hepatitis B or bacterial endocarditis, and be related to high doses of antibiotics.

Current theory holds that vasculitis is initiated by excessive circulating antigen, which triggers the formation of soluble antigen-antibody complexes. Then, because the reticuloendothelial system can't effectively clear these complexes, they're deposited in blood vessel walls (type III hypersensitivity). Theorists think that increased vascular permeability (associated with the release of vasoactive amines by platelets and basophils) enhances this deposition. The deposited complexes activate the complement cascade. The result is chemotaxis of neutrophils, which release lysosomal enzymes. This, in turn, causes vessel damage and necrosis. These effects may precipitate thrombosis, occlusion, hemorrhage, and tissue ischemia.

An additional factor in certain types of vasculitis is the formation of autoantibodies directed at the body's own cellular and extracellular proteins, which can lead to the activation of inflammatory cells or cytotoxicity (a type II hypersensitivity reaction). Patented antibodies being studied include those directed against cytoplasmic antigens of neutrophils and monocytes (antineutrophil cytoplasmic antibodies known as cANCA or pANCA) and those directed against surface antigens of endothelial cells (antiendothelial cell antibody, or AECA). The exact role of autoantibodies remains unclear.

Another mechanism that may contribute to vascular damage is the cell-mediated (T-cell) immune response, whereby circulating antigen triggers sensitized lymphocytes to release soluble mediators. This attracts macrophages, which release intracellular enzymes, causing vascular damage. They can also transform into the epithelioid and multinucleated giant cells that typify the granulomatous vasculitides. Macrophagic phagocytosis of immune complexes enhances granuloma formation

Atopic individuals can develop vasculitis after exposure to allergens. This type I hypersensitivity can lead to mast cell degranulation, hypereosinophilia, and inflammation, which, in turn, can lead to vasculitis.

Complications

Renal, cardiac, and hepatic involvement can be fatal if vasculitis isn't treated. Renal failure, renal hypertension, glomerulitis, fibrous scarring of the lung tissue, cerebrovascular accident, and GI bleeding are a few of the severe complications associated with vasculitis. Others include necrotizing vasculitis, spontaneous hemorrhage, intestinal obstruction, myocardial infarction, pericarditis, and rupture of mesenteric aneurysms.

Assessment findings

Patient history and physical assessment findings vary, depending on the blood vessels involved. (See [Types of vasculitis.](#))

Diagnostic tests

Not all vasculitis disorders can be diagnosed definitively by specific tests. The most useful general diagnostic procedure is biopsy of the affected vessel. In some disorders, arteriography may be informative.

Treatment

Appropriate treatment minimizes irreversible tissue damage associated with ischemia. In primary vasculitis, treatment may involve removal of an offending antigen or use of anti-inflammatory or immunosuppressant drugs. Antigenic drugs, food, and other offending environmental substances should be identified and eliminated, if possible.

Drug therapy in primary vasculitis typically involves daily administration of low-dose oral cyclophosphamide and corticosteroids. Antihypertensives and analgesics for acute pain are also given.

In rapidly fulminant vasculitis, the daily cyclophosphamide dose may be increased significantly for the first 2 to 3 days and then returned to the regular dose. In addition, the patient usually receives prednisone in daily divided doses for 7 to 10 days, with consolidation to a single morning dose by 2 to 3 weeks. When the vasculitis appears to be in remission, or when prescribed cytotoxic drugs take full effect, corticosteroid therapy is tapered to a single daily dose and then to an alternate-day schedule that may continue for 3 to 6 months.

ADVANCED PRACTICE

Types of vasculitis

TYPE	VESSELS INVOLVED	PEAK AGE AT ONSET (YEARS)	MALE:FEMALE RATIO	SIGNS AND SYMPTOMS	DIAGNOSIS
Polyarteritis nodosa (PAN)	Small to medium-sized arteries throughout the body. Lesions tend to be segmental, occur at bifurcations and branchings of arteries, and spread distally to arterioles. In severe cases, lesions circumferentially involve adjacent veins. They don't involve arterioles or venules.	40 to 60	2:1	Hypertension, abdominal pain, myalgia, headache, arthralgia, weakness, weight loss, mononeuropathy, and polyneuropathy	History of symptoms, elevated blood urea nitrogen and serum creatinine levels, elevated erythrocyte sedimentation rate (ESR), leukocytosis, anemia, thrombocytosis, depressed C3 complement, rheumatoid factor greater than 1:60, circulating immune complexes (tissue biopsy shows necrotizing vasculitis and immune deposits)
Allergic angiitis and granulomatosis (Churg-Strauss syndrome)	Small to medium-sized arteries throughout the body. Lesions tend to be segmental, occur at bifurcations and branchings of arteries, and spread distally to arterioles. In severe cases, lesions circumferentially involve adjacent veins. They don't involve arterioles or venules.	40 to 60	2:1	Resembles PAN with hallmark of severe pulmonary involvement	History of asthma, eosinophilia, increased serum IgI (tissue biopsy shows granulomatous inflammation with eosinophilic infiltration)
Microscopic polyangiitis	Small to medium-sized arteries and small vessels (arterioles, capillaries, venules) of the lungs and kidneys (different from PAN, in that smaller vessels are involved)	40 to 60	1:1	Fever, pulmonary congestion, hemoptysis, hematuria, abnormal urine sediment, weight loss, malaise	Involvement of lungs and kidneys, elevated ESR, 50% of patients positive for pANCA (tissue biopsy shows necrotizing vasculitis without immune deposits or granuloma formation)
Wegener's granulomatosis	Medium-sized to large vessels of the upper and lower respiratory tract and kidneys; may also involve small arteries and veins	40 to 50	1:1	Fever, pulmonary congestion, cough, malaise, anorexia, weight loss, mild to severe hematuria	Leukocytosis; elevated ESR, IgA, and IgG; low titer rheumatoid factor; circulating immune complexes; antineutrophil cytoplasmic antibody in more than 90% of patients, (renal biopsy shows focal segmental glomerulonephritis; tissue biopsy shows necrotizing vasculitis with granulomatous inflammation)
Temporal arteritis	Medium-sized to large arteries, most commonly branches of the carotid artery; involvement may skip segments	60 to 75	1:3	Fever, myalgia, jaw claudication, visual changes, headache (associated with polymyalgia rheumatica)	Decreased hemoglobin (Hb), elevated ESR (tissue biopsy shows panarteritis with infiltration of mononuclear cells, giant cells within vessel wall [seen in 50%], fragmentation of internal elastic lamina, and proliferation of intima)
Takayasu's arteritis (aortic arch syndrome)	Medium-sized to large arteries, particularly the aortic arch and its branches and, possibly, the pulmonary artery	15 to 25	1:9	Malaise, pallor, nausea, night sweats, arthralgia, anorexia, weight loss, pain or paresthesia distal to affected area, bruits, loss of distal pulses, syncope and, if carotid artery is involved, diplopia and transient blindness; may progress to heart failure or cerebrovascular accident	Decreased Hb, leukocytosis, positive LE cell preparation, and elevated ESR (arteriography shows calcification and obstruction of affected vessels; tissue biopsy shows inflammation of adventitia and intima of vessels and thickening of vessel walls)
Hypersensitivity vasculitis	Small vessels, especially of the skin	30 to 50	1:1	Palpable purpura, papules, nodules, vesicles, bullae, ulcers, chronic or recurrent urticaria	History of exposure to antigen, such as microorganism or drug (tissue biopsy shows leukocytoclastic angiitis, usually in postcapillary venules)
Mucocutaneous lymph node syndrome (Kawasaki syndrome)	Small to medium-sized vessels, primarily of the lymph nodes; may progress to involve coronary arteries	1 to 5	1:1	Fever; nonsuppurative cervical adenitis; edema; congested conjunctivae; erythema of oral cavity, lips, and palms; desquamation of fingertips; may progress to arthritis, myocarditis, pericarditis, myocardial infarction, and cardiomegaly	History of symptoms, elevated ESR (tissue biopsy shows intimal proliferation and infiltration of vessel walls with mononuclear cells; echocardiography is necessary)
Henoch-Schönlein purpura	Small vessels (arterioles, venules, capillaries), especially of skin and GI tract	5 to 20	1:1	Abdominal pain, bloody diarrhea, palpable purpura, maculopapular rash	History of symptoms; elevated serum IgA levels (tissue biopsy shows leukocytoclastic vasculitis)
Behçet's disease	Small vessels, primarily of the mouth and genitalia but also of the eyes, skin, joints, GI tract, and central nervous system	20 to 25	1:1	Recurrent oral ulcers, eye lesions, genital lesions, cutaneous lesions	History of symptoms

In secondary vasculitis, treatment focuses on the underlying disorder.

Nursing diagnoses

u Activity intolerance
 u Altered nutrition: Less than body requirements
 u Altered oral mucous membrane
 u Altered tissue perfusion (cardiopulmonary)
 u Body image disturbance
 u Decreased cardiac output
 u Hyperthermia
 u Impaired gas exchange
 u Impaired physical mobility
 u Impaired skin integrity
 u Ineffective breathing pattern
 u Pain
 u Risk for infection
 u Risk for injury
 u Sensory or perceptual alterations

Key outcomes

- u The patient will express feelings of comfort and relief of pain.
- u The patient will maintain body temperatures at normothermic levels.
- u The patient will express positive feelings about self.
- u The patient will attain hemodynamic stability.
- u The patient will demonstrate adequate ventilation.
- u The patient won't develop complications.

Nursing interventions

- u Assess for dry nasal mucosa in patients with Wegener's granulomatosis. Instill nose drops to lubricate the mucosa and to minimize crusting, or irrigate the nasal passages with warm normal saline solution.
- u Monitor vital signs and neurologic status. Use a Doppler ultrasonic flowmeter, if available, to auscultate blood pressure in patients who have Takayasu's arteritis and whose peripheral pulses are difficult to palpate.
- u Measure intake and output. Check daily for edema. Keep the patient well hydrated (about 3 L of fluid daily) to reduce the risk of hemorrhagic cystitis associated with cyclophosphamide therapy. Weigh the patient daily.
- u Monitor the patient's white blood cell and platelet counts during cyclophosphamide therapy to avoid severe leukopenia and thrombocytopenia. Assess for GI disturbances and monitor renal function tests.
- u Watch for signs and symptoms of organ involvement and treat accordingly.
- u To prevent falls ensure that the patient with decreased visual acuity has a safe environment.
- u Regulate environmental temperature to prevent additional vasoconstriction caused by cold.
- u Provide emotional support to help the patient and his family cope with an altered body image—the result of the disorder or its therapy. (For example, with Wegener's granulomatosis, saddle nose may develop. Corticosteroid therapy may cause weight gain, and cyclophosphamide therapy may cause alopecia.)

Patient teaching

- u Teach the patient and family members about the disease process.
- u Encourage the use of a smoking cessation program, when appropriate.
- u Teach the patient and family members to recognize adverse effects of drug therapy (for example, with corticosteroids) and to watch for signs of bleeding: black, tarry stools; hemoptysis; epistaxis; and multiple ecchymoses. Instruct them to report any of these findings to the doctor.
- u Advise the patient to wear warm clothes and gloves when going outside in cold weather.

Immunodeficiency disorders

Immunodeficiency disorders are caused by an absent or a depressed immune response and manifest in various forms. Immunodeficiency disorders include acquired immunodeficiency syndrome, chronic mucocutaneous candidiasis, common variable immunodeficiency, complement deficiencies, DiGeorge syndrome, selective IgA deficiency, and severe combined immunodeficiency disease.

ACQUIRED IMMUNODEFICIENCY SYNDROME

Currently one of the most widely publicized diseases, acquired immunodeficiency syndrome (AIDS) is marked by progressive failure of the immune system. Although it's characterized by gradual destruction of cell-mediated (T-cell) immunity, it also affects humoral immunity and even autoimmunity because of the central role of the CD4⁺ T lymphocyte in immune reactions. The resultant immunodeficiency makes the patient susceptible to opportunistic infections, unusual cancers, and other abnormalities that define AIDS.

The syndrome was first described by the Centers for Disease Control and Prevention (CDC) in 1981. Since then, the CDC has declared a case surveillance definition for AIDS and has modified it several times, most recently in 1993.

A retrovirus—the human immunodeficiency virus (HIV) type I—is the primary causative agent. Transmission of HIV occurs by contact with infected blood or body fluids and is associated with identifiable high-risk behaviors. It's therefore disproportionately represented in homosexual and bisexual men, I.V. drug users, neonates of HIV-infected women, recipients of contaminated blood or blood products (dramatically decreased since mid-1985), and heterosexual partners of people in the former groups. Because of similar routes of transmission, AIDS shares epidemiologic patterns with hepatitis B and sexually transmitted diseases (STDs).

The natural history of AIDS infection begins with infection by the HIV retrovirus, which is detectable only by laboratory tests, and ends with the severely immunocompromised, terminal stage of this disease. Depending on individual variations and the presence of cofactors that influence progression, the time elapsed from acute HIV infection to the appearance of symptoms (mild to severe) to the diagnosis of AIDS and, eventually, to death varies greatly. Combination antiretroviral therapy (for example, with zidovudine, zalcitabine, and others) and treatment and prophylaxis of common opportunistic infections can delay the natural progression of HIV disease and prolong survival.

Causes

AIDS results from infection with HIV, which strikes cells bearing the CD4⁺ antigen; the latter (normally a receptor for major histocompatibility complex molecules) serves as a receptor for the retrovirus and lets it enter the cell. HIV prefers to infect the CD4⁺ lymphocyte or macrophage but may also infect other CD4⁺ antigen-bearing cells of the GI tract, uterine cervical cells, and neuroglial cells. The virus gains access by binding to the CD4⁺ molecule on the cell surface along with a coreceptor (thought to be the chemokine receptor CCR5). After invading a cell, HIV replicates, leading to cell death, or becomes latent.

HIV infection leads to profound pathology, either directly, through destruction of CD4⁺ cells, other immune cells, and neuroglial cells, or indirectly, through the secondary effects of CD4⁺ T-cell dysfunction and resultant immunosuppression.

Transmission

HIV is transmitted by direct inoculation during intimate sexual contact, especially associated with the mucosal trauma of receptive rectal intercourse; transfusion of contaminated blood or blood products (a risk diminished by routine testing of all blood products); sharing of contaminated needles; and transplacental or postpartum transmission from infected mother to fetus (by cervical or blood contact at delivery and in breast milk).

Accumulating evidence suggests that HIV isn't transmitted by casual household or social contact. The average time between exposure to the virus and diagnosis of AIDS is 8 to 10 years, but shorter and longer incubation times have been recorded.

Complications

The infection process takes three forms:

- u immunodeficiency (opportunistic infections and unusual cancers)
- u autoimmunity (lymphoid interstitial pneumonia, arthritis, hypergammaglobulinemia, and production of autoimmune antibodies)
- u neurologic dysfunction (AIDS dementia complex, HIV encephalopathy, and peripheral neuropathies).

Assessment findings

HIV infection manifests itself in many ways. After a high-risk exposure and inoculation, the infected person usually experiences a mononucleosis-like syndrome, which may be attributed to a flu or other virus and then may remain asymptomatic for years. In this latent stage, the only sign of HIV infection is laboratory evidence of seroconversion.

When symptoms appear, they may take many forms:

- persistent generalized adenopathy
- nonspecific symptoms (weight loss, fatigue, night sweats, fevers)
- neurologic symptoms resulting from HIV encephalopathy
- opportunistic infection or cancer.

The clinical course varies slightly in children with AIDS. Their incubation time is shorter, with a mean of 17 months. Signs and symptoms resemble those in adults, except for findings related to STDs. Children show virtually all the opportunistic infections observed in adults, with a higher incidence of bacterial infections: otitis media, sepsis, chronic salivary gland enlargement, lymphoid interstitial pneumonia, *Mycobacterium avium* complex function, and pneumonias, including *Pneumocystis carinii*.

Diagnostic tests

The CDC defines AIDS as an illness characterized by one or more “indicator” diseases coexisting with laboratory evidence of HIV infection and other possible causes of immunosuppression. The CDC's current AIDS surveillance case definition requires laboratory confirmation of HIV infection in people who have a CD4⁺ T-cell count of 200 cells/μl or who have an associated clinical condition or disease.

Antibody tests

The most commonly performed tests, antibody tests indicate HIV infection indirectly by revealing HIV antibodies. The recommended protocol requires initial screening of people and blood products with an enzyme-linked immunosorbent assay (ELISA). A positive ELISA should be repeated and then confirmed by an alternative method, usually the Western blot or an immunofluorescence assay. Antibody testing isn't always reliable. Because the body takes a variable amount of time to produce a detectable level of antibodies, a “window” varying from a few weeks to as long as 35 months in one documented case allows an HIV-infected person to test negative for HIV antibodies.

Antibody tests are also unreliable in neonates because transferred maternal antibodies persist for 6 to 10 months. To overcome these problems, direct testing is performed to detect HIV. Direct tests include antigen tests (p24 antigen), HIV cultures, nucleic acid probes of peripheral blood lymphocytes with determination of HIV-1 RNA levels, and the polymerase chain reaction.

Additional tests to support the diagnosis and help evaluate the severity of immunosuppression include CD4⁺ and CD8⁺ T-lymphocyte subset counts, erythrocyte sedimentation rate, complete blood count, anergy testing, and serum beta₂-microglobulin, p24 antigen, and neopterin levels. Because many opportunistic infections in AIDS patients are reactivations of previous infections, patients are also tested for syphilis, hepatitis B, tuberculosis, toxoplasmosis and, in some areas, histoplasmosis.

Treatment

No cure has yet been found for AIDS; however, primary therapy for HIV infection includes three types of antiretroviral agents:

- protease inhibitors (PIs), such as ritonavir, indinavir, nelfinavir, and saquinavir
- nucleoside reverse transcriptase inhibitors (NRTIs), such as zidovudine, didanosine, zalcitabine, lamivudine, and stavudine
- nonnucleoside reverse transcriptase inhibitors (NNRTIs), such as nevirapine and delavirdine.

These agents, used in various combinations, are designed to inhibit HIV viral replication. Other potential therapies include immunomodulatory agents designed to boost the weakened immune system and anti-infective and antineoplastic agents to combat opportunistic infections and associated cancers; some are used prophylactically to help patients resist opportunistic infections.

Treatment protocols combine two or more agents in an effort to gain the maximum benefit with the fewest adverse reactions. Such regimens typically include one PI plus two NRTIs, or one NNRTI plus two NRTIs. Many variations and drug interactions are under study. Combination therapy helps to inhibit the production of resistant, mutant strains. Supportive treatments help to maintain nutritional status and relieve pain and other distressing physical and psychological symptoms.

Many pathogens in AIDS respond to anti-infective drugs but tend to recur after treatment ends. For this reason, most patients need continuous anti-infective treatment, presumably for life or until the drug is no longer tolerated or effective.

Treatment with zidovudine has proved effective in slowing the progression of HIV infection, decreasing opportunistic infections, and prolonging survival, but it often produces serious adverse reactions and toxicities. The drug is usually combined with other agents (such as lamivudine) but has also been used as a single agent for pregnant HIV-positive women. The recommendation is to take 100 mg every 4 hours for a total daily dose of 600 mg, or 500 mg if the patient doesn't want to interrupt sleep. Other NRTIs, such as didanosine and zalcitabine, may be used in combination regimens for patients who can't tolerate or no longer respond to zidovudine.

Nursing diagnoses

▫ Activity intolerance ▫ Altered family processes ▫ Altered health maintenance ▫ Altered nutrition: Less than body requirements ▫ Altered oral mucous membrane ▫ Altered protection ▫ Altered sexuality patterns ▫ Body image disturbance ▫ Fatigue ▫ Hopelessness ▫ Hyperthermia ▫ Impaired skin integrity ▫ Impaired tissue integrity ▫ Ineffective individual coping ▫ Knowledge deficit ▫ Powerlessness ▫ Risk for fluid volume deficit ▫ Risk for infection ▫ Social isolation

Key outcomes

- The patient won't experience fever, chills, and other signs and symptoms of illness.
- The patient will demonstrate use of protective measures, including conserving energy, maintaining a balanced diet, and getting plenty of rest.
- The patient will use support systems to assist with coping.
- The patient will voice feelings about changes in sexual identity.
- The patient will perform health maintenance activities according to the level of his ability.
- The patient won't develop complications of illness.
- The patient will comply with the treatment regimen.

Nursing interventions

- Recognize that a diagnosis of AIDS is profoundly distressing because of the disease's social impact and the discouraging prognosis. The patient may lose his job and financial security as well as the support of family and friends. Coping with an altered body image, the emotional burden of serious illness, and the threat of death may overwhelm the patient.
- Monitor the patient for fever, noting any pattern, and for signs of skin breakdown, cough, sore throat, and diarrhea. Assess for swollen, tender lymph nodes, and check laboratory values regularly.
- Avoid glycerine swabs for mucous membranes. Try normal saline or bicarbonate mouthwash for daily oral rinsing.

- u Record the patient's caloric intake.
- u Ensure adequate fluid intake during episodes of diarrhea.
- u Provide meticulous skin care, especially in the debilitated patient.
- u Encourage the patient to maintain as much physical activity as he can tolerate. Make sure his schedule includes time for both exercise and rest.
- u If the patient develops Kaposi's sarcoma, monitor the progression of lesions.
- u Monitor opportunistic infections or signs of disease progression, and treat infections as ordered. (See [Preventing AIDS transmission.](#))

Patient teaching

- u Combination antiretroviral therapy is used to maximally suppress HIV replication, thereby improving survival. Poor drug compliance may lead to resistance and treatment failure. Patients must understand that medication regimens must be followed closely and may be required for many years, if not throughout life.

PREVENTION

Preventing AIDS transmission

Health care workers and the public are advised to use precautions in all situations that risk exposure to blood, body fluids, and secretions. Diligently practicing standard precautions can prevent the inadvertent transmission of acquired immunodeficiency syndrome (AIDS), hepatitis B, and other infectious diseases that are transmitted by similar routes. In addition:

- u Educate the patient and his family members, sexual partners, and friends about disease transmission and prevention of extending the disease to others.
- u Inform the patient not to donate blood, blood products, organs, tissue, or sperm.
- u If the patient uses I.V. drugs, caution him not to share needles.
- u Inform the patient that high-risk sexual practices for AIDS transmission are those that exchange body fluids, such as vaginal or anal intercourse without a condom.
- u Discuss safe sexual practices, such as hugging, petting, mutual masturbation, and protected sexual intercourse. Abstaining is also the most protective method of not transmitting the disease.
- u Advise female patients of childbearing age to avoid pregnancy. Explain that an infant may become infected before birth, during delivery, or during breast-feeding.

- u Urge the patient to inform potential sexual partners and health care workers that he has HIV infection.
- u Teach the patient how to identify the signs of impending infection, and stress the importance of seeking immediate medical attention.
- u Involve the patient with hospice care early in treatment so he can establish a relationship.
- u If the patient develops AIDS dementia in stages, help him understand the progression of this symptom.

CHRONIC MUCOCUTANEOUS CANDIDIASIS

Also called moniliasis, chronic mucocutaneous candidiasis affects males and females alike and usually develops in childhood. This form of candidiasis is characterized by repeated infection with *Candida albicans*.

In some patients with chronic mucocutaneous candidiasis, an autoimmune response affects the endocrine system, inducing various endocrinopathies. In these patients, the prognosis depends on the severity of the associated endocrinopathy.

Causes

Although no characteristic immune system defects are known to cause this infection, anergy may play a role. Many patients have a diminished response to various antigens or to *Candida* organisms alone. In some patients, anergy may result from deficient microphage inhibitory factor, a mediator normally produced by lymphocytes. This leads researchers to think that the disease may result from an inherited defect in cell-mediated (T-cell) immunity. (Humoral immunity, mediated by B cells, remains intact and produces a normal antibody response to *C. albicans*.)

Complications

Patients with chronic mucocutaneous candidiasis seldom develop systemic infection. However, hepatic and endocrine failure associated with this disorder can be fatal. Patients with associated endocrinopathy seldom live to age 40.

Other complications include psychiatric disorders associated with physical disfigurement and multiple endocrine aberrations, Addison's disease, nephrotoxicity, hypoparathyroidism, hypocalcemia with seizures, diabetes mellitus, pernicious anemia, corticotropin deficiency, and ovarian failure.

Assessment findings

The patient may report speech and eating problems because of lesions of the mouth, nose, and palate. On inspection, you may see large, circular lesions on the skin, mucous membranes, nails, and vagina. The lesions may be beefy red and denuded.

The infection seldom produces systemic signs or symptoms, but in late stages, it can be associated with recurrent respiratory tract infections. Other associated conditions include severe viral infections that may precede the onset of endocrinopathy and, sometimes, hepatitis. If endocrinopathy develops as the disease progresses, the patient may complain of signs and symptoms related to the organs involved. For example, tetany commonly occurs as a result of hypoparathyroidism. You may also recognize symptoms of Addison's disease, hypothyroidism, diabetes mellitus, and pernicious anemia.

Diagnostic tests

Laboratory findings usually show a normal or decreased circulating T-cell count. In most patients, skin testing fails to detect delayed hypersensitivity to *Candida* even during the infectious stage (probably because migration inhibiting factor, which appears when T cells are activated, may not respond to *Candida*).

Abnormalities not related to immune dysfunction result from endocrinopathy. Laboratory findings may point to hypocalcemia, abnormal hepatic function, hyperglycemia, iron deficiency, and abnormal vitamin B₁₂ absorption (pernicious anemia).

Before diagnosing the patient's disease as chronic mucocutaneous candidiasis, diagnosis must rule out other immunodeficiency disorders associated with chronic candidal infection, especially DiGeorge syndrome, ataxia-telangiectasia, and severe combined immunodeficiency disease. All these diseases produce severe immunologic defects.

After diagnosis, typical studies include evaluation of adrenal, pituitary, thyroid, gonadal, pancreatic, and parathyroid functions as well as other careful diagnostic follow-up.

Treatment

Infection control is the main goal of treatment. Although miconazole and nystatin can produce sustained improvement, these topical antifungal agents ultimately fail to

control infection.

Systemic infections warrant vigorous treatment. Oral ketoconazole and injections of thymosin and levamisole can have a positive effect. Acyclovir may be indicated in viral infections. Iron replacement therapy (administered orally or I.M.) may also be necessary.

Nursing diagnoses

u Altered oral mucous membrane u Body image disturbance u Fatigue u Impaired skin integrity u Impaired tissue integrity u Ineffective individual coping u Pain u Risk for infection u Risk for injury u Sexual dysfunction

Key outcomes

- u The patient will express feelings of comfort and decreased pain.
- u The patient will express positive feelings about self.
- u The patient's skin integrity will remain intact.
- u The patient won't develop complications or they'll be minimized.
- u The patient will express feelings about sexual dysfunction.

Nursing interventions

- u Because candidal infections can be painful, provide meticulous skin and mucous membrane care to help prevent infection.
- u Supply bland, cool foods along with topical anesthetics for the patient with a sore mouth and tongue.
- u Encourage a nutritious diet as tolerated, and provide dietary teaching as indicated.
- u Give calcium infusions, as ordered, when endocrinopathy produces hypocalcemia. Monitor vital signs and cardiac rhythm during infusion therapy.
- u Refer the patient for appropriate counseling, for example, to obtain help coping with disfigurement or sexual dysfunction.

Patient teaching

- u Teach the patient and family members about the disease process.
- u Teach the patient and family members about medications, including information about the drug's purpose, schedule, and adverse effects.
- u Teach the patient to recognize and report progressive manifestations of the disease.
- u Emphasize the importance of taking ordered medications properly and for the prescribed length of time.
- u Instruct the patient to schedule and keep appointments with an endocrinologist for regular medical checkups.

COMMON VARIABLE IMMUNODEFICIENCY

Common variable immunodeficiency is marked by progressive deterioration of humoral (B-cell) immunity, which results in increased susceptibility to infection. Unlike X-linked agammaglobulinemia, this disorder usually produces symptoms after infancy and childhood, manifesting itself between ages 25 and 40. (See [X-linked infantile agammaglobulinemia](#).) It affects men and women equally and usually doesn't interfere with a normal life span or with normal pregnancy and offspring.

Common variable immunodeficiency (also known as acquired agammaglobulinemia or common variable agammaglobulinemia) may be associated with autoimmune diseases, such as systemic lupus erythematosus, rheumatoid arthritis, hemolytic anemia, and pernicious anemia, and with cancers, such as leukemia and lymphoma.

Causes

No one knows what causes common variable immunodeficiency. Most patients have a normal circulating B-cell count but defective synthesis or release of immunoglobulins. Many also exhibit progressive deterioration of cell-mediated (T-cell) immunity (detected by delayed hypersensitivity in skin testing).

X-linked infantile agammaglobulinemia

In X-linked infantile agammaglobulinemia (Bruton's agammaglobulinemia), all five immunoglobulins (IgM, IgG, IgA, IgD, and IgE), circulating B cells, and plasma cells in all lymphoid tissues are missing or deficient. (T cells are intact.) B cells and their precursors in the bone marrow and peripheral blood fail to mature and secrete immunoglobulins. This congenital disorder causes recurrent infections almost exclusively in male infants, affecting 1 in 50,000 to 100,000 neonates.

The infant typically stays symptom-free until age 6 months, when transplacental maternal immunity ends. Typical early infections include recurrent bacterial otitis media, pneumonia, dermatitis, bronchitis, and meningitis. Lymphadenopathy and splenomegaly are usually absent.

Common complications include hepatitis, enteroviral infections, and poliovirus. Infections usually leave some permanent damage, especially in the nervous or respiratory system. Dental caries, chronic otitis media, chronic sinusitis, pneumonia, failure to thrive, encephalitis, meningitis, and neoplastic disease are other complications.

A reliable diagnosis is difficult because recurrent infections are common even in normal infants. A process such as immunoelectrophoresis of serum detects missing or decreased IgM, IgA, and IgG. Antigenic stimulation confirms the inability to produce specific antibodies.

The prognosis is good with early treatment unless the infant contracts vaccine-induced polio or a persistent viral infection. Infection control and immune globulin replacement therapy are necessary. Other treatments include corticosteroid and antimetabolite therapy for dermatomyositis with echovirus.

Although no clear proof of genetic influence on disease occurrence exists, the disease does occur in siblings. Additionally, family members have a higher incidence of hypogammaglobulinemia, selective IgA deficiency, and autoimmune disease.

Complications

A spruelike syndrome with diarrhea, malabsorption, steatorrhea, and a protein-losing enteropathy (like inflammatory bowel disease) typically complicates common variable immunodeficiency. *Giardia lamblia* GI infection and upper and lower respiratory tract infections are also typical complications.

Other complications include conjunctivitis, dental caries, chronic otitis media, chronic sinusitis, failure to thrive, encephalitis, meningitis, neoplastic disorders, thrombocytopenia, granuloma, hemolytic anemia, oligoarthritis, and dermatomyocitis.

Assessment findings

Review the patient's history. Investigate disorders such as pyogenic bacterial infections that are characteristic of common variable immunodeficiency. Also, be alert for a history of chronic rather than acute infections (as in X-linked hypogammaglobulinemia).

Recurrent sinopulmonary infections, chronic bacterial conjunctivitis, atrophic gastritis with pernicious anemia, and malabsorption (often associated with infestation by *G. lamblia*) are usually the first clues to common variable immunodeficiency. Also suspect the disorder in an adult patient with unexplained bronchiectasis.

Other initial signs and symptoms include fever, weight loss, cough, abnormal sputum, rhinorrhea, sinus tenderness, tachypnea, shortness of breath, otitis media,

lymphadenopathy, fatigue, arthralgia, proximal muscle weakness, bruising or bleeding, a palpable spleen, and palpable lymph nodes.

Patients with common variable immunodeficiency can develop a nonseptic inflammatory arthritis similar to rheumatoid arthritis. Because septic arthritis has also been reported, a search for the inflicting organism should be undertaken in patients with new joint pain and inflammation, particularly if only one joint is affected.

Diagnostic tests

Characteristic diagnostic markers in this disorder are decreased serum immunoglobulin (Ig) M, IgA, and IgG levels detected by immunoelectrophoresis and a normal circulating B-cell count. Plasma cells seldom appear in the lymph nodes, bone marrow, and spleen but may be found in intestinal lamina propria. Rheumatoid factor and positive Coombs' test findings may be present. Antigenic stimulation confirms an inability to produce specific antibodies; cell-mediated immunity may be intact or delayed.

X-rays usually show signs of chronic lung disease or sinusitis. Regular X-ray and pulmonary function studies monitor infection in the lungs.

Treatment

Care and treatment measures for patients with common variable immunodeficiency are essentially the same as for patients with X-linked agammaglobulinemia. Antibiotics are preferred for combating infection. Weekly or monthly injections of immune globulin help to maintain the immune response. Because immune globulin is composed primarily of IgG, the patient may also need fresh frozen plasma infusions to provide IgA and IgM.

Chest physiotherapy may help to forestall or clear lung infections. Surgery may be indicated for sinus drainage; tubes, for chronic otitis media; and splenectomy, for hemolytic anemia.

Nursing diagnoses

⌞ Altered health maintenance ⌞ Altered nutrition: Less than body requirements ⌞ Altered protection ⌞ Diarrhea ⌞ Fluid volume deficit ⌞ Impaired gas exchange ⌞ Ineffective airway clearance ⌞ Pain ⌞ Risk for infection ⌞ Risk for injury

Key outcomes

- ⌞ The patient won't experience chills, fever, and other signs and symptoms of illness.
- ⌞ The patient will demonstrate the use of protective measures, including conserving energy, maintaining a balanced diet, and getting plenty of rest.
- ⌞ The patient and family members will identify strengths and weaknesses in maintaining health.
- ⌞ The patient will express feelings of comfort and a decreased level of pain.
- ⌞ The patient will expectorate sputum effectively.

Nursing interventions

- ⌞ Monitor the patient's vital signs closely for evidence of fever and, possibly, infection.
- ⌞ Encourage an age-appropriate diet.
- ⌞ Encourage rest during periods of infection.
- ⌞ Monitor pulmonary status.
- ⌞ Because immune globulin administration causes significant pain, administer injections deep into a large muscle mass, such as the gluteal or thigh muscle. Massage well. If the dose is more than 1.5 ml, divide it and inject the divided doses into more than one site. For frequent injections, rotate the injection sites. Because immune globulin is composed mainly of IgG, the patient may also need fresh frozen plasma infusions to provide IgA and IgM.
- ⌞ As ordered, administer antibiotics, antipyretics, and chest physiotherapy, including additional hydration and mucolytic, to forestall or treat infection.
- ⌞ Institute diet therapy, as recommended, to counteract the depleting effects of malabsorption syndrome and anemias. Be sure to involve the dietitian and doctor in devising an optimal nutrition plan.

Patient teaching

- ⌞ Teach the patient and family members about the disease process.
- ⌞ To avoid severe infection, teach the patient and his family how to recognize early signs and symptoms. Instruct them to avoid crowds and people who have active infections.
- ⌞ Encourage regular hearing tests.
- ⌞ Teach the importance of regular medical checkups.
- ⌞ Stress the importance of good nutrition and regular follow-up care. A cooked-food diet (one that contains no raw foods) may reduce bacteria in foods and beverages.
- ⌞ Explain to the patient that secondary conditions can coexist with the immunodeficiency. Advise him that these conditions may require additional or specialized treatment.

COMPLEMENT DEFICIENCIES

Complement is a series of circulating enzymatic serum proteins with nine functional components, labeled C1 through C9. Complement deficiency or dysfunction may increase susceptibility to infection and seems to be related to certain autoimmune disorders.

Theoretically, any complement component may be deficient or dysfunctional, and many such disorders are under investigation. Primary complement deficiencies are rare. The most common are C1, C2, and C4 deficiencies, and C5 familial dysfunction. (See [Major disorders associated with complement deficiencies.](#))

More common secondary complement abnormalities have been confirmed in patients with lupus erythematosus, in some with dermatomyositis, in one with scleroderma (and in his family), and in a few patients with gonococcal and meningococcal infections.

Some disorders associated with secondary deficiencies of complement are asplenia, sickle cell anemia, protein-deficient status, acute nephritis, immune complex disease, and bacteremia.

The prognosis varies with the abnormality and the severity of associated diseases.

Causes

Primary complement deficiencies are inherited as autosomal recessive traits, except for deficiency of C1 esterase inhibitor, which is autosomal dominant. Secondary deficiencies may follow complement-fixing (complement-consuming) immunologic reactions, such as drug-induced serum sickness, acute streptococcal glomerulonephritis, asplenia, sickle cell anemia, acute nephritis, bacteremia, and acute active systemic lupus erythematosus.

Major disorders associated with complement deficiencies

DEFICIENCY	ASSOCIATED CLINICAL CONDITIONS
C1q	Glomerulonephritis, systemic lupus erythematosus (SLE)
C1r	SLE-like syndrome
C2	SLE, discoid lupus erythematosus, juvenile rheumatoid arthritis, glomerulonephritis
C3	Recurrent pyogenic infections, glomerulonephritis
C4	SLE-like syndrome
C5	Recurrent disseminated neisserial infections, SLE
C6	Recurrent disseminated neisserial infections
C7	Recurrent disseminated neisserial infections, Raynaud's phenomenon
C8	Recurrent disseminated neisserial infections
C9	None identified
Properdin	Recurrent pyogenic infections, fulminant meningococcemia
C1 esterase inhibitor	Hereditary angioedema, increased incidence of several autoimmune diseases

Normally, immunoglobulin (Ig) G or IgM reacts with antigens as part of an immune response, activating C1, which then combines with C4, initiating the classical complement pathway, or cascade. (An alternative complement pathway involves the direct activation of C3 by the serum protein properdin, bypassing the initial components [C1, C2, and C4] of the classical pathway.) Complement then combines with the antigen-antibody complex and undergoes a sequence of complicated reactions that amplify the immune response against the antigen. This complex process is called complement fixation. Any deficiency in complement interferes with this system.

Complications

C1 esterase inhibitor deficiency may lead to severe or even laryngeal edema. Other complications include systemic lupus erythematosus, glomerulonephritis, and juvenile rheumatoid arthritis.

Assessment findings

Signs and symptoms vary with the specific deficiency.

A patient with C2 or C3 deficiency or C5 familial dysfunction is likely to have signs and symptoms of a bacterial infection, which may involve several body systems simultaneously. You may also find signs of such collagen vascular diseases as lupus erythematosus or signs of chronic renal failure in a patient with C2 deficiency.

In an infant with C5 familial dysfunction, assessment may uncover a failure to thrive, diarrhea, and seborrheic dermatitis. You may observe periodic swelling in the face, hands, abdomen, or throat that may lead to airway obstruction in a patient with C1 esterase inhibitor deficiency.

Diagnostic tests

Diagnosis of a complement deficiency is difficult and requires careful interpretation of both clinical features and laboratory results. Various complement deficiencies cause a low total serum complement level (CH50). Specific assays may help to confirm deficiency of specific complement components. For example, immunofluorescence of glomerular tissues in glomerulonephritis that reveals complement components and IgG strongly suggests complement deficiency.

Treatment

Although primary complement deficiencies have no known cure, the associated infections, collagen vascular disease, and renal disease require prompt treatment. Transfusion of fresh frozen plasma replaces complement components, but this treatment is controversial because it doesn't cure complement deficiencies and provides only transient beneficial effects. Although helpful, bone marrow transplantation can cause potentially fatal graft-versus-host disease (GVHD). Anabolic steroids and antifibrinolytic agents reduce acute swelling in patients with C1 esterase inhibitor deficiency. Primary management consists of antibiotic therapy and prophylaxis.

Nursing diagnoses

⌞ Altered growth and development ⌞ Altered nutrition: Less than body requirements ⌞ Altered protection ⌞ Body image disturbance ⌞ Hyperthermia ⌞ Impaired gas exchange ⌞ Impaired individual coping ⌞ Impaired skin integrity ⌞ Ineffective airway clearance ⌞ Ineffective family coping: Disabling ⌞ Ineffective individual coping ⌞ Risk for fluid volume deficit ⌞ Risk for infection ⌞ Risk for injury ⌞ Social isolation

Key outcomes

- ⌞ The patient will demonstrate age-appropriate skills and behaviors as much as possible.
- ⌞ The patient won't experience chills, fever, and other signs and symptoms of illness.
- ⌞ The patient will demonstrate protective measures, including conserving energy, maintaining a balanced diet, and getting plenty of rest.
- ⌞ The parents will establish eye contact and physical and verbal contact with the infant or child.
- ⌞ The parents will develop adequate coping mechanisms and support systems.

Nursing interventions

- ⌞ Closely monitor intake and output, serum electrolyte levels, and acid-base balance of a patient with renal infection. Watch for signs of infection and renal failure.
- ⌞ To maintain adequate ventilation, provide chest physiotherapy, as needed, to the patient with a respiratory tract infection.
- ⌞ After bone marrow transplantation, monitor the patient closely for signs of transfusion reaction and GVHD.
- ⌞ When caring for a patient with C1 esterase inhibitor deficiency, be prepared for emergency management of laryngeal edema that may result from angioedema. Keep airway equipment on hand.
- ⌞ Provide support to the parents in distress. Help them identify and use effective coping strategies. Refer them to a counselor, if needed.

Patient teaching

- u Teach the patient (or members of his family, if he's a child) the importance of avoiding infection, how to recognize its early signs and symptoms, and the need for prompt treatment if it occurs.
- u Teach about the disease process.
- u Teach about medication, purpose, dosage, and adverse effects.

DIGEORGE SYNDROME

DiGeorge syndrome—also known as congenital thymic hypoplasia or aplasia—is marked by a partial or total absence of cell-mediated immunity that results from a deficiency of T cells. It characteristically produces life-threatening hypocalcemia and is associated with abnormalities of the great vessels, atrial and ventricular septal defects, esophageal atresia, bifid uvula, short philtrum, mandibular hypoplasia, hypertelorism, and low-set notched ears. Also, the thymus may be absent or underdeveloped and abnormally located.

An infant with thymic hypoplasia (rather than aplasia) may experience a spontaneous return of cell-mediated immunity but can develop severe T-cell deficiencies later in life. This results in an exaggerated susceptibility to viral, fungal, and bacterial infections that may be overwhelming.

Few patients live beyond age 2 without fetal thymic transplantation. If transplantation, correction of hypocalcemia, and repair of cardiac anomalies can take place, the prognosis improves.

Causes

DiGeorge syndrome may result from abnormal fetal development of the third and fourth pharyngeal pouches (during the 6th to 12th week of gestation) that interferes with the formation of the thymus and parathyroid glands. As a result, the thymus is completely or partially absent and abnormally located, causing deficient cell-mediated immunity. (See [The thymus and immune response.](#))

This syndrome has been linked to maternal alcoholism and resultant fetal alcohol syndrome.

Complications

Failure of the parathyroid to develop properly results in life-threatening hypocalcemia that is unusually resistant to treatment. This can lead to seizures and central nervous system damage. Death commonly results from cardiac defects. Other complications include failure to thrive, anorexia, diarrhea, weight loss, recurrent infections, seizures, developmental delay, cancer, autoimmune disease, cardiac failure, and death.

Assessment findings

The parents of an older infant may report a history of repeated infections; however, signs are usually obvious at birth or shortly thereafter. The child also commonly exhibits signs of tetany, hyperphosphoremia, and hypocalcemia—the result of hypoparathyroidism, which is associated with DiGeorge syndrome.

PATHOPHYSIOLOGY

The thymus and immune response

Although the exact relation between the thymus and the immune system is unclear, possible thymic functions include:

- u destruction of T cells that would have mistaken components of the human organism as foreign during the fetal stage. This allows the fetus's immune system to establish the difference between self and nonself.
- u maturation of T cells in the thymic epithelium or mesenchymal cells. These mature cells help to regulate the humoral immune response.

Inspection of an infant with DiGeorge syndrome may reveal low-set ears, notched ear pinnae, a fish-shaped mouth, an undersized jaw, and abnormally wide-set eyes (hypertelorism) with antimongoloid eyelid formation (downward slant). Your assessment may also reveal signs of cardiovascular abnormalities, such as oxygen therapy—resistant cyanosis, tachypnea, and a palpable systolic bruit at the left sternal border.

Diagnostic tests

The sheep cell agglutination test reveals decreased or absent T cells. A chest X-ray shows that the thymus is absent. Immunoglobulin assays don't help in the diagnosis because the infant's antibodies usually come from maternal circulation. Low serum calcium, elevated serum phosphorus, and absent parathyroid hormone levels confirm hypoparathyroidism. Echocardiography can detect heart defects.

Treatment

Life-threatening hypocalcemia needs immediate, aggressive treatment, for example, with a rapid I.V. infusion of 10% calcium gluconate. Transplantation of thymic tissue can help the patient to develop immunocompetent T cells of host origin.

When possible, congenital cardiac deformities can be repaired with surgery.

Nursing diagnoses

- u Activity intolerance u Altered growth and development u Altered nutrition: Less than body requirements u Altered protection u Body image disturbance u Decreased cardiac output u Knowledge deficit u Risk for infection u Risk for injury

Key outcomes

- u The patient won't experience fever, chills, and other signs and symptoms of illness.
- u The patient will demonstrate use of protective measures, including conserving energy, maintaining a balanced diet, and getting plenty of rest.
- u The patient won't incur any injury.
- u The patient will demonstrate age-appropriate skills and behaviors as much as possible.
- u The patient will state and demonstrate understanding of what was taught.

Nursing interventions

- u During calcium infusion, monitor the patient's heart rate and take steps to avoid infiltration. Remember that the patient must receive vitamin D and sometimes parathyroid hormone with the calcium supplements to ensure effective use of calcium.
- u Provide a low-phosphorus diet.

- u Take steps to prevent infection.
- u Administer medications and monitor for effect.
- u Monitor for seizures and protect the patient from injury.
- u Monitor laboratory studies and trends.
- u Conduct electrocardiographic monitoring to observe potential cardiac complications.
- u Ensure that all blood products have been irradiated.
- u Administer oxygen therapy, as indicated.

Patient teaching

- u Teach the infant's parents how to recognize signs of infection and to seek immediate treatment if such signs occur. Also teach them to keep the infant away from crowds or any other potential sources of infection.
- u Teach the parents to provide good hygiene as well as adequate nutrition and hydration.
- u Teach the importance of regular visits to the doctor.

SELECTIVE IGA DEFICIENCY

Selective IgA deficiency is the most common immunoglobulin deficiency. IgA (the major immuno-globulin in human saliva, nasal and bronchial fluids, and intestinal secretions) guards against bacterial and viral infections. Consequently, selective IgA deficiency usually leads to chronic sinopulmonary infections, GI diseases, and other disorders.

Some patients with this disorder remain healthy throughout their lives; a few survive to age 70. These patients may have no signs or symptoms because they have extra amounts of low-molecular-weight IgM, which takes over IgA function and helps to maintain immunity. Morbidity is often associated with recurrent sinopulmonary infections, autoimmune disorders, and neoplastic disorders.

The age of onset varies. Some IgA-deficient children with recurrent respiratory disease and middle ear inflammation may begin to synthesize IgA spontaneously as recurrent infections subside and their condition improves.

Causes and pathophysiology

The exact cause of IgA deficiency is unknown. It may be linked with autosomal dominant or recessive inheritance, although the patterns aren't clearly established. An increased incidence is found in families with hypogammaglobulinemia.

Patients with IgA deficiency have a normal number of peripheral blood lymphocytes carrying IgA receptors and a normal amount of other immunoglobulins, which suggests that their B cells may not be secreting IgA. Occasionally, suppressor T cells appear to inhibit IgA. Patients with rheumatoid arthritis or systemic lupus erythematosus (SLE) are also IgA-deficient, pointing to a link between IgA deficiency and autoimmune disorders. A transient form of the deficiency seems to result from certain drugs, such as anticonvulsants. Toxoplasmosis, rubella, and cyto-megalovirus have produced IgA deficiency through congenital intrauterine infections.

Complications

Mild to severe chronic pulmonary disease (such as asthma) and chronic diarrheal diseases commonly result from IgA deficiency. A patient who develops significant levels of antibodies to IgA may have a severe anaphylactic reaction if he receives a transfusion of normal blood or blood products. Other complications include cancer, pneumonia, uncontrolled allergies, and complications from related disorders.

Assessment findings

Some IgA-deficient patients have no signs or symptoms. Among those who do develop symptoms, the most common complaint is chronic sinopulmonary infection. The patient may also complain of symptoms of other disorders. They include respiratory allergy, often triggered by infection; GI tract diseases, such as spruelike disease, ulcerative colitis, and regional enteritis; autoimmune diseases, such as rheumatoid arthritis, SLE, chronic hepatitis, and immunohemolytic anemia; and malignant tumors, such as squamous cell carcinoma of the lungs, reticulum cell sarcoma, and thymoma.

Diagnostic tests

Hematologic analyses of the IgA-deficient patient show serum IgA levels below 5 mg/dl. Although the patient usually has no IgA in his secretions, such levels are occasionally normal. The patient has normal IgE levels; his IgM levels may be normal or elevated in serum and secretions. Normally absent low-molecular-weight IgM may be present.

Hematocrit may be increased because of anemia. Coombs' test results may be positive and pulmonary function test results may be abnormal

Tests may also detect autoantibodies and antibodies against IgG (rheumatoid factor), IgM, and cow's milk. Cell-mediated immunity and secretory component (the glycopeptide that transports IgA) are usually normal, and most circulating B cells appear normal.

Treatment

Selective IgA deficiency has no known cure. The goal of treatment is to control symptoms of associated diseases, such as respiratory tract and GI infections, and treatment is the same as for a patient with normal IgA levels. In severe, recurrent infection, the patient may receive IgA-free gamma globulin preparation.

Washed packed cells may be administered to treat anemia.

Nursing diagnoses

u Altered health maintenance u Altered nutrition: Less than body requirements u Altered protection u Diarrhea u Impaired gas exchange u Risk for altered body temperature u Risk for infection

Key outcomes

- u The patient won't experience chills, fever, and other signs and symptoms of illness.
- u The patient will demonstrate the use of protective measures, including conserving energy, maintaining a balanced diet, and getting plenty of rest.
- u The patient and family members will identify strengths and weaknesses in maintaining health.
- u The patient's bowel movements will return to normal consistency.
- u The patient will maintain weight within an acceptable range.

Nursing interventions

- u Consult the dietitian to develop a nutritious diet that minimizes adverse effects from GI tract diseases, diarrhea, anemias, and autoimmune diseases.
- u If the patient needs a transfusion with blood products, minimize the risk of an adverse reaction by using washed red blood cells, or avoid the reaction completely by crossmatching the patient's blood with that of an IgA-deficient donor.
- u Monitor vital signs for infection.
- u Encourage activity and rest, a well-balanced diet, and adequate fluid intake.

- Administer antibiotics, antihistamines, and cromolyn, as ordered, and monitor effects.

Patient teaching

- Because IgA deficiency is lifelong, teach the patient steps he can take to avoid infection. Also teach him to recognize early signs of infection; tell him to seek treatment immediately if such signs occur.
- Advise the patient to use acetaminophen instead of aspirin or other nonsteroidal anti-inflammatory drugs for mild pain relief.
- Teach the patient how to perform deep-breathing exercises.

SEVERE COMBINED IMMUNODEFICIENCY DISEASE

Cell-mediated (T-cell) and humoral (B-cell) immunity are either deficient or absent in severe combined immunodeficiency disease (SCID), which predisposes the patient to infection from all classes of microorganisms during infancy. Defective B-cell and T-cell function may also cause other immunodeficiency disorders (see [Immunodeficiency with eczema and thrombocytopenia](#)). Three types of SCID have been identified: reticular dysgenesis, the most severe type, in which the hematopoietic stem cell fails to differentiate into lymphocytes and granulocytes; Swiss-type agammaglobulinemia, in which the hematopoietic stem cell fails to differentiate into lymphocytes alone; and enzyme deficiency, such as adenosine deaminase deficiency, in which the buildup of toxic products in the lymphoid tissue causes damage and subsequent dysfunction.

SCID affects more males than females and occurs in 1 in every 100,000 to 500,000 births. Most untreated infants die of infection within 1 year of birth.

Immunodeficiency with eczema and thrombocytopenia

Immunodeficiency with eczema and thrombocytopenia (Wiskott-Aldrich syndrome) arises from defective B-cell and T-cell function. Risks for leukemia and lymphoma also increase.

This syndrome affects 4 per 1 million male neonates, resulting from an X-linked recessive trait that impairs immunity and causes production of small, short-lived platelets. The prognosis is poor; death usually follows massive bleeding (in infancy), cancer, or severe infection (early in childhood). The average life span of 4 years seldom extends past age 10.

Signs of thrombocytopenia bloody stools, bleeding circumcision site, petechiae, and purpura subside as an affected neonate ages. At about age 6 months, recurrent systemic infections and hepatosplenomegaly develop. At about age 1, eczema develops and progressively worsens.

Diagnostic findings include normal or elevated immunoglobulin (Ig) E, decreased IgM, normal IgG and IgA, and low (or no) isohemagglutinin levels. Initially normal cell-mediated immunity diminishes with age. Sputum and throat cultures commonly disclose infecting organisms. Hemoglobin levels and hematocrit may suggest anemia. Coombs' test results may be positive. Urinalysis may indicate hematuria.

Treatments include platelet transfusion to limit bleeding, aggressive antibiotic therapy to control infection, immune globulin infusion to boost immunity, and topical corticosteroids and antipruritic agents to control eczema and itching. Treatment with transfer factor or bone marrow transplantation helps some patients. Splenectomy may reduce the risk for serious hemorrhage by increasing platelet count.

Causes

SCID is usually transmitted as an autosomal recessive trait, although it may be X-linked. In most cases, the genetic defect seems associated with failure of the stem cell to differentiate into T and B cells. Many molecular defects, such as mutation of the kinase ZAP-70, can cause SCID. X-linked SCID results from a mutation of a subunit of the interleukin (IL)-2, IL-4, and IL-7 receptors. Less commonly, SCID results from enzyme deficiency.

Another theory is that the thymus or bursa equivalent fails to develop normally or that there is a defect in the thymus and bone marrow, which are responsible for T- and B-cell development.

Complications

Without treatment, most infants die of infection within 1 year of birth. Such infections usually are caused by *Salmonella*, *Escherichia coli*, *Pseudomonas*, cytomegalovirus, *Pneumocystis carinii*, and *Candida* organisms Common viral infections, such as chickenpox, are also usually fatal.

Other complications include pneumonia, oral ulcers, failure to thrive, and dermatitis.

Assessment findings

An infant with SCID has a history of extreme susceptibility to infection within the first few months of life but probably won't show signs of any gram-negative infections until about age 6 months because of protection by maternal IgG.

On assessment, you may commonly observe that the infant appears emaciated and fails to thrive, and you may note signs of chronic otitis media and sepsis. You may also find signs of the usual childhood diseases, such as chickenpox. Other assessment findings depend on the type and site of infection. For instance, an infant with severe watery diarrhea may have a GI infection from *Salmonella* or *E. coli*.

ASSESSMENT TIP *P. carini* pneumonia usually strikes a severely immunodeficient infant in the first 3 to 5 weeks of life. Onset is typically insidious, with gradually worsening cough, low-grade fever, tachypnea, and respiratory distress. A chest X-ray shows unilateral pulmonary infiltration.

Diagnostic tests

Defective humoral immunity is hard to detect before an infant reaches age 5 months. Before that age, even normal infants have only small amounts of serum IgM and IgA, and normal IgG levels merely reflect maternal IgG. Tests that show a severely diminished or absent T-cell number and function and a lymph node biopsy that shows an absence of lymphocytes can confirm a diagnosis of SCID.

A chest X-ray characteristically shows bilateral pulmonary infiltrates.

Treatment

The goal of treatment is to restore immune response and prevent infection. Specific antibiotic therapy is used to treat infection. The patient needs histocompatible bone marrow transplantation to correct immunodeficiency. Bone marrow cells must be matched for histocompatibility, using both human leukocyte antigen and mixed leukocyte culture, so siblings usually serve as donors. Parental marrow can now be used successfully after it's depleted of T cells, which could cause fatal acute graft-versus-host disease. T cells are removed with monoclonal antibodies or lectin columns. Immunoglobulin may be given I.V. with dosages varying according to the severity of the illness.

Fetal thymus and liver transplantation have met with limited success. Immune globulin may also play a role in treatment. Some SCID infants have received long-term protection by being isolated in a completely sterile environment. This approach doesn't work for an infant who already has recurring infections.

Nursing diagnoses

⌞ Altered growth and development ⌞ Altered oral mucous membrane ⌞ Altered parenting ⌞ Altered protection ⌞ Anxiety ⌞ Diarrhea ⌞ Impaired gas exchange ⌞ Impaired skin integrity ⌞ Ineffective family coping: Disabling ⌞ Pain ⌞ Risk for infection ⌞ Social isolation

Key outcomes

- ⌞ The patient will demonstrate age-appropriate skills and behaviors as much as possible.
- ⌞ The patient won't experience chills, fever, and other signs of illness.
- ⌞ The patient will demonstrate protective measures, including conserving energy, maintaining a balanced diet, and getting plenty of rest.
- ⌞ The parents will establish eye, physical, and verbal contact with the infant or child.
- ⌞ The parents will develop adequate coping mechanisms and support systems.

Nursing interventions

- ⌞ Constantly monitor the infant for early signs of infection. If infection develops, provide prompt and aggressive drug therapy and supportive care, as ordered.
- ⌞ Watch for adverse effects of any medications given. Avoid vaccinations, and give only irradiated blood products if a transfusion is ordered.
- ⌞ Although SCID infants must remain in strict protective isolation, try to provide a stimulating atmosphere to promote growth and development.
- ⌞ Encourage parents to visit their child often, to hold him, and to bring him toys that can be easily sterilized.
- ⌞ Maintain a normal day and night routine, and talk to the child as much as possible. If parents can't visit, call them often to report on the infant's condition.
- ⌞ Provide emotional support for the family, and encourage the parents to seek genetic counseling.

Patient teaching

- ⌞ Ensure that the parents understand the need and proper technique for strict protective isolation.
- ⌞ Teach how to recognize the signs and symptoms of infection and to notify the doctor promptly when they appear.
- ⌞ Teach about medication, dosage, purpose, and adverse effects.

INTRODUCTION

Blood, one of the body's major fluid tissues, continuously circulates through the heart and blood vessels, carrying vital elements to every part of the body.

Reviewing blood basics

Blood performs several physiologically vital functions through its special components: the liquid portion (plasma) and the formed constituents (erythrocytes, leukocytes, and platelets) that are suspended in it. Erythrocytes, or red blood cells (RBCs), carry oxygen to the tissues and remove carbon dioxide from them. Leukocytes, or white blood cells (WBCs), participate in inflammatory and immune responses. Plasma carries antibodies and nutrients to tissues and carries waste away; coagulation factors in plasma, with platelets (thrombocytes), control clotting. (See [Coagulation factors](#)).

The average person has 5 to 6 L of circulating blood, which constitutes 5% to 7% of body weight (as much as 10% in premature neonates). Blood is three to five times more viscous than water, with an alkaline pH of 7.35 to 7.45, and is either bright red (arterial blood) or dark red (venous blood), depending on the degree of oxygen saturation and the hemoglobin level.

Formation and characteristics

Hematopoiesis occurs primarily in the red bone marrow of the long bones and axial skeleton where primitive cells (stem cells) produce the precursors of erythrocytes (normoblasts), leukocytes, and thrombocytes (megakaryocytes). During embryonic development, blood cells are derived from mesenchyma and form in the yolk sac. As the fetus matures, blood cells are produced in the liver, spleen, and thymus; by the 5th month of gestation, blood cells also begin to form in the bone marrow. After birth, blood cells are usually produced only in the marrow.

Blood's functions

The most important function of blood is to *transport oxygen* (bound to RBCs inside hemoglobin) from the lungs to the body tissues and to *return carbon dioxide* from these tissues to the lungs. Blood also performs the following vital defensive and protective functions:

- ▮ provides complement, a group of immunologically important protein substances in plasma
- ▮ transports granulocytes and monocytes to defend the body against pathogens by phagocytosis production and delivery of antibodies (by way of WBCs) formed by plasma cells and lymphocytes
- ▮ provides specific immunity against viruses and cancer cells through sensitized lymphocytes.

Other functions of blood include control of hemostasis by platelets, plasma, and coagulation factors that repair tissue injuries and prevent or halt bleeding; regulation of acid-base and fluid balance; regulation of body temperature by carrying off excess heat generated by the internal organs for dissipation through the skin; and transportation of nutrients and regulatory hormones to body tissues and transportation of metabolic wastes to the organs of excretion (kidneys, lungs, and skin).

Blood dysfunction

Because of the rapid reproduction of bone marrow cells and the short life span and minimal storage in the bone marrow of circulating cells, bone marrow cells and their precursors are particularly vulnerable to physiologic changes that can affect cell production. Resulting blood disorders may be primary or secondary, quantitative or qualitative, or both; they may involve some or all blood components.

Quantitative blood disorders result from increased or decreased cell production or cell destruction; qualitative blood disorders stem from intrinsic cell abnormalities or plasma component dysfunction. Specific causes of blood disorders include trauma, chronic disease, surgery, malnutrition, drugs, exposure to toxins and radiation, and genetic and congenital defects that disrupt production and function. For example, depressed bone marrow production or mechanical destruction of mature blood cells can reduce the number of RBCs, platelets, and granulocytes, resulting in pancytopenia (anemia, thrombocytopenia, granulocytopenia). Increased production of multiple bone marrow components can follow myeloproliferative disorders.

RBC development

The tissues' demand for oxygen and the blood cells' ability to deliver it regulate RBC production. Consequently, hypoxia (or tissue anoxia) stimulates RBC production by triggering the formation and release of erythropoietin, a hormone that activates bone marrow to produce RBCs. Erythropoiesis may also be stimulated by androgens.

The formation of an erythrocyte begins with an uncommitted stem cell that may eventually develop into an RBC. Such formation requires certain vitamins—B₁₂ and folic acid—and minerals, such as copper, cobalt and, especially, iron, which is vital to hemoglobin's oxygen-carrying capacity. Iron is obtained from various foods and is absorbed in the duodenum and upper jejunum, leaving any excess for temporary storage in reticuloendothelial cells, especially those in the liver. Iron excess is

stored as ferritin and hemosiderin until it's released for use in the bone marrow to form new RBCs.

Coagulation factors	
The following is a list of coagulation factors and their synonyms. All coagulation factors are located in plasma except for factor III, which is found in tissue cells.	
FACTOR	SYNONYM
Factor I	Fibrinogen
Factor II	Prothrombin
Factor III	Tissue thromboplastin
Factor IV	Calcium ion
Factor V	Labile factor
Factor VII	Conversion accelerator
Factor VIII	Antihemophilic factor
Factor IX	Plasma thromboplastin component
Factor X	Stuart-Prower factor
Factor XI	Plasma thromboplastin antecedent
Factor XII	Hageman factor
Factor XIII	Fibrin stabilizing factor

RBC disorders

Both quantitative and qualitative abnormalities constitute RBC disorders. Deficiency of RBCs (anemia) can follow any condition that destroys or inhibits the formation of these cells. Common factors leading to this deficiency include:

- u congenital or acquired defects that cause bone marrow aplasia and suppress general hematopoiesis (aplastic anemias) or erythropoiesis
- u drugs, toxins, and ionizing radiation
- u metabolic abnormalities (sideroblastic anemias)
- u deficiencies of vitamins (vitamin B₁₂ deficiency or pernicious anemia), iron, or minerals (iron, folic acid, copper, and cobalt deficiency anemias) that cause inadequate RBC production
- u excessive chronic or acute blood loss (posthemorrhagic anemia)
- u chronic illnesses, such as renal disease and cancer
- u intrinsically or extrinsically defective RBCs (sickle cell anemia).

Comparatively few conditions lead to an increased RBC count. Such conditions include:

- u abnormal proliferation of all bone marrow elements (polycythemia vera)
- u a single-element abnormality (for instance, an increase in the RBC count that results from erythropoietin excess, which is the result of hypoxemia or pulmonary disease)
- u reduced plasma cell volume, which causes an apparent corresponding increase—relative, not absolute—in RBC concentration
- u chronic hypoxic lung disease.

WBC development and function

WBCs protect the body against harmful bacteria and infection. They are classified as granular leukocytes (basophils, neutrophils, and eosinophils) or as nongranular leukocytes (lymphocytes, monocytes, and plasma cells). (See [Two types of leukocytes.](#))

Most WBCs are produced in bone marrow; however, lymphocytes and plasma cells complete their maturation in the lymph nodes. Although WBCs have a poorly defined tissue life span, some granular leukocytes (granulocytes) have a circulating half-life of less than 6 hours, some monocytes may survive for weeks or months, and certain lymphocytes last for years.

Normally, WBCs range from 5,000 to 10,000/μl and comprise the following elements:

- u *Neutrophils*, the predominant form of granulocyte, make up about 60% of WBCs; they help devour invading organisms by phagocytosis.
- u *Eosinophils*, minor granulocytes, defend against parasites and participate in allergic reactions, pulmonary infections, and dermatologic infections.
- u *Basophils*, minor granulocytes, release heparin and histamine into the blood and participate in delayed hypersensitivity reactions.
- u *Monocytes*, along with neutrophils, help devour invading organisms by phagocytosis. They also help to process antigens for lymphocytes and form macrophages in the tissues.
- u *Lymphocytes* primarily occur in two forms: B cells and T cells. B cells aid antibody synthesis and T cells regulate cell-mediated immunity.
- u *Plasma cells* develop from lymphocytes that reside in the tissues and produce antibodies. A recently identified large granular lymphocyte is thought to become the important antitumor cell called a natural killer cell.

WBC disorders

A temporary increase in the production and release of mature WBCs is a normal response to infection. An abnormal increase in immature WBC precursors and their accumulation in bone marrow or lymphoid tissue are characteristic of leukemia. These nonfunctioning WBCs (blasts) provide no protection against infection, crowd out other vital components—RBCs, platelets, mature WBCs—and spill into the bloodstream, sometimes infiltrating organs and impairing their function.

WBC deficiencies may result from inadequate cell production, drug reactions, ionizing radiation, infiltrated bone marrow (cancer), congenital defects, aplastic anemias, folic acid deficiency, and hypersplenism. The most common types of WBC deficiencies are granulocytopenia and lymphocytopenia; monocytopenia occurs less frequently.

Platelets and platelet disorders

Platelets are small (2 to 4 microns in diameter), colorless, disk-shaped cytoplasmic cells that split from cells in bone marrow called megakaryocytes. Platelets have a life span of 7 to 10 days and perform three vital functions:

- u initiating contraction of damaged blood vessels to minimize blood loss
- u forming hemostatic plugs in injured blood vessels
- u with plasma, providing materials that accelerate blood coagulation, notably platelet factor 3.

Platelet disorders include thrombocytopenia (platelet decrease), thrombocytosis (platelet excess), and thrombocytopathy (platelet dysfunction). Thrombocytopenia may result from congenital deficiency or acquired deficiency (exposure to drugs and ionizing radiation, cancerous infiltration of bone marrow, abnormal sequestration in the spleen, abnormal mechanical destruction, or infection).

Thrombocytosis occurs with certain diseases, such as cancer. Thrombocytopathy usually results from disease (such as uremia and hepatic failure) or medication (such as salicylates and nonsteroidal anti-inflammatory drugs).

Plasma

Plasma is a clear, straw-colored fluid that consists mainly of proteins (chiefly albumin, globulin, and fibrinogen) held in aqueous suspension. Other components of plasma include glucose, lipids, amino acids, electrolytes, pigments, hormones, respiratory gases (oxygen and carbon dioxide), and products of metabolism, such as urea, uric acid, creatinine, and lactic acid.

Two types of leukocytes
Leukocytes vary in size, shape, and number. They're classified as granular or nongranular.
Granulocytes
The most numerous leukocytes, granulocytes include basophils, containing cytoplasmic granules that stain readily with alkaline dyes; neutrophils, which are finely granular and recognizable by their multinucleated appearance; and eosinophils, which stain with acidic dyes.
Nongranulocytes
Nongranular leukocytes include lymphocytes, monocytes, and plasma cells. They have few, if any, granulated particles in the cytoplasm.

Plasma's fluid characteristics—including osmotic pressure, viscosity, and suspension qualities—depend on its protein content. Plasma components regulate acid-base balance and immune responses, and mediate coagulation and nutrition.

Hemostasis and clotting

In a complex process called hemostasis, platelets, plasma, and coagulation factors interact to control bleeding. When tissue injury occurs, local vasoconstriction and platelet clumping (aggregation) at the injury site initially help to prevent hemorrhage.

The extrinsic pathway (stimulated by tissue injury) or intrinsic pathway (stimulated by vessel injury or a foreign body in the bloodstream) activates the clotting process. A stabler clot is formed when each pathway merges with the final common pathway. In the final common pathway, prothrombin is converted to thrombin and fibrinogen is converted to fibrin, which creates a fibrin clot that lasts for 2 to 3 days.

Assessment

Because many signs and symptoms of hematologic disorders are nonspecific and systemic, such as malaise and light-headedness, assessment can be difficult. However, certain key findings may alert you to the possibility of a hematologic disorder. They include abnormal bleeding, petechiae, ecchymoses, fatigue, weakness, dyspnea with or without exertion, fever, lymphadenopathy, and joint and bone pain.

History

Biographic data, including the patient's ethnic background and current and previous occupations, can provide important clues in identifying disorders associated with toxin exposure and hereditary disorders, such as sickle cell anemia and pernicious anemia.

Exploring the patient's complaints may reveal useful information about his symptoms, including onset, duration, precipitating or exacerbating factors, and relief measures. His health history may yield additional clues, such as allergies, immunizations, previously diagnosed illnesses, past hospitalizations and surgeries, past blood product transfusions, and current medications. Note any past illnesses that required immunosuppressive therapy, such as splenectomy or certain drugs, and any disorders that affect bone marrow function such as hepatitis.

A review of the patient's lifestyle may reveal behaviors that can adversely affect hematologic function (for instance, poor dietary habits causing malnutrition or increased alcohol intake causing folic acid deficiency).

Physical examination

The patient with a hematologic disorder may have above- or below-normal temperature, tachycardia, hypotension, and tachypnea. His skin color may appear pale (possibly indicating decreased hemoglobin content), cyanotic (possibly indicating excessive deoxygenated hemoglobin), ruddy (possibly indicating polycythemia), or erythematous (possibly accompanying inflammation and fever).

Red-streaked areas over the lymph nodes may indicate an acute lymphatic disorder, such as acute lymphadenitis. Inspection of the skin and mucous membranes may reveal jaundice and purpuric lesions, petechiae, ecchymoses, and telangiectases. Dry, coarse skin may indicate iron deficiency anemia; itchy skin may result from polycythemia vera; and red palms may indicate iron deficiency anemia.

The patient's mucous membranes may reveal bleeding, swelling, redness, and ulcerations. A smooth tongue can indicate vitamin B₁₂ deficiency or iron deficiency anemia.

Inspection of the patient's fingernails may reveal longitudinal striations, a sign of anemia; koilonychia (spoon nail), characteristic of iron deficiency anemia; or nail clubbing from chronic tissue hypoxia.

The patient's eyes may appear jaundiced and the conjunctivae may appear pale. Retinal hemorrhages and exudates suggest severe anemia and thrombocytopenia. On inspection, the patient's abdomen may appear enlarged, distended, or asymmetrical.

Auscultation over the liver and spleen may reveal rubbing sounds that fluctuate with respirations, possibly indicating peritoneal inflammation or infarction. Percussion over all quadrants helps to determine liver and spleen size. Palpation of the lymph nodes, liver, and spleen may detect enlargement. Congestion caused by cell overproduction, as in polycythemia, or excessive cell destruction, as in hemolytic anemia, can cause hepatomegaly or splenomegaly. Tenderness of sternal nodes

may indicate anemia.

Diagnosing hematologic disorders

Laboratory studies that help determine blood composition, production, and function are vital in diagnosing hematologic disorders. Other common studies include tests to evaluate the coagulation and agglutination properties of the blood and biopsies to evaluate the blood's formed elements.

Blood composition

Commonly performed tests include the following:

- u *Peripheral blood smear* shows maturity and morphologic characteristics of blood elements and determines qualitative abnormalities.
- u *Complete blood count* is used to determine the number of blood elements in relation to volume and to quantify abnormalities (RBCs, WBCs, and platelets).

RBC function

Various tests evaluate RBC function, including the following:

- u *Hematocrit*, or packed cell volume, indicates the percentage of RBCs per fluid volume of whole blood.
- u *Hemoglobin* is used to measure the amount (grams) of hemoglobin per 1 ml of whole blood to determine oxygen-carrying capacity.
- u *Reticulocyte count* is used to assess RBC production by determining the concentration of this erythrocyte precursor.
- u *Schilling test* is used to determine absorption of vitamin B₁₂ (necessary for erythropoiesis) by measuring excretion of radioactive B₁₂ in the urine.
- u *Mean corpuscular volume (MCV)* describes the RBC in terms of size. Immature or iron-deficient cells have increased MCV.
- u *Mean corpuscular hemoglobin (MCH)* indicates the average amount of hemoglobin per RBC. The MCH is decreased in iron deficiency anemia.
- u *Mean corpuscular hemoglobin concentration* determines the average hemoglobin concentration of 100 ml of packed RBCs.
- u *Sucrose hemolysis test* assesses the susceptibility of RBCs to hemolyze with complement.
- u *Sideroblast test* detects stainable iron (available for hemoglobin synthesis) in normoblastic RBCs.
- u *Hemoglobin electrophoresis* demonstrates abnormal hemoglobin, such as sickle cell anemia.

Coagulation tests

Commonly performed tests include the following:

- u *Platelet count* discloses the number of platelets.
- u *Bleeding time (Ivy bleeding time)* is used to assess the platelets' capacity to stop bleeding in capillaries and small vessels by measuring the duration of bleeding after a standard skin incision. Used along with the platelet count, it can help to detect the presence of such disorders as von Willebrand's disease, disseminated intravascular coagulation (DIC), severe hepatic or renal disease, and hemolytic disease of the newborn.
- u *Capillary fragility test* is used to measure the capillaries' ability to remain intact under increasing intracapillary pressure. It can help detect thrombocytopenia, DIC, polycythemia vera, and von Willebrand's disease.
- u *Activated partial thromboplastin time (APTT)* is used to evaluate intrinsic pathway clotting factors. It helps in preoperative screening for bleeding tendencies and aids in monitoring heparin therapy.
- u *Partial thromboplastin time* also aids in evaluating intrinsic pathway clotting factors. It is less sensitive and less frequently performed than APTT.
- u *Prothrombin time (PT, Quick's test, or pro time)* indirectly measures prothrombin and helps to evaluate prothrombin, fibrinogen, and extrinsic coagulation factors V, VII, and X. It's used to monitor oral anticoagulant therapy.
- u *Plasma thrombin time (thrombin clotting time)*, which measures how quickly a clot forms, detects abnormalities in thrombin fibrinogen reaction. It helps to identify a fibrinogen deficiency or defect, diagnose DIC and hepatic disease, and monitor heparin, streptokinase, and urokinase therapy.
- u *Plasma fibrinogen test* is used to determine the amount of fibrinogen (factor I) available in plasma to help form fibrin clots. Fibrinogen levels are decreased in hepatic failure and DIC but increased in hepatic cirrhosis and some lymphoproliferative disorders, such as lymphoma.
- u *Fibrin degradation products (FDPs or fibrin split products)* show the amount of clot breakdown products in serum. Normally cleared rapidly, FDPs are elevated in such clotting disorders as DIC.
- u *Antithrombin III test* helps to determine the cause of impaired coagulation, especially hypercoagulation. Antithrombin III levels are decreased in clotting disorders, such as DIC, and may be increased during therapy with oral anticoagulants.
- u *D-dimer test* measures a specific fibrin monomer fragment of FDPs to determine if FDPs are caused by normal mechanisms or by excessive fibrinolysis. The fibrin monomer fragments are present in severe clotting disorders, such as DIC.
- u *Factor VIII assay* identifies the quantity of this factor, which commonly is reduced in hemophilia.
- u *One-stage factor assays*: Extrinsic coagulation system helps to detect a deficiency of factor II, V, or X when PT and APTT are prolonged. The *intrinsic coagulation system* helps to identify a deficiency of factor VIII, IX, or XII when PT is normal and APTT is abnormal.

WBC function

The following laboratory studies are used to evaluate WBC function:

- u *WBC count and differential* establish the quantity and maturity of polymorphonuclear granulocytes or bands, basophils, eosinophils, lymphocytes, and monocytes.
- u *Quantified T4/T8 lymphocyte test* determines helper and suppressor agents important to immune function in human immunodeficiency virus (HIV) infection; may also be reported as a T4/T8 ratio.
- u *Complement fixation ratio* detects the quantity of complement and antibody complexes indicative of infection.
- u *Absolute T4 helper count* provides the CD4+ T-cell count, which is used to monitor patients with HIV infection.
- u *Immunoglobulin (Ig) test* measures the levels of IgG, IgA, and IgM to detect immune incompetence caused by low antibody levels.

Plasma

The following laboratory studies are used to assess aspects of plasma:

- u *Erythrocyte sedimentation rate* measures the rate of RBC settling out of plasma. It may detect infection or inflammation.
- u *Electrophoresis of serum proteins* determines the amount of various serum proteins, which are classified by mobility in response to an electrical field.
- u *Immunoelectrophoresis of serum proteins* separates and classifies serum antibodies (immunoglobulins), using specific antisera.

Agglutination tests

The following tests are used to evaluate the ability of the blood's formed elements to react to foreign substances by clumping together:

- u *ABO blood typing* helps to prevent lethal transfusion reactions. It types blood into A, B, AB, and O groups, according to the presence of major antigens A and B on RBC surfaces and according to serum antibodies anti-A and anti-B.
- u *Rh typing* classifies blood by the presence or absence of the Rh_o(D) antigen on the surface of RBCs to ensure compatibility of transfused blood.
- u *Crossmatching* establishes the compatibility or incompatibility of donor and recipient blood before transfusion.
- u *Direct antiglobulin test (direct Coombs' test)* demonstrates the presence of IgG antibodies (such as antibodies to Rh factor), complement, or both on the surface of circulating RBCs. It is used to diagnose hemolytic disease of the newborn and aids in differential diagnosis of hemolytic anemias.
- u *Antibody screening test (indirect Coombs' test)*, a two-step test, detects the presence of IgG antibodies on RBCs in recipient or donor serum before transfusion.
- u *Leukoagglutinin test* differentiates between transfusion reactions by detecting antibodies that react with WBCs.

Bone marrow biopsy

Because most hematopoiesis occurs in bone marrow, histologic and hematologic bone marrow examination helps to diagnose thrombocytopenia, anemias, polycythemia, and DIC.

Anemias are characterized by reduced hemoglobin levels. The anemias include aplastic or hypoplastic anemias, folic acid deficiency anemia, iron deficiency anemia, pernicious anemia, sickle cell anemia, sideroblastic anemias, and thalassemia. They may result from one or more of these pathophysiologic processes: diminished hemoglobin or red cell production, increased red cell destruction, or blood loss.

APLASTIC OR HYPOPLASTIC ANEMIAS

Aplastic and hypoplastic anemias are potentially fatal and result from injury to or destruction of stem cells in bone marrow or the bone marrow matrix, causing pancytopenia (anemia, leukopenia, thrombocytopenia) and bone marrow hypoplasia.

Although often used interchangeably with other terms for bone marrow failure, aplastic anemias correctly refer to pancytopenia resulting from the decreased functional capacity of a hypoplastic, fatty bone marrow. These disorders usually produce fatal bleeding or infection, particularly when they're idiopathic or stem from chloramphenicol use or infectious hepatitis. Mortality for aplastic anemias with severe pancytopenia is 80% to 90%.

Causes

Aplastic anemias usually develop when damaged or destroyed stem cells inhibit red blood cell (RBC) production. Less commonly, they develop when damaged bone marrow microvasculature creates an unfavorable environment for cell growth and maturation. About half of such anemias result from drugs (such as chloramphenicol), toxic agents (such as benzene), or radiation. The rest may result from immunologic factors (suspected but unconfirmed), severe disease (especially hepatitis), viral infection (especially in children), and preleukemic and neoplastic infiltration of bone marrow. (See [Causes of acquired aplastic anemias.](#))

Idiopathic anemias may be congenital. Two such forms of aplastic anemia have been identified: Congenital hypoplastic anemia (Blackfan-Diamond anemia) develops between ages 2 and 3 months, and Fanconi's syndrome, between birth and age 10. In the absence of a consistent familial or genetic history of aplastic anemia, researchers suspect that these congenital abnormalities result from an induced change in fetal development, such as in maternal rubella or cytomegalovirus infection.

Complications

Life-threatening hemorrhage from the mucous membranes is the most common complication of aplastic or hypoplastic anemias because affected patients develop alloimmunization, which can make platelet transfusions ineffective. Immunosuppression can lead to secondary opportunistic infections.

Assessment findings

The patient's history may not help to establish the disease onset because the symptoms often develop insidiously. The patient may report signs and symptoms of anemia (progressive weakness and fatigue, shortness of breath, and headache) or signs of thrombocytopenia (easy bruising and bleeding, especially from the mucous membranes [nose, gums, rectum, vagina]).

Inspection may reveal pallor if the patient is anemic, and ecchymosis, petechiae, or retinal bleeding if thrombocytopenia is present. You may note alterations in the level of consciousness and weakness if bleeding into the central nervous system has occurred.

Auscultation may reveal bibasilar crackles, tachycardia, and a gallop murmur if severe anemia results in heart failure.

The patient may also have signs and symptoms of an opportunistic infection (most commonly, a bacterial infection). Fever, oral and rectal ulcers, and sore throat may indicate the presence of an infection but without characteristic inflammation.

Diagnostic tests

- Confirmation of aplastic anemia requires a series of laboratory tests. Characteristic blood study results include:
- RBC count of 1 million/ μ l or less, usually with normochromic and normocytic cells (although macrocytosis [larger-than-normal erythrocytes] and anisocytosis [excessive variation in erythrocyte size] may exist); very low absolute reticulocyte count
 - elevated serum iron levels (unless bleeding occurs) but normal or slightly reduced total iron-binding capacity; hemosiderin is present, and tissue iron storage is visible microscopically
 - decreased platelet and white blood cell counts.

Bone marrow biopsies performed at several sites may yield a dry tap or show severely hypocellular or aplastic marrow, with a varying amount of fat, fibrous tissue, or gelatinous replacement; absence of tagged iron (because the iron is deposited in the liver rather than in bone marrow) and megakaryocytes; and depression of erythroid elements.

Differential diagnosis must rule out paroxysmal nocturnal hemoglobinuria and other diseases in which pancytopenia is common.

Treatment

Effective treatment must eliminate any identifiable cause and provide vigorous supportive measures, such as packed RBC, platelet, and experimental histocompatibility antigen-matched leukocyte transfusions. Even after elimination of the cause, recovery can take months or may never occur. Bone marrow transplantation is the treatment of choice for anemia due to severe aplasia and for patients who need constant RBC transfusions. (See [Nursing interventions in bone marrow transplantation.](#))

Causes of acquired aplastic anemias

Drugs, toxic agents, and radiation cause about one-half of all cases of acquired aplastic anemias. Examples and other causes are listed below.

Drugs

Antibiotics (chloramphenicol, cephalosporins, sulfonamides and, rarely, penicillins), anti-inflammatory drugs (phenylbutazone, indomethacin, gold, and penicillamine), anticonvulsants (especially phenytoin, ethosuximide, and carbamazepine), antineoplastics, diuretics (including hydrochlorothiazide), phenothiazines, antidiabetic drugs, antithyroid drugs, antimalarials, zidovudine, antiarrhythmics (procainamide)

Chemicals and toxins

Pesticides, aromatic hydrocarbons (benzene), heavy metals

Infections

Hepatitis C, Epstein-Barr virus, Venezuelan equine encephalitis, cytomegalovirus, miliary tuberculosis

Rheumatoid and autoimmune diseases

Systemic lupus erythematosus, rheumatoid arthritis, graft-versus-host disease

Other causes

Paroxysmal nocturnal hemoglobinuria, radiation, thymoma, pregnancy, idiopathic causes

The patient with low leukocyte counts is at risk for infection. Prevention of infection may range from frequent hand washing to filtered air flow. The infection itself may require specific antibiotics; however, they are not given prophylactically because they tend to encourage resistant strains of organisms. Patients with low hemoglobin levels may need respiratory support with oxygen in addition to blood transfusions.

Other appropriate forms of treatment include corticosteroids to stimulate erythroid production (successful in children, unsuccessful in adults); marrow-stimulating agents, such as androgens (which are controversial); antilymphocyte globulin (experimental); and immunosuppressant agents (if the patient doesn't respond to other therapy).

Nursing interventions in bone marrow transplantation

In bone marrow transplantation, 500 to 700 ml of marrow usually are aspirated from the pelvic bones of a human leukocyte antigen (HLA)-compatible (allogeneic) donor. In certain malignant disorders, autologous (self donor) and peripheral stem cell transplants are performed. In such cases, stem cells are harvested and stored before the patient undergoes chemotherapy, which suppresses bone marrow. After chemotherapy, the stored cells are infused to repopulate the bone marrow and rescue the patient from aplasia. This procedure has effected long-term healthy survival in about one-half the patients with severe aplastic anemia. Bone marrow transplantation may also be effective in treating patients with hematologic cancers (leukemia, lymphoma, and multiple myeloma), certain immunodeficiency diseases, and solid-tumor cancers.

Because bone marrow transplantation carries serious risks, it requires infection prevention techniques, such as good hand washing, particulate filter air flow, a primary nurse, and strict aseptic technique.

Before marrow infusion

- ▮ Assess the patient's understanding of bone marrow transplantation. If necessary, correct any misconceptions, and provide additional information, as appropriate. Explain that the success of the procedure depends on the disease stage and an HLA-identical sibling match.
- ▮ Explain that chemotherapy and, possibly, radiation therapy are necessary to remove existing cells that may cause resistance to transplantation.
- ▮ To suppress the patient's immune system, various preparatory regimens may be used, including parenteral cyclophosphamide. This treatment requires aggressive hydration to prevent hemorrhagic cystitis. In conjunction with cyclophosphamide, the patient may receive additional chemotherapy or total-body irradiation. To control nausea and vomiting, give the patient an antiemetic such as ondansetron, granisetron or, occasionally, lorazepam, as needed.
- ▮ Because alopecia is a common adverse effect of high-dose cyclophosphamide therapy, urge the patient to choose a wig or scarf before treatment begins.
- ▮ Total-body irradiation given in one dose or daily for several consecutive days follows chemotherapy, inducing total marrow aplasia. Inform the patient that cataracts, GI disturbances, and sterility are possible adverse effects.
- ▮ Assess venous access. If necessary, the patient may have an indwelling central venous catheter inserted.

During marrow infusion

- ▮ Monitor the patient's vital signs to detect hypersensitivity reactions.
- ▮ Watch for complications of marrow infusion, such as pulmonary embolus and volume overload.
- ▮ Reassure the patient throughout the procedure.

After marrow infusion

- ▮ Continue to monitor vital signs every 4 hours. Watch for fever and chills, which may be the only signs of infection.
- ▮ Be alert for bradycardia, nausea, garlic taste in the mouth, and hypocalcemia, which can be caused by marrow preservatives.
- ▮ Give prophylactic antibiotics as ordered.
- ▮ To reduce the possibility of bleeding, don't administer medication rectally or I.M. Administer methotrexate, corticosteroids, or cyclosporine, as ordered, to prevent graft-versus-host (GVH) disease, a potentially fatal complication of transplantation. Watch for signs and symptoms of GVH disease, such as maculopapular rash, jaundice, arthralgia, and diarrhea, and for signs of failure to engraft, such as pancytopenia.
- ▮ Administer vitamins, steroids, and iron and folic acid supplements, as ordered. Blood products, such as platelets and packed red blood cells, may also be indicated, depending on the results of daily blood studies.
- ▮ Give good mouth care every 2 hours. Use chlorhexidine or other bactericidal mouthwash to prevent candidiasis and other mouth infections.
- ▮ Provide meticulous skin care, paying close attention to pressure points and open sites, such as I.V. sites.
- ▮ Teach the patient measures to prevent infection, such as avoiding crowds and people with known infection.
- ▮ Instruct the patient to avoid activities that have an increased risk of injury or bleeding, such as playing contact sports and using a razor blade. Suggest that the patient shave with an electric razor.
- ▮ For more information, refer the patient to the Aplastic Anemia Foundation of America.

A group of agents called colony-stimulating factors encourage the growth of specific cellular components and show some promise in trials of patients who have received chemotherapy or radiation therapy. These agents include granulocyte colony-stimulating factor, granulocyte-macrophage colony-stimulating factor, and erythropoietic stimulating factor.

Nursing diagnoses

⌞ Activity intolerance ⌞ Altered oral mucous membrane ⌞ Altered thought processes ⌞ Altered tissue perfusion (cerebral, cardiopulmonary) ⌞ Decreased cardiac output ⌞ Fatigue ⌞ Impaired gas exchange ⌞ Impaired physical mobility ⌞ Ineffective thermoregulation ⌞ Pain ⌞ Risk for infection

Key outcomes

- ⌞ The patient will state the need to increase activity level gradually.
- ⌞ The patient's blood pressure and pulse and respiratory rates will remain within prescribed limits during activity.
- ⌞ The patient's cardiac output will remain within range.
- ⌞ The patient will exhibit adequate ventilation.
- ⌞ The patient will express feelings of comfort and decreased pain.

Nursing interventions

- ⌞ Focus your efforts on helping to prevent or manage hemorrhage, infection, adverse effects of drug therapy, and blood transfusion reaction.
- ⌞ If the patient's platelet count is low (less than 20,000/μl), prevent hemorrhage by avoiding I.M. injections, suggesting the use of an electric razor and a soft toothbrush, humidifying oxygen to prevent drying of mucous membranes (dry mucosa may bleed), and promoting regular bowel movements through the use of a stool softener and a diet to prevent constipation (which can cause rectal mucosal bleeding). Apply pressure to venipuncture sites until bleeding stops. Detect bleeding early by checking for blood in urine and stool and assessing skin for petechiae.
- ⌞ Help prevent infection by washing your hands thoroughly before entering the patient's room, making sure the patient is receiving a nutritious diet (high in vitamins and proteins) to improve his resistance, and encouraging meticulous mouth and perianal care.
- ⌞ Make sure throat, urine, nasal, stool, and blood cultures are done regularly and correctly to check for infection.
- ⌞ If the patient has a low hemoglobin level, which causes fatigue, schedule frequent rest periods. Administer oxygen therapy, as needed.
- ⌞ Ensure a comfortable environmental temperature for a patient experiencing hypothermia or hyperthermia.
- ⌞ If blood transfusions are necessary, assess for a transfusion reaction by checking the patient's temperature and watching for the development of other signs and symptoms, such as rash, urticaria, pruritus, back pain, restlessness, and shaking chills.
- ⌞ To prevent aplastic anemia, monitor blood studies carefully in the patient receiving anemia-inducing drugs.

Patient teaching

- ⌞ Teach the patient to avoid contact with potential sources of infection, such as crowds, soil, and standing water that can harbor organisms.
- ⌞ Reassure and support the patient and his family by explaining the disease and its treatment, particularly if the patient has recurring acute episodes. Explain the purpose of all prescribed drugs, and discuss possible adverse reactions, including those he should report promptly.
- ⌞ Tell the patient who doesn't require hospitalization that he can continue his normal lifestyle with appropriate restrictions (such as regular rest periods) until remission occurs.
- ⌞ Support efforts to educate the public about the hazards of toxic agents. Tell parents to keep toxic agents out of their children's reach. Encourage people who work with radiation to wear protective clothing and a radiation-detecting badge and to observe plant safety precautions. Those who work with benzene (solvent) should know that 10 parts per million is the highest safe environmental level and that a delayed reaction to benzene may develop.
- ⌞ Refer the patient to the Aplastic Anemia Foundation of America for additional information and assistance.

FOLIC ACID DEFICIENCY ANEMIA

Folic acid deficiency anemia is a common, slowly progressive megaloblastic anemia. It's most prevalent in infants, adolescents, pregnant and lactating women, alcoholics, and elderly people and in people with malignant or intestinal diseases.

Causes

- Alcohol abuse suppressing the metabolic effects of folate is probably the most common cause of folic acid deficiency anemia. Additional causes include:
- ⌞ poor diet (common in alcoholics, narcotic addicts, elderly people who live alone, and infants, especially those with infections or diarrhea). Some adolescents whose diet consists mainly of nonnutritious food develop folate deficiency.
 - ⌞ impaired absorption (due to intestinal dysfunction from such disorders as celiac disease, tropical sprue, regional jejunitis, and bowel resection)
 - ⌞ bacteria competing for available folic acid
 - ⌞ excessive cooking of foods, which destroys the available nutrient
 - ⌞ limited storage capacity in infants
 - ⌞ prolonged drug therapy with such drugs as anticonvulsants, estrogens, and methotrexate
 - ⌞ increased folic acid requirements during pregnancy; during rapid growth periods in infancy (especially in surviving premature infants); during childhood and adolescence because of consumption of folate-poor calf's milk; and in patients with neoplastic diseases and some skin diseases, such as exfoliative dermatitis.

Foods high in folic acid content		
Folic acid (pteroylglutamic acid, folacin) is found in most body tissues, where it acts as a coenzyme in metabolic processes involving 1-carbon transfer. It's essential for formation and maturation of red blood cells and for synthesis of deoxyribonucleic acid. Although body stores are comparatively small (about 70 mg), this vitamin is plentiful in most well-balanced diets. However, because folic acid is water-soluble and heat-labile, it's easily destroyed by cooking. Also, about 20% of folic acid intake is excreted unabsorbed. Insufficient daily folic acid intake (less than 50 μg/day) usually induces folic acid deficiency within 4 months. Below is a list of foods high in folic acid content.		
FOOD	MCG/100 G	
Asparagus spears		109
Beef liver		294
Broccoli spears		54
Collards (cooked)		102
Mushrooms		24
Oatmeal		33
Peanut butter		57
Red beans		180
Wheat germ		305

Complications

Folic acid deficiency anemia produces no complications.

Assessment findings

The patient's history may reveal severe, progressive fatigue, the hallmark of folic acid deficiency. Associated findings include shortness of breath, palpitations, diarrhea, nausea, anorexia, headaches, forgetfulness, and irritability. The impaired oxygen-carrying capacity of the blood from lowered hemoglobin levels may produce complaints of weakness and light-headedness.

Inspection may reveal generalized pallor and jaundice. The patient may appear wasted. Cheilosis and glossitis may be present. Folic acid deficiency anemia doesn't cause neurologic impairment unless it's associated with vitamin B₁₂ deficiency.

Diagnostic tests

The Schilling test and a therapeutic trial of vitamin B₁₂ injections distinguish between folic acid deficiency anemia and pernicious anemia. Significant findings on blood studies include macrocytosis, decreased reticulocyte count, increased mean corpuscular volume, abnormal platelets, and serum folate levels less than 4 mg/ml.

Treatment

Medical treatment consists primarily of folic acid supplements and elimination of contributing causes. Supplements may be given orally (1 to 5 mg/day) or parenterally (to patients who are severely ill, have malabsorption, or are unable to take oral medication). Many patients respond favorably to a well-balanced diet. (See [Foods high in folic acid content.](#))

Nursing diagnoses

u Activity intolerance u Altered growth and development u Altered nutrition: Less than body requirements u Altered oral mucous membrane u Altered thought processes u Altered tissue perfusion (cerebral) u Diarrhea u Fluid volume deficit u Impaired gas exchange

Key outcomes

- u The patient will state the need to increase activity level gradually.
- u The patient's blood pressure and pulse and respiratory rates will remain within prescribed limits during activity.
- u The patient will remain hemodynamically stable.
- u The patient's bowel movements will return to normal.
- u The patient will experience no further weight loss.

Nursing interventions

- u If the patient has severe anemia, plan activities, rest periods, and necessary diagnostic tests to conserve his energy. Monitor his pulse rate often; tachycardia indicates that his activities are too strenuous.
- u Advise the patient to report signs and symptoms of decreased perfusion to vital organs (dyspnea, chest pain, dizziness).
- u If the patient has glossitis, emphasize the importance of good oral hygiene. Suggest regular use of a mild or diluted mouthwash and a soft toothbrush. Oral anesthetics can be used to allay discomfort.
- u Because a sore mouth and tongue make eating painful, ask the dietitian to give the patient nonirritating foods. If these symptoms make talking difficult, supply a pad and pencil or some other aid to facilitate nonverbal communication; explain this problem to the family.
- u To ensure accurate Schilling test results, make sure that all urine excreted over a 24-hour period is collected and that the specimens remain uncontaminated by bacteria.
- u Provide a well-balanced diet, including foods high in folate, such as dark green leafy vegetables, organ meats, eggs, milk, oranges, bananas, dry beans, and whole-grain breads. Offer between-meal snacks, and encourage the family to bring favorite foods from home.
- u Monitor fluid and electrolyte balance, particularly in the patient who has severe diarrhea and is receiving parenteral fluid replacement therapy.

Patient teaching

- u To prevent folic acid deficiency anemia, emphasize the importance of a well-balanced diet high in folic acid. Identify alcoholics and other high-risk people with poor dietary habits, and try to arrange for appropriate counseling. Tell mothers who are not breast-feeding to use commercially prepared formulas.
- u Teach the patient to meet daily folic acid requirements by including a food from each food group in every meal. If the patient has a severe deficiency, explain that diet only reinforces folic acid supplementation and isn't therapeutic by itself. Urge compliance with the prescribed course of therapy. Advise the patient not to stop taking the supplements when he begins to feel better.
- u Warn the patient to guard against infections, and tell him to report signs of infection promptly, especially pulmonary and urinary tract infections, because the patient's weakened condition may increase susceptibility.

IRON DEFICIENCY ANEMIA

Iron deficiency anemia is a common disease worldwide; it affects 10% to 30% of the adult population of the United States. It's most prevalent among premenopausal women, infants (particularly premature or low-birth-weight infants), children, adolescents (especially girls), alcoholics, and elderly people (especially those who are unable to cook). The prognosis after replacement therapy is favorable.

Causes and pathophysiology

Iron deficiency anemia stems from an inadequate supply of iron for optimal formation of red blood cells (RBCs), which produces smaller (microcytic) cells with less color on staining. Body stores of iron, including plasma iron, decrease, as does transferrin, which binds with and transports iron. Insufficient body stores of iron lead to a depleted RBC mass and, in turn, to a decreased hemoglobin concentration (hypochromia) and decreased oxygen-carrying capacity of the blood. (See [Iron absorption and storage.](#))

Iron deficiency can result from any of the following:

- u inadequate dietary intake of iron, as in prolonged nonsupplemented breast- or bottle-feeding of infants; during periods of stress, such as rapid growth in children and adolescents; and in elderly patients existing on a poorly balanced diet
- u iron malabsorption, as in chronic diarrhea, partial or total gastrectomy, and malabsorption syndromes, such as celiac disease
- u blood loss secondary to drug-induced GI bleeding (from anticoagulants, aspirin, steroids) or due to heavy menses, hemorrhage from trauma, GI ulcers, malignant tumors, and varices
- u pregnancy, in which the mother's iron supply is diverted to the fetus for erythropoiesis
- u intravascular hemolysis-induced hemoglobinuria or paroxysmal nocturnal hemoglobinuria
- u mechanical erythrocyte trauma caused by a prosthetic heart valve or vena cava filter.

Complications

Possible complications of this disorder include infection and pneumonia. In a child, iron deficiency anemia can cause pica, which may lead to eating lead-based paint

and can result in lead poisoning. Another complication is bleeding, which may be identified by ecchymotic areas on the skin, hematuria, and gingival bleeding.

Iron absorption and storage
<p>Iron is essential to erythropoiesis and is abundant throughout the body. Two-thirds of total body iron is found in hemoglobin; the other third, mostly in the reticuloendothelial system (liver, spleen, and bone marrow), with small amounts in muscle, serum, and body cells.</p> <p>Adequate dietary ingestion of iron and recirculation of iron released from disintegrating red cells maintain iron supplies. The duodenum and upper part of the small intestine absorb dietary iron. Such absorption depends on gastric acid content, the amount of reducing substances (ascorbic acid, for example) present in the alimentary canal, and dietary iron intake. If iron intake is deficient, the body gradually depletes its iron stores, causing decreased hemoglobin levels and, eventually, signs and symptoms of iron deficiency anemia.</p>

The most significant complication of iron deficiency anemia stems from over-replacement of oral or I.M. iron supplements. Hemochromatosis (excessive iron deposits in tissue) can result, affecting the liver, heart, pituitary glands, and joints. Iron poisoning can occur in children when toxic levels are allowed to build up during therapy.

Assessment findings

Iron deficiency anemia can persist for years without signs and symptoms. The characteristic history of fatigue, inability to concentrate, headache, and shortness of breath (especially on exertion) may not develop until long after iron stores and circulating iron become low. The patient may report increased frequency of infections and pica, an uncontrollable urge to eat strange things, such as clay, starch, ice and, in children, lead. A female patient may give a history of menorrhagia.

In chronic iron deficiency anemia, the patient history may include complaints of dysphagia and neuromuscular effects, such as vasomotor disturbances, numbness and tingling of the extremities, and neuralgic pain. Inspection may reveal a red, swollen, smooth, shiny, and tender tongue (glossitis). The corners of the mouth may be eroded, tender, and swollen (angular stomatitis). Inspection may also reveal spoon-shaped, brittle nails.

A patient with advanced iron deficiency anemia may develop tachycardia because decreased oxygen perfusion causes the heart to compensate with increased cardiac output. In such a patient, the oxygen saturation level may be below 90%.

Diagnostic tests

Blood studies and stores in bone marrow may confirm iron deficiency anemia. However, the results of these tests can be misleading because of complicating factors, such as infection, pneumonia, blood transfusion, and iron supplements. Characteristic blood study results include:

- u low hemoglobin levels (males, less than 12 g/dl; females, less than 10 g/dl)
- u low hematocrit (males, less than 47 ml/dl; females, less than 42 ml/dl)
- u low serum iron levels with high binding capacity
- u low serum ferritin levels
- u low RBC count with microcytic and hypochromic cells (in early stages, RBC count may be normal, except in infants and children)
- u decreased mean corpuscular hemoglobin in severe anemia.

Bone marrow studies reveal depleted or absent iron stores (done by staining) as well as normoblastic hyperplasia.

GI studies, such as guaiac stool tests, barium swallow and enema, endoscopy, and sigmoidoscopy, rule out or confirm the diagnosis of bleeding causing the iron deficiency.

Diagnosis must rule out other forms of anemia, such as those that result from thalassemia minor, cancer, and chronic inflammatory, hepatic, and renal disease.

Treatment

The underlying cause of anemia must first be determined; then iron replacement therapy can begin. The treatment of choice is an oral preparation of iron or a combination of iron and ascorbic acid (which enhances iron absorption). In rare cases, iron may have to be administered I.M., for instance, if the patient is noncompliant with the oral preparation, if he needs more iron than he can take orally, if malabsorption prevents adequate iron absorption, or if a maximum rate of hemoglobin regeneration is desired. (See [Injecting iron solutions.](#))

Total-dose I.V. infusions of supplemental iron can be administered to pregnant and elderly patients with severe iron deficiency anemia. The patient should receive this painless infusion of iron dextran in normal saline solution over 8 hours. To minimize the risk of an allergic reaction to iron, an I.V. test dose of 0.5 ml should be given first.

Injecting iron solutions

For deep I.M. injections of iron solutions, use the Z-track technique to avoid subcutaneous irritation and discoloration from leaking medication.

1 Choose an injection site

Rotate the injection sites in the upper outer quadrant of the buttocks.

2 Displace tissues

Choose a 19G to 20G, 2" to 3" (5- to 7.5-cm) needle. After drawing up the solution, change to a fresh needle to avoid tracking the solution through to subcutaneous tissue. Draw 0.5 cc of air into the syringe as an air-lock.

Displace the skin and fat at the injection site firmly to one side.

3 Inject the solution

Clean the area and insert the needle. Aspirate to check for entry into a blood vessel. Inject the solution slowly followed by the 0.5 cc of air in the syringe.

After injecting the solution, wait 10 seconds.

4 Release the tissues

Pull the needle straight out and release the tissues.

Apply direct pressure to the site, but don't massage it. Caution the patient not to exercise vigorously for at least 15 minutes after the injection.

WARNING

Recognizing iron overdose

Excessive iron replacement is demonstrated when such signs and symptoms as diarrhea, fever, severe stomach pain, nausea, and vomiting occur.

Notify the doctor promptly when these signs and symptoms occur and administer prescribed treatments. For this acute condition, treatment includes giving iron-binding agents (deferoxamine), inducing vomiting that produces systemic alkalization, and giving anticonvulsants.

Nursing diagnoses

- u Activity intolerance
- u Altered growth and development
- u Altered nutrition: Less than body requirements
- u Altered oral mucous membrane
- u Altered thought processes
- u Altered tissue perfusion (cerebral, cardiopulmonary)
- u Fatigue
- u Impaired gas exchange
- u Knowledge deficit
- u Pain

Key outcomes

- u The patient will maintain adequate ventilation.
- u The patient will maintain weight without further loss.
- u The patient's blood pressure and pulse and respiratory rates will remain within prescribed limits during activity.
- u The patient will express feelings of increased energy.
- u The patient will express feelings of comfort and decreased pain.

Nursing interventions

- u Note signs or symptoms of decreased perfusion to vital organs (dyspnea, chest pain, dizziness) and signs of neuropathy, such as tingling in the periphery. Provide oxygen therapy as necessary to help prevent and reduce hypoxia.
- u Assess the family's dietary habits for iron intake, noting the influence of childhood eating patterns, cultural food preferences, and family income on adequate nutrition.
- u Because a sore mouth and tongue make eating painful, ask the dietitian to give the patient nonirritating foods. If these symptoms make talking difficult, supply a pad and pencil or some other communication aid. Provide diluted mouthwash or, in especially severe conditions, swab the patient's mouth with tap water or warm saline solution. Oral anesthetic diluted in saline solution can also be used.
- u As ordered, administer analgesics for headache and other discomfort, and monitor their effectiveness.
- u Evaluate the patient's drug history. Certain drugs, such as pancreatic enzymes and vitamin E, can interfere with iron metabolism and absorption; aspirin, steroids, and other drugs can cause GI bleeding.
- u Provide frequent rest periods to decrease physical exhaustion. Plan activities so that the patient has sufficient rest between them. Monitor the patient's pulse rate often; tachycardia indicates that his activities are too strenuous.
- u If the patient receives iron I.V., monitor the infusion rate carefully and observe for an allergic reaction. Stop the infusion and begin supportive treatment immediately if the patient shows signs of an adverse reaction. Also, watch for dizziness and headache and for thrombophlebitis around the I.V. site.
- u Use the Z-track injection method when administering iron I.M. to prevent skin discoloration, scarring, and irritating iron deposits in the skin.
- u Monitor the patient for iron replacement overdose. (See [Recognizing iron overdose.](#))
- u Provide good nutrition and meticulous care of I.V. sites such as those used for blood transfusions to help prevent infection.
- u Monitor the patient's compliance with the prescribed iron supplement therapy.

Patient teaching

- u Reinforce the doctor's explanation of the disorder, and answer any questions. Be sure the patient fully understands the prescribed treatments and possible complications.
- u Ask about possible exposure to lead in the home (especially for children) or on the job. Teach the patient and his family about the dangers of lead poisoning, especially if the patient reports pica.
- u Advise the patient not to stop therapy even if he feels better because replacement of iron stores takes time.
- u Inform the patient that milk or an antacid interferes with absorption but that vitamin C can increase absorption. Instruct the patient to drink liquid supplemental iron through a straw to avoid staining his teeth.
- u Tell the patient to report adverse effects of iron therapy, such as nausea, vomiting, diarrhea, and constipation, which may require a dosage adjustment or supplemental stool softeners.
- u Teach the basics of a nutritionally balanced diet—red meats, green vegetables, eggs, whole wheat, iron-fortified bread, and milk. Explain that no food in itself contains enough iron to treat iron deficiency anemia; an average-sized person with anemia would have to eat at least 10 lb (4.5 kg) of steak daily to receive therapeutic amounts of iron.
- u Warn the patient to guard against infections because his weakened condition may increase his susceptibility. Stress the importance of meticulous wound care, periodic dental checkups, good hand-washing techniques, and other measures to prevent infection. Also tell the patient to report any signs of infection, including temperature elevation and chills.
- u Because an iron deficiency may recur, explain the need for regular checkups and to comply with prescribed treatments. (See [Preventing iron deficiency anemia.](#))

PERNICIOUS ANEMIA

Pernicious anemia—also known as Addison's anemia—is a megaloblastic anemia characterized by decreased gastric production of hydrochloric acid and deficiency of intrinsic factor, a substance normally secreted by the parietal cells of the gastric mucosa that is essential for vitamin B₁₂ absorption. The resulting deficiency of vitamin B₁₂ causes serious neurologic, psychological, gastric, and intestinal abnormalities. Increasingly fragile cell membranes induce widespread destruction of red blood cells (RBCs), resulting in low hemoglobin levels.

In the United States, pernicious anemia is most common in New England and the Great Lakes region because of ethnic concentration. It's rare in children, Blacks, and Asians. Onset typically is between ages 50 and 60; incidence increases with advancing age.

Causes and pathophysiology

Familial incidence of pernicious anemia suggests a genetic predisposition. This disorder is significantly more common in patients with immunologically related diseases, such as thyroiditis, myxedema, and Graves' disease.

An inherited autoimmune response may cause gastric mucosal atrophy and, consequently, decreases hydrochloric acid and intrinsic factor production. Intrinsic factor deficiency impairs vitamin B₁₂ absorption. The resultant vitamin B₁₂ deficiency inhibits the growth of all cells, particularly RBCs, leading to insufficient and deformed RBCs with poor oxygen-carrying capacity.

PREVENTION

Preventing iron deficiency anemia

Public health officials can play a vital role in the prevention of iron deficiency anemia by:

- teaching the basics of a nutritionally balanced diet—red meats, green vegetables, eggs, whole wheat, iron-fortified bread, cereals, and milk. (No food in itself contains enough iron to treat iron deficiency anemia; an average-sized person with anemia would have to eat 10 lb [4.5 kg] of steak daily to receive therapeutic amounts of iron.)
- emphasizing the need for high-risk individuals—such as premature infants, children under age 2, and pregnant women—to receive prophylactic oral iron, as ordered by a doctor. (Children under age 2 should also receive supplemental cereals and formulas high in iron.)
- assessing a family's dietary habits for iron intake and noting the influence of childhood eating patterns, cultural food preferences, and family income on adequate nutrition.
- encouraging families with deficient iron intake to eat meat, fish, or poultry; whole or enriched grain; and foods high in ascorbic acid.
- carefully assessing a patient's drug history because certain drugs, such as pancreatic enzymes and vitamin E, may interfere with iron metabolism and absorption and because aspirin, steroids, and other drugs may cause GI bleeding. (Teach patients who must take gastric irritants to take these medications with meals or milk.)

Pernicious anemia also impairs myelin formation. Initially, it affects the peripheral nerves but gradually it extends to the spinal cord, causing neurologic dysfunction.

Secondary pernicious anemia can result from partial removal of the stomach, which limits the amount of productive mucosa.

Complications

Patients treated with vitamin B₁₂ injections have few permanent complications. Those who go untreated may experience permanent neurologic disability (including paralysis) and psychotic behavior; they also may lose sphincter control of bowel and bladder, and some may die of the disorder. Although the reason is unclear, the incidence of peptic ulcer disease is four to five times greater in patients with pernicious anemia than in the general population.

Assessment findings

Although pernicious anemia usually has an insidious onset, the patient's history may reveal the characteristic triad of symptoms: weakness; a beefy red, sore tongue; and numbness and tingling in the extremities. The patient may also complain of nausea, vomiting, anorexia, weight loss, flatulence, diarrhea, and constipation.

On inspection, the lips, gums, and tongue appear markedly bloodless. Slightly jaundiced sclera and pale to bright yellow skin may be present with hemolysis-induced hyperbilirubinemia.

The patient's pulse rate is rapid, and auscultation may reveal a systolic murmur. Percussion or palpation may reveal an enlarged liver and spleen.

When neurologic involvement occurs, the patient may complain of weakness in the extremities; peripheral numbness and paresthesia; disturbed position sense; lack of coordination; impaired fine finger movement; light-headedness; headache; altered vision (diplopia, blurred vision), taste, and hearing (tinnitus); loss of bowel and bladder control; and, in males, impotence.

You may observe that the patient is irritable, depressed, delirious, and ataxic and has memory loss. You also may note positive Babinski's and Romberg's signs and optic muscle atrophy. Although some of these symptoms are temporary, irreversible central nervous system changes may occur before treatment is initiated.

Complaints of weakness, light-headedness, and fatigue stem from the impaired oxygen-carrying capacity of the blood owing to lowered hemoglobin levels. Compensatory increased cardiac output may cause palpitations, dyspnea, orthopnea, tachycardia, premature beats and, eventually, heart failure.

Diagnostic tests

The results of blood studies, bone marrow examination, gastric analysis, and the Schilling test establish the diagnosis. Laboratory screening must rule out other anemias with similar symptoms, such as folic acid deficiency anemia, because treatment differs. Diagnosis must also rule out vitamin B₁₂ deficiency resulting from malabsorption due to GI disorders, gastric surgery, radiation therapy, or drug therapy.

Blood study results that suggest pernicious anemia include:

- decreased hemoglobin levels (4 to 5 g/dl) and decreased RBC count
- increased mean corpuscular volume (under 120 mm³); because larger-than-normal RBCs *each* contain increased amounts of hemoglobin, mean corpuscular hemoglobin concentration is also increased
- possibly low white blood cell and platelet counts and large, malformed platelets
- serum vitamin B₁₂ levels less than 0.1 µg/ml
- elevated serum lactate dehydrogenase levels.

Bone marrow studies reveal erythroid hyperplasia (crowded red bone marrow) with increased numbers of megaloblasts but few normally developing RBCs. Gastric analysis shows an absence of free hydrochloric acid after histamine or pentagastrin injection.

The Schilling test is the definitive test for pernicious anemia. In this test, the patient receives a small (0.5- to 2-mcg) oral dose of radioactive vitamin B₁₂ after fasting for 12 hours. A larger (1-mg) dose of nonradioactive vitamin B₁₂ is given I.M. 2 hours later as a parenteral flush, and the radioactivity of a 24-hour urine specimen is measured. About 7% of the radioactive B₁₂ dose is excreted in the first 24 hours; people with pernicious anemia excrete less than 3%. (Normally, vitamin B₁₂ is absorbed, and excess amounts are excreted in the urine; in pernicious anemia, the vitamin remains unabsorbed and is passed in the stool.) When the Schilling test is repeated with intrinsic factor added, the test shows normal excretion of vitamin B₁₂.

Important serologic findings may include 1F antibodies and parietal cell antibodies.

Treatment

Early I.M. vitamin B₁₂ replacement can reverse pernicious anemia and may prevent permanent neurologic damage. An initial high dose of parenteral vitamin B₁₂ causes rapid RBC regeneration. Within 2 weeks, hemoglobin should increase to normal and the patient's condition should markedly improve. Because rapid cell regeneration increases the patient's iron requirements, concomitant iron replacement is necessary to prevent iron deficiency anemia. After the patient's condition improves, vitamin B₁₂ doses can be decreased to maintenance levels and given monthly. Because such injections must be continued for life, patients should learn self-administration.

If anemia causes extreme fatigue, the patient may require bed rest until hemoglobin increases. If he is critically ill, with severe anemia and cardiopulmonary distress, he may need blood transfusions, digitalis, a diuretic, and a low-sodium diet for heart failure. Most important is the replacement of vitamin B₁₂ to control the condition that led to this failure. Antibiotics help to combat accompanying infections, and topical anesthetics can relieve mouth pain.

Nursing diagnoses

▫ Activity intolerance ▫ Altered nutrition: Less than body requirements ▫ Altered oral mucous membrane ▫ Altered tissue perfusion (cardiopulmonary) ▫ Fatigue ▫ Impaired gas exchange ▫ Impaired physical mobility ▫ Impaired swallowing ▫ Pain ▫ Risk for infection ▫ Risk for injury ▫ Self-care deficit ▫ Sensory or perceptual alterations

Key outcomes

- u The patient will state understanding of the need to increase activity level gradually.
- u The patient's blood pressure and pulse and respiratory rates will remain within prescribed limits during activity.
- u The patient will remain hemodynamically stable.
- u The patient will modify lifestyle to minimize risk of decreased tissue perfusion.
- u Hemoglobin levels and hematocrit will return to normal.
- u The patient will maintain adequate ventilation.
- u The patient's clotting profile will remain within specified normal limits.
- u The patient and family members will demonstrate prevention and safety measures.

Nursing interventions

- u If the patient has severe anemia, plan activities, rest periods, and necessary diagnostic tests to conserve his energy. Monitor pulse rate often; tachycardia indicates that his activities are too strenuous.
- u Advise the patient to report signs and symptoms of decreased perfusion to vital organs (dyspnea, chest pain, dizziness) and symptoms of neuropathy, such as tingling in the periphery.
- u To ensure accurate Schilling test results, make sure that all urine excreted over a 24-hour period is collected and that the specimens remain uncontaminated by bacteria.
- u Provide a well-balanced diet, including foods high in vitamin B₁₂ (meat, liver, fish, eggs, and milk). Offer between-meal snacks, and encourage the family to bring favorite foods from home.
- u Because a sore mouth and tongue make eating painful, ask the dietitian to avoid giving the patient irritating foods. If these symptoms make talking difficult, supply a pad and pencil or some other aid to facilitate nonverbal communication; explain this problem to the family. Provide diluted mouthwash or, with severe conditions, swab the patient's mouth with tap water or warm saline solution. Oral anesthetics diluted in normal saline solution also may be used.
- u If the patient is incontinent, establish a regular bowel and bladder routine. After the patient is discharged, a visiting nurse should follow up on this schedule and make adjustments, as needed.
- u If neurologic damage causes behavioral problems, assess mental and neurologic status often; if necessary, give tranquilizers as ordered, and if needed, apply a soft restraint at night.
- u Institute safety precautions to prevent falls.

Patient teaching

- u Warn the patient to guard against infections, and tell him to report signs of infection promptly, especially pulmonary and urinary tract infections, because the patient's weakened condition may increase susceptibility.
- u Caution the patient with a sensory deficit to avoid exposure to extreme heat or cold on the extremities.
- u If neurologic involvement is present, advise the patient to avoid clothing with small buttons and activities of daily living that require fine motor skills.
- u Stress that vitamin B₁₂ replacement isn't a permanent cure and that these injections must be continued for life, even after symptoms subside.
- u If possible, teach the patient or his caregiver proper injection techniques.
- u Teach family members to observe for confusion and irritability and to report these findings to the doctor.
- u To prevent pernicious anemia, emphasize the importance of vitamin B₁₂ supplements for patients who have had extensive gastric resections or who follow strict vegetarian diets.

SICKLE CELL ANEMIA

Sickle cell anemia is a congenital hemolytic disease that results from a defective hemoglobin molecule (hemoglobin S) that causes red blood cells (RBCs) to become sickle shaped. Such cells impair circulation, resulting in chronic ill health (fatigue, dyspnea on exertion, swollen joints), periodic crises, long-term complications, and premature death.

Sickle cell anemia is most common in tropical Africans and in people of African descent; about 1 in 10 African-Americans carries the abnormal gene. If 2 such carriers have offspring, each child has a 1-in-4 chance of developing the disease. Overall, 1 in every 400 to 600 black children has sickle cell anemia. This disease also occurs in Puerto Rico, Turkey, India, the Middle East, and the Mediterranean area. Possibly, the defective hemoglobin S–producing gene has persisted because in areas where malaria is endemic, the heterozygous sickle cell trait provides resistance to malaria and is actually beneficial.

Comparing normal and sickled red blood cells	
As you can see, the properties of normal round and sickled red blood cells (RBCs) vary in more ways than shape.	
NORMAL CELLS	SICKLED CELLS
	
u 120-day life span	u 30- to 40-day life span
u Hemoglobin (Hb) has normal oxygen-carrying capacity	u 12 to 14 g of Hb/ml
u Hb A	u 6 to 9 g of Hb/ml
u RBCs destroyed at normal rate	u Hb S
u Hb has decreased oxygen-carrying capacity	u RBCs destroyed at accelerated rate

Penicillin prophylaxis can decrease morbidity and mortality from bacterial infections.

Causes and pathophysiology

Sickle cell anemia results from homozygous inheritance of the hemoglobin S–producing gene, which causes substitution of the amino acid valine for glutamic acid in the beta hemoglobin chain. Heterozygous inheritance of this gene results in sickle cell trait, a condition with minimal or no symptoms. The patient with sickle cell trait is a carrier; he can pass the sickle cell gene to his offspring.

In sickle cell anemia, the abnormal hemoglobin S found in the patient's RBCs becomes insoluble whenever hypoxia occurs. As a result, these RBCs become rigid, rough, and elongated, forming a crescent or sickle shape. Such sickling can produce hemolysis (cell destruction). (See [Comparing normal and sickled red blood cells.](#))

Each person with sickle cell anemia has a different hypoxic threshold and different factors that precipitate a sickle cell crisis. Illness, cold exposure, and stress are known to precipitate sickling crises in most people. (See [What happens in sickle cell crisis.](#))

In addition, these altered cells accumulate in capillaries and smaller blood vessels, making the blood more viscous. Normal circulation is impaired, causing pain, tissue infarctions, and swelling. Such blockage causes anoxic changes that lead to further sickling and obstruction.

Complications

Sickle cell anemia causes long-term complications. An adult with this disease may develop chronic obstructive pulmonary disease, heart failure, or organ infarction, such as retinopathy and nephropathy. Splenic infarctions are common and often cause significant necrosis early in life, so that splenomegaly leads to a small, nodular, and malfunctioning spleen (see [Hypersplenism](#)). Infection or repeated occlusion of small blood vessels and consequent infarction or necrosis of major organs commonly cause premature death. For example, cerebral blood vessel occlusion causes cerebrovascular accident and is the most common cause of death in severe sickle cell disease. Frequent sickling and hyperviscosity can lead to heart murmurs and heart failure.

Assessment findings

Signs and symptoms usually don't develop until after age 6 months because large amounts of fetal hemoglobin protect infants for the first few months after birth.

Characteristically, the patient history in sickle cell anemia includes chronic fatigue, unexplained dyspnea or dyspnea on exertion, joint swelling, aching bones, chest pain, ischemic leg ulcers (especially around the ankles), and an increased susceptibility to infection. The patient's medical history may include pulmonary infarctions and cardiomegaly.

Inspection may reveal jaundice or pallor. A young child may appear small for his age; an older child may experience delayed growth and puberty. Inspection of an adult usually reveals a spiderlike body build (narrow shoulders and hips, long extremities, curved spine, and barrel chest).

Typically, assessment of the patient's vital signs reveals tachycardia. Palpation may disclose hepatomegaly and, in children, splenomegaly. (Splenomegaly is usually absent in adults because the spleen shrinks over time.) Auscultation may detect systolic and diastolic murmurs.

- In sickle cell crisis, assessment findings include the following:
- u history of recent infection, stress, dehydration, or other conditions that provoke hypoxia, such as strenuous exercise, high altitude, unpressurized aircraft, cold, and vasoconstrictive drugs
 - u complaints of sleepiness with difficulty awakening, severe pain and, sometimes, hematuria
 - u pale lips, tongue, palms, and nail beds; lethargy; listlessness; and often irritability
 - u body temperature over 104° F (40° C) or a temperature of 100° F (37.8° C) that persists for 2 or more days.

The following characteristic signs and symptoms help determine the type of crisis the patient is experiencing:

- u A *painful crisis* (vaso-occlusive crisis, infarctive crisis), the most common crisis and hallmark of this disease, usually appears periodically after age 5. It results from blood vessel obstruction by rigid, tangled sickle cells, which causes tissue anoxia and, possibly, necrosis. Characteristics of a painful crisis are severe abdominal, thoracic, muscle, or bone pain and, possibly, increased jaundice, dark urine, and a low-grade fever. Patients with long-term disease may experience autosplenectomy, where splenic damage and scarring are so extensive that the spleen shrinks and becomes impalpable, leading to increased susceptibility to *Streptococcus pneumoniae* sepsis, which can be fatal without prompt treatment. After the crisis subsides (in 4 days to several weeks), infection may develop, producing lethargy, sleepiness, fever, and apathy.
- u An *aplastic crisis* (megaloblastic crisis) results from bone marrow depression and is associated with infection (usually viral). It's characterized by pallor, lethargy, sleepiness, dyspnea, possible coma, markedly decreased bone marrow activity, and RBC hemolysis.
- u An *acute sequestration crisis* occurs in infants between ages 8 months and 2 years and may cause sudden, massive entrapment of RBCs in the spleen and liver. This rare crisis causes lethargy and pallor and, if untreated, commonly progresses to hypovolemic shock and death.
- u A *hemolytic crisis* is rare and usually affects patients who have glucose-6-phosphate dehydrogenase deficiency with sickle cell anemia. It probably results from complications of sickle cell anemia, such as infection, rather than from the disorder itself. In hemolytic crisis, degenerative changes cause liver congestion and hepatomegaly. Chronic jaundice worsens, although increased jaundice doesn't always indicate a hemolytic crisis.

PATHOPHYSIOLOGY

What happens in sickle cell crisis

Sickle cell crisis occurs when a patient with sickle cell anemia experiences cellular oxygen deprivation, for example, from an infection, exposure to cold or high altitude, or overexertion.

Sickle cell anemia results from an alteration in the molecular structure of hemoglobin: One amino acid is substituted for another. This deprives the red blood cells of needed oxygen. In response, their altered hemoglobin molecules aggregate, sickling cells and causing cellular, vascular, and tissue damage. The result is disabling pain and, ultimately, tissue necrosis.

Diagnostic tests

A positive family history and typical clinical features suggest sickle cell anemia; a stained blood smear showing sickle cells and hemoglobin electrophoresis showing hemoglobin S confirm it. Electrophoresis should be done on umbilical cord blood samples at birth to provide sickle cell disease screening for all neonates at risk. Additional laboratory studies show low RBC counts, elevated white blood cell and platelet counts, decreased erythrocyte sedimentation rate, increased serum iron levels, decreased RBC survival, and reticulocytosis. Hemoglobin levels may be low or normal.

A lateral chest X-ray may be performed to detect the characteristic “Lincoln log” deformity. This spinal abnormality develops in many adults and some adolescents with sickle cell anemia, leaving the vertebrae resembling logs that form the corner of a cabin.

An ophthalmoscopic examination to detect cork-screw or comma-shaped vessels in the conjunctivae, another sign of this disease, may also be performed.

Treatment

Although sickle cell anemia can't be cured, treatments can alleviate symptoms and prevent painful crises. Certain vaccines, such as polyvalent pneumococcal and *Haemophilus influenzae* B vaccine; anti-infectives, such as low-dose oral penicillin; and chelating agents, such as deferoxamine, can minimize complications resulting from the disease and from transfusion therapy.

Hypersplenism

Hypersplenism causes peripheral blood cell deficiency as the spleen's filtering and phagocytic functions accelerate, removing antibody-coated, aging, abnormal, and functionally normal cells. The enlarged spleen can trap up to 90% of normal platelets and 45% of red blood cells (RBCs).

Hypersplenism may be idiopathic (primary) or secondary to disorders such as rheumatoid arthritis, malaria, sickle cell anemia, and polycythemia vera. Infection, anemia, and hemorrhage can complicate hypersplenism.

The patient typically has frequent infections. He may complain of weakness, easy bruising, a sore mouth due to lacerations and, rarely, abdominal pain. Assessment findings may include fever, rapid pulse rate, palpitations, a tender and enlarged spleen, and signs of the underlying problem.

A high spleen-liver ratio of radioactivity (after I.V. infusion of chromium-labeled RBCs or platelets) indicates splenic destruction or sequestration. Complete blood count shows hemoglobin levels as low as 4 g/dl, white blood cell count less than 4,000/ μ l, platelet count less than 125,000/ μ l, and an elevated reticulocyte count. Splenic scan and angiography may be useful. Biopsy is risky and therefore avoided.

Secondary hypersplenism necessitates treatment of the underlying disease. Splenectomy is indicated in a transfusion-dependent patient who doesn't respond to other therapy. Occasionally, splenectomy hastens blood cell destruction in the bone marrow and liver.

Other medications, such as analgesics, may help to relieve the pain of vaso-occlusive crisis. Iron supplements may be given if folic acid levels are low. A good antisickling agent isn't yet available; the most commonly used drug, sodium cyanate, has many adverse effects.

Treatment begins before age 4 months with prophylactic penicillin. If the patient's hemoglobin level decreases suddenly or if his condition deteriorates rapidly, hospitalization is needed for transfusion of packed RBCs.

In an acute sequestration crisis, treatment may include sedation and administration of analgesics, blood transfusion, oxygen therapy, and large amounts of oral or I.V. fluids. Despite the effectiveness of transfusions, some clinicians limit them because they increase blood viscosity and the risk of vascular occlusion.

Nursing diagnoses

u Altered growth and development u Altered tissue perfusion (peripheral) u Body image disturbance u Fatigue u Hyperthermia u Impaired gas exchange u Impaired tissue integrity u Knowledge deficit u Pain u Risk for fluid volume deficit

Key outcomes

- u The patient will demonstrate age-appropriate skills and behaviors to the extent possible.
- u The patient will exhibit adequate ventilation.
- u The patient will maintain collateral circulation.
- u The patient's fluid volume will remain in the normal range; input will equal output.
- u The patient will express feelings of comfort and decreased pain.
- u The patient's peripheral pulses will be present and strong.
- u The patient's skin color and temperature will remain unchanged.

Nursing interventions

- u Encourage the patient to talk about his fears and concerns. Try to stay with him during periods of severe crisis and anxiety. Provide reassurance, when possible, but always answer his questions honestly.
- u If a male patient develops sudden, painful priapism, reassure him that such episodes are common and have no permanent harmful effects.
- u Ensure that the patient receives adequate amounts of folic acid–rich foods, such as leafy green vegetables. Encourage adequate fluid intake to hydrate the patient; give parenteral fluids, if necessary. Provide eggnog, ice pops, and milkshakes to meet fluid requirements.
- u Apply warm compresses, warmed thermal blankets, and warming pads or mattresses to painful areas of the patient's body. Consider the weight of the warming appliance to avoid aggravating pain. Never apply cold to a painful area.
- u Administer analgesics and antipyretics as necessary. Each patient's level of pain is different; some may require acetaminophen to control the pain; others may have continuous pain during crisis while receiving morphine.
- u When cultures demonstrate the presence of infection, administer antibiotics as ordered. Also administer prophylactic antibiotics as ordered. Use strict aseptic technique when performing treatments.
- u Encourage bed rest with the head of the bed elevated to decrease tissue oxygen demand. Administer oxygen only if the patient is experiencing severe dyspnea.
- u Administer blood transfusions, as ordered. Use strict aseptic technique.
- u If the patient requires general anesthesia for surgery, help ensure that he receives adequate ventilation to prevent hypoxic crisis. Make sure the surgeon and the anesthesiologist are aware that the patient has sickle cell anemia, and provide a preoperative transfusion of packed RBCs as needed.

Patient teaching

- u To help prevent exacerbation of sickle cell anemia, advise the patient to avoid tight clothing that restricts circulation.
- u Warn against strenuous exercise, vasoconstricting medications, cold temperatures (including drinking large amounts of ice water and swimming), unpressurized aircraft, high altitude, and other conditions that provoke hypoxia.
- u Stress the importance of normal childhood immunizations, meticulous wound care, good oral hygiene, regular dental checkups, and a balanced diet as safeguards against infection.
- u Emphasize the need for prompt treatment of infection.
- u Explain the need to increase fluid intake to prevent dehydration that results from impaired ability to properly concentrate urine. Tell parents to encourage a child with sickle cell anemia to drink more fluids, especially in the summer, by offering milkshakes, ice pops, and eggnog.
- u To encourage normal mental and social development, warn parents against being overprotective. Although the child must avoid strenuous exercise, he can enjoy most everyday activities.
- u Refer parents of children with sickle cell anemia for genetic counseling to answer their questions about the risk to future offspring. Recommend screening of other family members to determine if they are heterozygote carriers.
- u Because delayed growth and late puberty are common, reassure an adolescent patient that he will grow and mature.
- u Review the symptoms of vaso-occlusive crisis so that the patient and his family will recognize and treat it early. As appropriate, explain how to care for this condition at home. Prepare parents for an infant's first vaso-occlusive crisis (called “hand-foot crisis”), during which the infant's hands, feet, or both swell and become painful.
- u Inform the patient and his parents that if he must be hospitalized for a vaso-occlusive crisis, I.V. fluids and parenteral analgesics may be administered. He also may receive oxygen therapy and blood transfusions.
- u If appropriate, discuss how special conditions, such as surgery and pregnancy, may affect the patient.
- u Stress to the patient the need to inform all health care providers that he has this disease before he undergoes any treatment, especially major surgery. Explain that any procedure that involves general anesthesia necessitates adequate ventilation to prevent hypoxic crisis. Urge him to wear medical identification stating that he has sickle cell anemia.
- u Warn women with sickle cell anemia that they are poor obstetric risks. However, their use of oral contraceptives is also risky; refer them for birth control counseling. If such women do become pregnant, they should maintain a balanced diet during pregnancy and may benefit from a folic acid supplement.
- u If necessary, arrange for psychological counseling to help the patient cope. Suggest that he join an appropriate support group, such as the National Association for Sickle Cell Disease.

SIDEROBLASTIC ANEMIAS

Sideroblastic anemia is an umbrella term for a group of heterogenous disorders with a common defect: failure to use iron in hemoglobin synthesis despite the

availability of adequate iron stores. As a result, iron is deposited in the mitochondria of normoblasts, and characteristic rings surround the nucleus of this cell.

Sideroblastic anemias can be acquired or hereditary; the acquired form, in turn, can be primary or secondary. In many instances, hereditary sideroblastic anemia responds to treatment with pyridoxine (vitamin B₆). Correction of the secondary acquired form depends on the causative disorder; the primary acquired (idiopathic) form resists treatment and usually proves fatal within 10 years after onset of complications or a concomitant disease.

Causes

Hereditary sideroblastic anemia is most prevalent in young males and appears to be transmitted by X-linked inheritance; females are carriers and usually show no signs of this disorder.

The acquired form may be secondary to ingestion of or exposure to toxins, such as alcohol and lead, or to drugs, such as isoniazid and chloramphenicol. It can also occur as a complication of neoplastic and inflammatory diseases, such as lymphoma, rheumatoid arthritis, lupus erythematosus, multiple myeloma, tuberculosis, and severe infections.

The primary acquired form, whose cause is unknown, is most common in elderly people but occasionally develops in young people. It's often associated with thrombocytopenia or leukopenia.

Complications

Increased total body iron (hemochromatosis) can result in severe cardiac, hepatic, and pancreatic disease. Respiratory complications also can occur. These complications are most common in elderly patients who have primary acquired sideroblastic anemia. About 10% of patients with this disorder develop acute myelogenous leukemia.

Assessment findings

Sideroblastic anemias usually produce nonspecific clinical effects that can exist for several years before being identified. The patient's history may reveal anorexia, fatigue, weakness, and dizziness. The patient may also have a history of dyspnea.

On inspection, you may observe pale skin and oral mucous membranes. You may also note slight jaundice, caused by excessive iron accumulation in the liver, and petechiae or bruises, caused by thrombocytopenia.

Palpation may reveal enlarged lymph nodes. If iron accumulates in the liver and the patient has jaundice, palpation also may disclose hepatosplenomegaly.

Hereditary sideroblastic anemia is associated with increased GI absorption of iron, causing signs of hemosiderosis (eventually, hepatomegaly, cardiomyopathy and, possibly, endocrine problems). Additional symptoms in secondary sideroblastic anemia depend on the underlying cause.

Diagnostic tests

Ringed sideroblasts on microscopic examination of bone marrow aspirate stained with Prussian blue dye confirm the diagnosis.

Microscopic examination of blood shows erythrocytes to be hypochromic or normochromic and slightly macrocytic. Red cell precursors may be megaloblastic, with anisocytosis (abnormal variation in red blood cell [RBC] size) and poikilocytosis (abnormal variation in RBC shape).
